lining of the lobule consists of superficial (luminal) A cells that are involved in milk synthesis.^{1,18} The B cells (basal) have stem cell activity.^{1,18} Finally, there are myoepithelial cells located around the alveoli and small excretory mild ducts between the inner aspect of the basement membrane and the tunica propria. These cells are stimulated hormonally.

The lobules are surrounded by connective tissue, but there is no distinct fascia separating the lobules. The connective tissue (stroma) that surrounds the lobules (intralobar) is dense and fibrocollagenous, whereas the intralobular connective tissue has a loose texture, which allows the rapid expansion of secretory tissue during pregnancy. The fibrous tissue surrounds the glandular components and extends to the skin and nipple, assisting in the mechanical coherence of the gland. The interlobar stroma contains variable amounts of adipose tissue, which contributes largely to the increase in breast size at puberty.

Blood supply

The blood supply of the breast is derived from the axillary, internal thoracic artery (internal mammary artery) and the intercostal arteries^{2,19} (Figure 37.3). The largest vessels arise from the internal thoracic artery, the perforating branches of which pierce the chest wall adjacent to the sternal edge in the first to fourth intercostal spaces, giving blood to the inner quadrants. Additionally, the internal thoracic artery gives rise to the posterior intercostal arteries, and branches of the intercostal arteries penetrate the deep surface of the breast. The axillary artery gives off the superior thoracic artery, the pectoral branch of the thoracoacromial artery, the lateral thoracic artery and the subscapular artery. Multiple muscle-perforating branches of the thoracoacromial artery perforate the pectoralis major to enter the breast from the upper quadrant. The lateral thoracic artery traverses along the lower border of the pectoralis minor muscle. During its course along the muscle, it gives off the external mammary artery, which comes ventrally through the muscle to supply the upper outer quadrant of the breast. All of these arteries connect with each other by collateral branches in both the breast and the overlying skin. Overall, 60% of the breast is supplied by the internal thoracic artery, 30% by the lateral thoracic artery, and 10% by minor contributions from the thoracoacromial, intercostals, subscapular and thoracodorsal arteries.¹

The venous drainage heads towards an anastomotic plexus in the subcutaneous tissue beneath and around the areola. This plexus then drains towards the periphery via large subcutaneous veins. These veins then follow their arteries and drain to the intercostals and axillary veins and to the internal thoracic veins. Of note is their communication with the prevertebral venous plexus.

Nerve supply

The innervation of the breast is principally by somatic sensory nerves and autonomic nerves accompanying the blood vessels. The somatic sensory nerve supply is via the supraclavicular nerves (C3, C4) superiorly and laterally from the lateral branches of the thoracic intercostal nerves.⁶ The medial

Figure 37.3 Vascular anatomy of the breast area.

aspects of the breast receive supply from the anterior branches of the thoracic intercostal nerves, which penetrate the pectoralis major to reach the breast skin. These lateral and medial cutaneous branches come from the second through to the sixth intercostal nerves. The major supply of the upper outer quadrant of the breast is via the intercostobrachial nerve (C8, T1). It gives a large branch to the breast as it traverses the axilla. The location of the nerves within the breast varies quite often. After passing through the intercostal spaces, the nerves ramify within the breast, sometimes passing along the deep fascia, sometimes passing superficially through the substance of the breast.

With regard to the all-important innervation to the NAC, the anterior and lateral branches of the intercostal nerves and, in particular, the lateral branch of the fourth intercostal nerve tend to ramify predominantly to the subareolar plexus, although lesser and variable contributions from other surrounding intercostal nerves also ramify to the area. Most of the time this lateral branch takes a subglandular course within the pectoral fascia to approach the nipple from the posterior surface, running along the same septum that carries the vascular network.²⁰ On the other hand the medial nipple innervation is most commonly derived from anterior cutaneous branches of the third and fourth intercostal nerves, which take a more superficial approach in the subcutaneous tissue and become more superficial as they reach the medial areola.^{3,6,11}

Lymphatic drainage

The lymphatic drainage of the breast is diffuse and variable. It works through two sets of lymphatic vessels: the superficial (subepithelial or subdermal) and the deep^{1,13} (Figure 37.4). The subepithelial plexus connects to subdermal lymphatic vessels by vertical lymphatics and from them to the deep plexus. In the breast, the subepithelial and subdermal plexus are confluent with the subareolar plexus in which the fine lymphatics of the lactiferous ducts and the lymphatics of the NAC also converge. From the deep lymphatics, the lymph flows towards the axillary and internal thoracic nodes. There are 20–30 lymph nodes in the axilla, divided into five anatomical groups.² The apical nodes unite into the subclavian trunk; on the left side this trunk drains directly into the thoracic duct whereas on the right side it may empty directly into the jugulosubclavian junction or into a common right lymphatic duct.

From a clinic and pathologic point of view the lymph nodes within the axilla are divided into three levels based on the location of the nodes relative to the pectoralis minor muscle.^{1–3,13} Level I nodes are situated inferiorly or laterally to the lower border of the pectoralis minor. This group includes the external mammary, axillary vein and scapular lymph nodes. Level II nodes lie deep or behind the pectoralis minor and include the central lymph node group and the subclavicular nodes. Finally, level III nodes are situated above the upper border of the pectoralis minor muscle and include the subclavicular and apical

Figure 37.4 Structure anatomy of the inner breast and lymphatic mapping of the breast area.

node groups. The internal thoracic lymph nodes lie along the internal thoracic vessels and are very small. They drain the inner aspect of the mammary gland and also the anterior chest wall, the anterior portion of the diaphragm, the upper portion of the rectus sheath and muscle and the superior portion of the liver. Another group of nodes – the intercostal nodes – take a small part to the lymphatic drainage of the breast. These lie near the rib heads and receive deep lymph vessels from the postero-medial aspect of the chest and some drainage from the lateral extremity of the mammary gland.

The lymphatic drainage from the breast can run different routes before getting to the nodes.³ It may go lateral, medial, transpectoral and retropectoral. The lateral route is the most important, about 75% of all lymphatic drainage passes to the axillary nodes whereas the remainder principally drains medially into the internal thoracic lymph nodes. It is important to underline that any part of the breast could drain into either group although there is a tendency of the lateral group to drain towards the axilla and of the medial to drain towards the internal thoracic lymph nodes.

Transpectoral drainage happens through Rotter's nodes that are situated beneath the pectoralis major muscle. They drain into lymphatics along the thoracoacromial artery to the subclavicular group of level III.

The last route of drainage is the retropectoral, in which the superior and internal aspects of the breast drain into the subclavicular node group in the axilla, passing through the lymphatics located along the inferior portions of the pectoralis muscles. Lymphatics do not normally drain across the contralateral side and this has to be taken into consideration in cancer patients.²

Physiology of the breast

Physiologically, the breast is an organ specialized for milk formation (lactation), including synthesis, secretion and ejection of milk.^{1-4,9,10,18} The secretory units of the breasts are the alveoli, small saccules in continuity with the lactiferous ducts. A complex network of hormones and growth factors controls the production of milk by these secretory units. The fluctuation of these hormones results in important histologic changes in the breast during pregnancy and during the menstrual cycle.^{1,4,5,18}

Oestrogen is the main female hormone responsible for breast development and maintenance. It leads to growth of the ductal system and also maturation and prominence of the nipples, resulting in proliferation of the ductal epithelium, myoepithelial cells and surrounding stroma. Oestrogen is lipid soluble and in a woman's body is made by the ovaries and to a lesser extent by the adrenal glands. It is stimulated to act in the presence of other hormones such as hydrocortisone, insulin-like growth factors and growth hormones.

Progesterone is released by the ovaries and induces development of the terminal ducts and lobulo-alveolar structures. Like oestrogen, it needs the presence of the other hormones, such as growth hormones and insulin, to respond. Both oestrogen and progesterone can increase connective tissue and fat in the breast, thereby leading to the rounded form of the fully developed breast.

Prolactin is produced by the acidophilic cells of the anterior pituitary gland. It cooperates with oestrogen in ductal development and with progesterone in lobulo-alveolar development. Together with cortisol and insulin prolactin helps to differentiate alveolar cells into milk-secreting cells. Generally speaking, it stimulates mammary growth and differentiation and ultimately milk production. Prolactin is primarily stimulated by the thyrotropin-releasing hormone (TRH) and inhibited by dopamine, but it can also be produced by cells in the breast, behaving as a paracrine or autocrine factor.

Oxytocin is a peptide hormone that is synthesized in the hypothalamus and released by the posterior pituitary gland (neurohypophysis). The act of nursing (the sucking reflex) stimulates its release.¹⁻⁴ Oxytocin causes myoepithelial cells to contract, which squeezes milk out from the lobules into the lactiferous ducts.

Human placental lactogen (hPL) is produced by the maternal placenta and serum levels continue to rise throughout pregnancy. It is related to breast growth and differentiation during pregnancy and reaches a peak during the final weeks of gestation, preparing the breast for milk production. Its serum levels decline rapidly after birth.

During the menstrual cycle there is a fluctuating alternation of hormones. In the follicular phase (the days from the first day of menstruation to the ovulation) follicle-stimulating hormone (FSH) levels rise, stimulating the development of follicles and their secretion of oestrogen.^{1,4} Increased oestrogen levels give

rise to cellular mitoses within the epithelial cells of the breast and also increase the blood flow, leading to an increase in breast volume due to intralobular oedema and enhanced cellular proliferation. The luteal phase is initiated by a peak of luteinizing hormone (LH), which leads to an increase in progesterone.^{1,4} As a consequence the mammary ducts begin to dilate and the alveolar epithelial cells to differentiate into secretory cells. Breast epithelial cell proliferation increases tremendously during the luteal phase of the menstrual cycle. With the onset of menstruation the rapid decline in the circulating levels of oestrogen and progesterone in the breast causes a regression of the secretory activity of the epithelium and the breast volume decreases, along with the tissue oedema, reducing the breast volume observed one week after menstruation.

During pregnancy, the breast reaches its maximum development.¹⁻⁵ High levels of oestrogen and progesterone are maintained by the corpus luteum initially and by the placenta during the latter phase. Oestrogen stimulates the ducts and lobules to proliferate and the glandular epithelium replaces the fat tissue. In the second trimester, progesterone activates the secretory epithelium. During the last trimester the alveolar and ductal spaces are filled with colostrum and towards the end of pregnancy there is a rise in prolactin circulation and the production of milk, fat and proteins begins.

After birth, the decrease of oestrogen and progesterone releases the inhibition on prolactin and lactogenesis begins. There are three main lactogenic hormones that act alongside the actions of glucocorticoids, insulin and thyroxine for milk production: prolactin, hPL and oxytocin. hPL prepares the breast for lactogenesis during the final weeks of pregnancy. Soon after delivery hPL disappears and prolactin acts as the sole lactogenic hormone. It causes the synthesis and secretion of milk into the alveolar spaces. Oxytocin causes the myoepithelial cells to contract, increasing milk delivery. The sucking reflex promotes the increase in both prolactin, stimulating more production, and oxytocin, increasing its release.¹⁻⁴

During the first days after birth, the mother's breast does not produce real milk, but it produces colostrum, with a high immunoglobulin concentration that enhances the underdeveloped immune system of the infant. After 5-7 days the milk becomes filled with all the nutrients and antibodies necessary for growth. When breastfeeding stops, the milk is being produced for several months but in lesser amounts. The breast usually returns to its previous size.

The breast undergoes several changes when a woman reaches the age of around 50 years old and enters the menopause. The loss of oestrogen and progesterone as a consequence of diminished ovarian function produces several general symptoms and changes within the mammary gland. The systemic symptoms include night sweats, mood disturbances, vaginal dryness, hot flashes and difficulty sleeping.¹⁻⁴ In the breast there is a decrease of number of lobular units, causing a loss of glandular tissue, which is replaced with adipose tissue. The breast eventually sags, becoming flatter and less voluminous.

Introduction

Breast augmentation is the most popular aesthetic surgery procedure. Despite or perhaps because of this, it has had a chequered history in comparison to other major aesthetic procedures. The vast amount of space and literature devoted to the subject is not only a testament to its pre-eminence in the field, but also results in arrays of differing opinions and philosophies.^{1–33} This is, perhaps, chiefly because of the use of prosthetic devices and intermittent controversy regarding their safety.^{8,34–36} Czerny reported the first breast augmentation when he transferred a lipoma from a patient's back to the breast.³⁷ Over the years many injectable as well as implantable materials have been used, including shellac, beeswax, epoxy resin, petroleum jelly, Teflon, polyurethane and polyvinyl alcohol to name a few. In 1961 injectable silicone was reported by Uchida.³⁸ The introduction of the silicone breast gel implant by Cronin and Gerow in 1962 revolutionized breast augmentation surgery.³⁹

Silicone, or dimethylpolysiloxane, was first developed during World War II in the field of aircraft engineering. Its softness and inert nature made it the perfect prosthetic substrate for medicine.⁴⁰ Silicone breast implants can be divided into five generations based on the shell thickness, texture and implant fill (Table 38.1). The other major clinically applicable implants are saline implants. Alternative implant materials have been developed over the years, including polyvinylpyrrolide, triglyceride and hydrogel, but none have withstood the test of time.^{9,41} Current implants available on the market are variations on the same theme, divided by gel fill into saline and silicone.^{1,5,8,15,36,42} The silicone fill is subdivided (a) into form-stable and soft, based on level of cross-linkage; (b) by shell into textured and smooth; and finally (c) by shape into round versus anatomical. Following the controversy involving connective tissue disorders in the early 1990s, silicone implants have been once again given US Food and Drug Administration (FDA) approval for use in breast augmentations. They were never subject to bans in the rest of the Western world for the purposes of augmentation.⁴³

Implant evolution

The first-generation implants manufactured by Dow Corning were composed of viscous silicone gel contained in a thick, teardrop-shaped shell. Seams and a Dacron patch present on the periphery and posteriorly, respectively, were thought to help stabilize the implant in position. The high early capsular contracture rates resulted in an evolutionary step towards a second generation of softer implants in the mid to late 1970s, which were smooth, seamless and contained less viscous silicone.^{44,45} Although this reduced the capsular contracture rates somewhat, they were associated with a phenomenon known as 'gel bleed', related to small molecular weight particles of silicone diffusing across the thin silicone elastomer shells. This in turn has been implicated in the pathogenesis of capsular contracture.^{46,47} Recognition of this led manufacturers to develop a third generation of implants with a strengthened silicone shell. Two layers of high-performance elastomer formed the shell, with a fluorosilicone coating barrier between them.

The fourth generation of textured implants was developed partly in response to a desire to emulate the natural pores in polyurethane foam.⁴⁸ Polyurethane foam applied as a thin layer in the 1970s onto the implant shells resulted in very low capsular contracture rates. The process of delamination of the foam from the implant resulted in a non-contractile capsule, which was immobile yet had a soft feel.^{35,49–51} These shells were withdrawn in 1990 after concerns were raised about the carcinogenic nature of the polyurethane by-products,³⁵ but the good clinical outcomes led to development of two forms of pores by American manufacturers: Biocell developed by McGhan Medical and Siltex developed by Mentor. Biocell is composed of an irregular open pore textured surface with an average density of 3.1 pores/mm² and an average pore size of 289 µm. These pores are created by a lost salt technique and develop the capsule through an adhesive effect.⁵² Although this is similar to polyurethane there is no delamination. This shell characteristic has been used for both saline as well as silicone-filled implants, resulting in immobile

Table 38.1 Alloplastic material

Implant generation	Production period	Shell characteristics	Silicone gel characteristics	Shape
First	1962–1970	Thick shell (average 0.25 mm), Dacron patch	Thick viscous	Anatomical
Second	1970–1982	Thin shells (average 0.13 mm), no patch, smooth surface	Less viscous softer gel	Round
Third	1982–1992	Thick low bleed shells, smooth surface ¹	More viscous than second generation	Round
Fourth	1993–present	Thick, strong, low bleed shell, smooth and textured surfaces	More viscous cohesive gel	Round and anatomical
Fifth	1993–present	Thick, strong, low bleed shell, smooth and textured surfaces	Cohesive and form-stable gel	Round and large array of anatomical

yet soft implant feel and lower contracture rates.⁵³ Siltex is a textured surface characterized by a pattern of nodules ranging in height from 65 to 150 μm and in width from 60 to 275 μm .⁵² Implants made of this material do not adhere to the surrounding tissues, so they are mobile in the pocket. They also have lower contracture rates, whether saline or silicone filled.⁵⁴

The fifth generation of silicone implants are textured implants with form-stable silicone. This is achieved by increasing the cross-linkage of the silicone gel, allowing the implants to maintain their shape in all positions.^{36,55,56} The only dual-chamber implant that remains on the market is the Becker inflatable implant.

Saline implants were first reported by the French, as part of a drive for a less invasive and smaller scar surgery in 1965.⁵⁷ This remained the initial motivation for their commercial development in the United States rather than the nature of the filler or capsular contracture rates. The main disadvantage of these devices is their deflation rate and feel. The deflation rates in the initial offerings were as high as 75% at 3 years. The shells were thickened with a room-temperature vulcanized process. This reduced their deflation rates. In relation to their feel there are two main issues – surface wrinkles and the round ball appearance when overfilled.^{57,58} The current accepted rate of deflation is at 1–4% for the first 10 years.⁵⁹

Capsular contracture pathophysiology and study outcomes

Capsular contracture remains the most significant drawback of breast implants.^{12,60,61} The risk of capsular contractures warranting revisional surgery is estimated to be anywhere from 5 to as high as 59%.^{62,63} Most capsular contractures occur in the first 18 months post surgery.^{4,10,13,60,62–66} Baker devised the most commonly described classification of capsular contractures, but one drawback is that it suffers from a relative subjectivity of assessment.⁶⁷ The pathogenesis of capsular contractures remains unclear and is most likely multifactorial. Two theories have emerged as major contenders – the scar formation^{68,69} and infective theories.^{1,70–73}

Histologically, these capsules are made of an inner layer of cellular elements, synovial type metaplasia, fibrocytes and multinucleated giant cells, a middle layer of vascular networks and an outer layer of collagen bundles.^{36,44,47,52,74,75} A plethora of studies have been produced to implicate any and all factors involved in surgery, the device fill and shell; surgical access incision and pocket; use of antiseptics and antibiotics; use of drains, as well as surgical technique.^{18,31,70–72,76–78} Subpectoral pockets were developed in response to the contention that protection, coverage and regular contraction of the muscle would hinder and disrupt the formation of periprosthetic capsule. The fact that no one definitive study exists controlling for all variables indicates strongly that capsular contractures are most likely a result of multiple factors.^{28,31,66,79}

A large number of studies have been produced over the years, especially at the inception of each generation of implants to proclaim their superiority over the previous generation. Many if not most of these studies have lacked a rigorous scientific methodology in double blinding, randomizing, assessing and follow-up criteria, which weakens their assertions.^{64,80} More recent studies have shown a trend to reduced capsular contracture rates during follow-up: 15–20% for the Inamed,⁶⁰ 2.4% for the Mentor 6-year follow-up series and 1.7% for the Danish registry series.⁸¹ It is interesting to note that in all these series secondary operations ranged between 4.8% for the Danish series and 18–28% in the Mentor and Inamed series respectively. Another interesting fact is the almost universal (91%), use of the inframammary approach in the Mentor series (reporting lower capsular contracture rates) and the almost even distribution of the periareolar and inframammary approaches in the Inamed series.

In general, however, the choices are related to: access incision, implant type, type of surgical pocket, periprosthetic drains, and the use of perioperative antibiotics and irrigation of the pocket with antiseptics and/or antibiotics solution.

Access incision

The most commonly used access incisions available for primary breast augmentation are transaxillary, inframammary and periareolar. Umbilical incision and access remains in the realms of surgical possibilities, with little reasonable surgical philosophical

justification in the opinion of the authors. The debate regarding the relative merit of each access site has been ferociously debated over the years by the great and the good. There is compelling evidence that in addition to reduced access, periareolar incision exposes the implant to potentially higher risks of bacterial contamination and as such is associated with increased capsular contracture rates.^{82,83} An interesting finding was increased rates of capsular contracture in transaxillary incisions in comparison to both inframammary and periareolar incisions.⁸⁴

Implant type

One of the major advantages of saline implants was originally thought to be their lower rate of capsular contracture. Early intracellular evidence of silicone in macrophages from silicone implants was held to be an indication of their superiority and reason for reduced capsular contracture rates. Similar evidence, however, has since been demonstrated in saline implants.^{85–87}

Saline versus silicone

Supporting evidence demonstrating lower contracture rates for saline-filled implants came relatively early on.^{65,88–90} Despite the early enthusiasm and convictions of surgeons that saline implants resulted in lower capsular contracture rates, there have been many contradictory results. Most recently, a systematic analysis of randomized controlled trials failed to demonstrate a clear reduction of capsular contractures with the use of saline implants.⁹¹

Surgical pockets

Subglandular

A systemic review published in 2006 reviewed the results of various trials comparing textured and smooth implants in subglandular breast augmentation.⁶⁴ They identified six randomized controlled trials.^{53,54,63,74,76,92–94} Four trials used saline and two used silicone gel. In total, these trials included a total of 235 patients. One trial did not show any difference between capsular contracture rates,⁹² whereas the remainder confirmed a lower capsular contracture rate for patients with textured implants.

Subpectoral

A study of 55 breasts, which is one of the only major, randomized trials of this kind, compared textured and smooth silicone implants placed in the submuscular pocket. The final outcome trended towards lower capsular contracture rates in the textured group (from 15% to 8.6%) but the results were not statistically significant.⁹⁵

Finally, a more recent meta-analysis using most of the above studies demonstrated a five-fold increased incidence of capsular contractures with smooth implants.⁶²

Periprosthetic drains

There is some evidence that periprosthetic drains are associated with a higher risk of infection and also capsular contractures. Many surgeons advocate not using drains in primary breast augmentation.^{96,97}

Perioperative antibiotics and irrigation of pocket with antiseptics and/or antibiotics solution

Periprosthetic and subclinical infection theory has a significant body of evidence behind it.^{71,73,98,99} What is less clear is whether it is in fact the cause of capsular contracture. It has been shown that up to 80% of female breast samples contain bacteria.¹⁰⁰ Bacterial presence in up to 83% of nipple secretions is considered a cautionary tale for the use of periareolar incisions.¹⁰¹ The most commonly implicated organism is a coagulase-negative *Staphylococcus epidermidis*, although many other organisms have been isolated. Basic science evidence of an accelerated capsular contracture following *Staphylococcus aureus* contamination has also been demonstrated.¹⁰²

The results of pocket irrigation with antiseptics and use of antibiotics have been contradictory.^{1,54,70,71} Adams and colleagues used a triple antibiotic solution, the Adam's solution (1 g cefazolin, 80 mg gentamicin and 50 000 bacitracin, replaced by 50 mL povidone–iodine from 2000 onwards mixed with 500 mL normal saline) to show a reduction of capsular contracture (Baker III/IV) rates to 1.8 for primary augmentation and 0% for augmentation mastopexy during a 6-year prospective clinical study.¹⁰³ This is supported by other similar studies showing a reduction in capsular contracture rates.¹⁰⁴

Use of Betadine irrigation of the implant pocket first championed by Burkhardt and colleagues^{54,76} as a means of reducing capsular contractures has been confirmed to reduce capsular contracture rates and to have no deleterious effects on the silicone shell of the implants, as reported by one anecdotal case.¹⁰⁵ On the other hand, Gylbert and colleagues were unable to show any statistically significant difference in capsular contracture rates, using preoperative antibiotics in primary breast augmentation.⁶⁵

Indications

Glandular hypomastia may occur as a developmental or involutional process and affects a significant number of women. Developmental hypomastia is often seen as primary mammary hypoplasia, or as a sequela of thoracic hypoplasia (Poland's syndrome) or other chest wall deformities. Involutional hypomastia may develop in the postpartum setting and may be exacerbated by breastfeeding or significant weight loss. When compared to the norm, inadequate breast volume may lead to a negative body image, feelings of inadequacy and low self-esteem. These disturbances may adversely affect a patient's interpersonal relationships, sexual fulfillment and quality of life.

The initial consultation for augmentation should begin with open-ended questions about the patient's goals and expectations for the procedure. Patients today have often spent some time researching the procedure either through friends or through the internet. The surgeon should be able to form an impression of the patient as a well-informed, psychiatrically stable person with appropriately realistic expectations for the procedure. Any

concerns about the patient's level of understanding, unrealistic expectations or self-esteem issues should be fully explored prior to proceeding with surgery. A careful medical history and physical examination is essential for the assessment of risk factors and candidacy for breast augmentation.

The ideal size and shape of the female breast is inherently subjective and relates to both personal preference and to cultural norms. However, most surgeons will agree that there are certain shared characteristics which represent the aesthetic ideal of the female breast form. These characteristics include a profile with a sloping or full upper pole and a gently curved lower pole with the nipple–areolar complex at the point of maximal projection. The breast structure itself may be thought of as the breast parenchyma resting on the anterior chest wall surrounded by a soft tissue envelope made up of skin and subcutaneous fat. Clearly, the resulting form of the breast after augmentation mammoplasty will be determined by the dynamic interaction of the breast implant, the parenchyma and the soft tissue envelope.

Assessment and implant selection

Patients seeking breast augmentation need to undergo a thorough consultation process. At the initial consultation the breast should be assessed against the patient's expectation. In order to facilitate this crucial process a number of methods are available.

A thorough physical examination begins with observation and careful documentation of any signs of chest wall deformity or spinal curvature. It is imperative to document and draw attention to any asymmetry of breast size, nipple position or inframammary fold (IMF) position. Careful palpation of all quadrants of the breast and axilla is required to rule out any dominant masses or suspicious lymph nodes. While palpating the breast, the surgeon should carefully assess the quantity and compliance of the parenchyma and soft tissue envelope. The soft tissue pinch test is a useful method of assessment, in which the superior pole of the breast is gathered between the examiner's thumb and index finger, measuring the thickness of the intervening tissue. In general, a pinch test result of <2 cm will often indicate a need for subpectoral placement of the implant. It is also important to characterize the amount, quality and distribution of the breast parenchyma as it may be necessary to reshape or redistribute the parenchyma to achieve the desired shape of the breast mound. The elasticity of the skin should also be characterized by observing its resistance to deflection and noting any signs of skin redundancy or stretch marks.

Manufacturers have developed a preoperative planning system to facilitate patient assessment and implant selection. In addition, the authors utilize 4-D technology to assess both patient's chest wall and soft tissue abnormalities. Chest wall, soft tissue asymmetries and combinations of both are important to identify preoperatively. This tool is also utilized to understand the patient's perception of the desired look by

showing the outcomes of using different sizes and styles of implant. This is also then projected in the operating room for surgical planning.

Operative techniques

Preoperative markings

The general principles of surgery need to be observed even more stringently when use of prosthetic material is involved. Once the patient has been appropriately informed and consented by the surgeon, the most basic operative technique decisions involve choices in access incision and pocket creation. Use of sterile technique, no-touch approach and perioperative antibiotics are naturally essential.

Access incision

Inframammary

This is by far the most common and versatile access incision. It allows clear dissection, subsequent visualization of the implant pocket and placement of the implant in any pocket. The evidence also suggests that it is associated with least capsular contractions.^{82–84} This may be due to clear visualization and 'dry' technique, allowing good haemostasis and reduced risk of bacterial contamination through the incision and operative field. Its direct access to the glandular–muscular interface and overlap allows manipulation of either or both for the best symmetrical and aesthetically pleasing outcome.

The drawbacks of this access are the relative visibility of the scar, its site and placement. The incision should be placed in the predicted location of the new IMF, which has been determined and marked preoperatively. An incision length of up to 5.0 cm is required. The incision should be designed with the majority of the incision lateral to the breast midline, as this will place the resulting scar in the deepest portion of the new IMF.

Periareolar approach

The periareolar approach for augmentation mammoplasty was described by Jenny in 1972. The principal advantage of this incision is that the resulting scar is usually well-camouflaged and quite inconspicuous. The periareolar approach allows easy adjustment of the IMF and direct access to the parenchyma for scoring and release when the lower pole of the breast is constricted. Whether this is a transparenchymal approach or periparenchymal via dissection to the inferior pole, this incision allows for access for creation of subglandular, submuscular as well as subfascial pockets. In addition to the higher risk of contamination and apparent association with higher capsular contracture rates, it is associated with reduced sensitivity of the nipple–areolar complex (NAC) as well as increased rates of periareolar pain.^{82,83,106} The dissenting view has been offered by a much smaller series of 20 patients not showing any difference between the two incision types.¹⁰⁷

In pigmented skin the risk of keloid and depigmentation remains high. It is also exceedingly difficult to place many cohesive or anatomically shaped implants through this incision. Despite the evidence, this access continues to enjoy popularity with many surgeons who argue for its use given the 'direct' access, 'remote' control of the IMF and 'invisible' incision.¹⁰⁸ In the opinion of the authors in light of the basic science and clinical series evidence there is no justification in using the peri-areolar incision.

Transaxillary incision

This incision technique was first developed in the 1970s as an open technique, before being adapted to a minimally invasive approach.¹⁰⁹ Although this technique theoretically offers access to creation of all three implant pockets, the traditional open technique involved blunt dissection of the inferior origins of the pectoralis major muscle for creation of the submuscular pocket. The open blunt technique led to a series of suboptimal aesthetic outcomes. This was in part due to uneven coverage of the implant and its malposition owing to, in particular, a lack of controlled dissection of the vascular inferomedial aspect of pectoralis major.³² This is also where major intercostal vessels traverse the space, increasing the risk of haematomas. As saline implants became popular, especially in the United States, proponents of this technique increased. Introduction of saline implants through a 2–3 cm incision, enhanced by precision view allowed by endoscopic assistance, became a major standard. Currently, the technique is performed with a slightly longer incision of 4–5 cm for use of silicone implants. Although textured implants can be placed via this incision, anatomical-shaped implants cannot routinely be placed.³² The IMF is lowered 1–2 cm depending on size and asymmetry through this technique.

The proponents of this technique point to its track record in safety, its minimal incision hidden in the axilla and remote access and better control of the IMF.³² With the exception of the evidence implicating this incision in increased capsular contractures,⁸⁴ the authors believe that this technique is more anatomically and surgically sound than the periareolar technique but less versatile than the inframammary incision. However, the purported control over the IMF is offset, in the opinion of the authors, by the fact that there is little or no possibility for a nuanced manipulation of the gland–muscle interface or position at the IMF. This is imperative in view of the authors, as it gives a more direct control on the NAC-to-IMF distance as well as the shape of the lower pole. Despite this, Tebbetts reports excellent equivalent outcomes with both dual-plane and transaxillary techniques with long-term follow-up.³⁰

Transumbilical

This technique was developed in the 1990s.¹¹⁰ The first large series reported by Dowden argued for its use based on the following: versatility (access to both subpectoral and subglandular pockets), minimal scarring and no implant tension on

wound, reduced loss of nipple sensation, elimination of deadspace, and, finally, good control of the implant pocket.¹¹¹ This technique is only suited to inflatable saline implants. It involves blunt dissection over the rectus sheath towards the breast. Creation of the subglandular or subpectoral pockets is achieved by means of avulsion of the tissues, including the inferior pectoralis major (for the subpectoral pocket). Despite purported good results by Dowden and other surgeons, the authors feel this is not a surgically sound technique. It has poor to no visualization of the operative field, which defines surgery and its planned accuracy. It only has application for inflatable saline implants. Its safety based on basic surgical principles cannot be recommended in comparison to any of the other incisions.

Pocket creation

Subglandular

The original implant pockets were dissected in a subglandular plane. Where soft tissue envelope is considered thick enough, many surgeons continue to use a subglandular pocket for implant placement.

Submuscular

This approach is developed in either a complete or partial submuscular pocket. The lower edge of the pectoralis major is dissected off the chest wall and the lower sternum. For a total submuscular pocket it may be necessary to also dissect serratus anterior and the external oblique off the chest wall. The issues of animation of the implants with contraction, the implants riding too high and the wide cleavage are well-known drawbacks of the submuscular plane. By definition with this technique it can sometimes be difficult to place the NAC on the most projected part of the breast tissue.

Tebbetts described the dual-plane technique as a means of addressing the various shortcomings with each technique and allowing a nuanced approach to implant placement and pocket dissection.^{28,31} He described dissection of tissue in both submuscular as well as subglandular planes. The lower edge of the pectoralis major is dissected in all cases followed by dissection of the breast tissue from the underlying pectoralis major. He described three different levels of dissection of the breast tissue–muscle interface and redraping of the pectoralis major muscle on the implant as projected NAC level (Figure 38.1):

- Type I: No dissection, the inferior border of the muscle covers the implant and entire NAC level.
- Type II: The inferior border of the muscle drapes over the implant to the level of the NAC.
- Type III: The inferior border of the muscle retracts to the superior margin of the NAC.

The authors believe that appropriate utilization of the dual-plane technique provides the most flexible and nuanced approach for implant positioning and placement. It goes a long way to alleviating the implant animation problem due to muscle

Figure 38.1 Schematic diagram representing the extent of dissection of breast parenchyma off the pectoralis major and subsequent pectoral release in dual-plane breast augmentation. Source: Tebbetts, 2006.³⁰ Reproduced with permission of Lippincott Williams & Wilkins.

contraction. It allows a good soft tissue coverage of the upper pole, and facilitates not only the expansion of the lower pole but eases adjustment of the IMF should that be necessary. Additionally, this technique has been shown to reduce capsular contracture rates.⁶⁶

Subfascial

This is a more recent technique. Here, the implant is placed under the pectoralis major fascia. Very low or no capsular contractures in patients undergoing this technique have been reported.¹¹² The authors have little experience with this technique, but observe that the pectoralis major fascia is rather thin

and indeed may not alleviate the issues of implant animation or optimal NAC position on the breast mound.¹¹³

Personal preference

Preoperative markings are made with the patient in the upright position and are useful as a reference point during the actual procedure. The surgeon should mark the chest midline in the frontal view from the suprasternal notch to the xiphoid process, the existing IMFs and the likely position of the new IMFs as the proposed limits of the dissection. The patient is then

asked to place her arms behind her head to visualize the displacement of the nipple and the true IMF. The senior author uses the Akademikliniken method for preoperative markings. The two vital parameters to determine are the vertical position of the implant on the chest wall and the position of the new IMF. This latter is determined by the width and projection of the implant, the amount of breast glandular tissue and the characteristics of the skin envelope. The natural shape of breasts is not circular nor spherical; ideal implants in the opinion of the authors are form-stable anatomical implants, simulating natural breast shape. The ideal natural appearance of the NAC is at mid-height of an anatomical form-stable implant. The NAC is elevated with augmentation; the easiest way to simulate this is by asking the patient to clasp her hands over her head and marking this against the sternum at midline. Central points are relatively constant as reference positions. Based on these markings the mid-height of the implant is determined on the chest wall.

The next step is to determine the position of the new IMF. There are multiple ways of estimating this. In general, for small breasts the IMF is lowered by about 1.0 cm, for moderately sized breasts it is lowered by 1.0–1.5 cm and for larger breasts it is lowered by 1.5–2.0 cm. Another way to determine this is by pinching the lower pole breast tissue with a caliper and dividing the value by 2. These would have to be slightly modified for ptotic breasts, where there is excessive skin at the lower pole.

The patient is then placed in the supine position, centred on the operating table with the pelvis directly over the flexion point of the bed. The arms must be well secured to the armboards, which are placed at 90° angles to the torso. These preparations are required so that the patient may be placed in the upright seated position as often as needed during the procedure. The sterile preparation and draping of the anterior chest must provide visualization of the patient's shoulders as an important anatomical reference point. Triple antibiotic solution irrigation is used for all implant cases regardless of the incision type.

The authors use the inframammary incision approach in all procedures. The location of the incision is based on the implant choice with the added subglandular tissue. The senior author in almost all cases creates a dual-plane II–III pocket with anatomical implants. The pocket is precisely dissected to snugly accommodate the implant. After creation of the subglandular plane, the lateral border of the pectoralis major muscle is identified. The muscle edge can be lifted by forceps to allow easy entry into the submusculofascial plane. This plane is readily identified by the wispy areolar connective tissue and ease of dissection. An extended electrocautery instrument is used to complete the dissection. The inferior origin of the pectoralis major is released from lateral to medial at the level of the IMF. Division of the pectoralis continues medially to the sternal border. Partial deep division may selectively be carried out 1–3 cm above the xiphoid, depending on which implant is used. Lateral dissection is avoided in order to let the implant push the pocket out itself and to reduce the risk of injury to the lateral neurovascular bundles.

The nerves can be stretched to accommodate the implant but should be preserved to minimize postoperative sensory changes.

When the pectoralis major muscle is elevated, care must be taken to leave the pectoralis minor down on the chest wall. This will minimize bleeding and allow correct placement of the implant. Once adequate haemostasis is obtained and pocket dimensions are finalized, the pocket is irrigated with an antibiotic-containing solution, and the implants are carefully placed by a minimal-touch technique and change of glove. Implant 'sizers' are avoided to reduce unnecessary pocket manipulations and possible contamination of it.

After the implants are in place, the patient is placed in a 90° upright position and evaluated from various perspectives. Any asymmetry or underdissected areas are marked, and the patient is placed back in the supine position. A multilayer closure is performed with absorbable suture. It is important to close off the implant pocket with a separate layer of suture before closing the skin. No drains are placed. Once closure is complete, Steri-Strips are applied along the direction of the incisions and a post-surgical bra is fitted (Figure 38.2).

Complications and treatment

There are inherent risks involved with all surgical procedures, and when they involve a prosthetic device these are considered more significant and have to be considered over longer follow-up time periods. Some may be considered trivial, others are devastating to both patient and surgeon. Regardless of estimated likelihood, these all should be discussed in detail with patients undergoing aesthetic surgery. They generally pertain to aesthetic outcome and surgical complications.

Aesthetic outcomes that are salient in the discussion with the patient include capsular contractures, malposition of implant, implant visibility/palpability/rippling, sensory and asymmetrical position changes to NAC, breast size asymmetry, contour deformities, galactorrhoea, skin stretch deformities, glandular atrophy over time and need for device change with passage of time.^{16,36,60,81,106,107} Surgical complications that need to be addressed include postoperative haematoma, device failure/rupture/rotation (anatomical implants)/infection, hypertrophic/keloid scarring as well as implant-related T-cell lymphoma.^{12,60,81,114,115}

Aesthetic and sensory outcomes

Capsular contractures

These are by far the most common reason for reoperation. Premarketing studies from Inamed,⁶⁰ Mentor⁵ and the Danish registry reports⁸¹ are among comprehensive studies addressing complications following breast augmentation. The topic of capsular contractures, the study outcomes and preventative strategies have been discussed at length in the previous section. During follow-up of 5373 women, the Danish registry study indicated that over a mean follow-up period of 3.8 years 4% of women underwent secondary surgery. Once the patient presents

Figure 38.2 (a, b, c) Preoperative appearance antero-posterior, three quarters and lateral views. (d) Projected nipple-areolar complex after augmentation. (e) Relative markings at rest. (f, g, h) Postoperative views.

with a significant capsular contracture of Baker III/IV grades, the only option is surgery. This surgery can take the form of capsulotomy, scoring and device exchange alone, capsulectomy and device exchange or neo-pocket creation and device exchange. Considering the discussion in the previous sections about the cause of capsular contractures and the roles of bio-films, bacterial inoculation and contamination of the capsule, the authors feel that it is good surgical principle to excise the capsule where and when possible to create a new implant pocket and exchange the device.

More recently the use of acellular dermal matrix (ADM) has found a place in the debate on capsular contractures. Much like the concept of a 'fire break' skin graft in Dupuytren's disease, ADM has been found to prevent incorporation into the forming capsule. Histologic, basic science and clinical evidence indicate that placement of ADM yields an abrupt disruption of the forming capsule, thereby alleviating capsular contractures. The authors favour the use of ADM in revisional augmentation surgery.^{116–120}

Malposition is the second most common problem associated with breast augmentation and one of the most common reasons for revisional surgery. This occurs in about 1.2–1.6% of cases.^{81,83} The implant can be displaced in any direction – medially, laterally, superiorly or inferiorly – resulting in symmastia (when medial displacement is bilateral), fall into the axilla or a double-bubble deformity. Double-bubble deformity is defined in type I, the so-called 'waterfall deformity'; the implant sits superiorly to the breast and skin envelope that have 'slipped' over the implant with ptosis. This type is most commonly seen when complete submuscular pockets are used or when the breast is suffering from significant ptosis (grade III) prior to surgery and augmentation rather than augmentation mastopexy is performed. Type II deformity is related to incorrect lowering of the IMF during surgery, when the implant sits below the well-formed IMF and breast tissue.¹²¹

Malpositioned implants can be difficult to treat. In the lateral implant displacement, which is most commonly due to overdissection of the implant pocket or contraction of the pectoralis major muscle, the lateral part of the pocket can be excised and

closed or simply closed to tighten the pocket more medially. Use of ADM in all malposition revisional surgery has been described and must be considered in the planning stage.^{122,123}

Synmastia is notoriously difficult to treat. It is the result of over-dissection of the medial pocket and the sternal origins of the pectoralis major muscle in the submuscular planes.¹²⁴ Here the use of ADM can be most useful, the capsule can be used to augment the medial border of the pocket in addition to a layer of ADM placed medially. A reduction in implant size where possible is helpful.

Wrinkling/rippling

This is most commonly reported with the saline implants, particularly in textured subtypes. In a recent study this was reported to be observed in 37.5% of cases and was not related to underfilled, recommended filled or overfilled devices.¹²⁵ It is also more common when implant-to-parenchymal ratio is greater than 50%.⁶⁸

Asymmetries

All breasts are asymmetrical, so preoperative observation and documentation is good practice. The patient is made aware of these, which hopefully makes possible asymmetries as a result of the augmentation procedure more acceptable.

NAC sensory changes

As discussed previously, these are more common in periareolar approaches.¹⁰⁶ In the normal course of an inframammary or transaxillary approach, transient altered sensation may occur. Generally it is considered that permanent changes are more common when implants larger than 350 mL are used. Although Mofid and colleagues,¹⁰⁷ in assessing a small cohort of patients and controls using accurate measurements, argued that changes occur in all patients undergoing augmentation operations, in general the extent of this change is linear in relationship to the volume of the implants.

Surgical complications

Haematomas

These are not common – usually in the order of 1% risk⁸¹ – but they must be evacuated. Many authors have noted that persistent haematomas or significant seromas lead to capsular contractures.^{68,69}

Device failure

More recent generations of implants have proved to be more reliable than earlier versions. As noted previously saline implants now enjoy an approximately 4% deflation over the first 10 years.⁵⁹ The Inamed 6-year follow-up study of silicone implants reports a 3.5% device failure.⁶⁰

Infection and exposure

This is a dreaded complication for both patient and surgeon. The reported rates of infection are between 0.9% and 1.9%.^{5,81} The clinical picture presents along a spectrum. Traditionally, the

implants were removed and the patient was prescribed antibiotics. However recently, salvage procedures have become more common. These range from closed-system antibiotics irrigation to conservative wound care and passive drainage in addition to systemic antibiotics. The more aggressive end of the spectrum involves exchange of the implant, provision of coverage with muscle or using posterior capsule. Spear reports a very good salvage rate of infected or exposed implants with seemingly good medium-term follow-ups.¹¹⁵ However, given the discussion above pertaining to capsular contracture and presence of biofilms, the authors are of the opinion that in the long term these patients will inevitably develop capsular contractures. Except in the mildest cases the authors advocate capsulectomy and exchange of implant after the initial infection has been treated and the tissues have regained some of their suppleness.

Late seromas

Appearance of a late seroma in an augmented breast is a source of concern for both patient and surgeon alike. Its management despite flow charts and various reports^{126–128} becomes more a matter of surgical principles and judgement in the authors' view. It is ultimately a decision related to the cause of seroma. There are three main possibilities – idiopathic, infective or neoplastic – and each broadly requires a different approach. The 20 mL estimated volume on ultrasound remains the threshold for seroma formation that the authors consider.

Many authors treat seromas with antibiotics empirically and observe the clinical progression of the patient. We believe that if a patient presents with a new-onset late seroma, an ultrasound-guided diagnostic aspiration is mandatory. The fluids are all analysed for microscopy, culture and cytology with Wright Giesma-stained smears, for positive immunohistochemistry for CD30-positive cells, anaplastic lymphoma kinase protein, translocation studies and others indicated in consultation with the haematology/oncology team. Where the fluid is sterile, the idiopathic seroma may be an indication of a subclinical infection of the biofilm, which may not be picked up on microscopy or culture. In these cases if persistent and unresolved with a course of antibiotics, the authors advocate a capsulectomy and device exchange. Our assumption is that there is a subclinical biofilm infection, which will not be resolved with antibiotics treatment.

Where clinically mild, the infective seroma can often be treated with antibiotics. Although this may not lead to capsular contractures in the short term, this has to be weighed against long-term anticipation of capsular contracture as a consequence of subclinical biofilm infection. The decision as to when and if the device should be exchanged, along with a capsulectomy and where possible change of implant pocket, must be discussed and weighed against secondary surgery and its inherent risks as a revisional augmentation procedure. Where the seroma is of a malignant nature (anaplastic large T-cell lymphoma (ALCL)), the treatment option is referral to the breast and haematology/oncology teams. Removal of the implant and capsulectomy is part of the treatment regime.

Rotation

Rotation is not a problem with traditional implants. The anatomical implants have the advantage of filling the lower pole and are especially useful with patients with mild ptosis (grade II good skin envelope) who are not willing to undergo or not suitable for augmentation mastopexy. However, up to 1% of anatomical implants undergo rotation in their pockets which requires secondary corrective surgery.^{22,26,97,123}

T-Cell lymphoma

T-Cell lymphoma is a lymphoproliferative disorder that has been diagnosed in association with breast implants. Malignant cells have been isolated infiltrating the capsule as well as in the periprosthetic seroma fluid. Its immunohistochemical markers are uniform expression of CD30 protein, ALK, clonal T-cell rearrangement as well as the presence of t(2;5) translocation.¹²⁹ Treatment has varied from removal of implant with or without capsulectomy, followed by either standard chemotherapy or local radiotherapy.³⁴

This is considered an association as the statistical analysis along with anatomical site suggest an absolute increase in the risk of developing ALCL with breast augmentation. However, clear pathogenesis theories have not been put forward.

Scar formation

Keloid and hypertrophic scar formation need to be discussed with patients preoperatively. Their treatment is part of the standard algorithm discussed elsewhere in this book.

Autologous fat injection

Fat grafts have become a popular means of soft tissue augmentation in plastic surgery in recent years. Traditionally, concerns regarding survival and calcification had led to a ban of the procedure by the American Society of Plastic Surgery. However, this has changed in recent years with better understanding of fat and stem cells as well as better techniques for harvesting and engrafting.¹³⁰ With regard to meaningful breast augmentation, however, fat-based autologous augmentation, despite its obvious attraction, remains a goal rather than an attainable outcome.

One of the more novel techniques developed so far involves the BRAVA-based technique. This device, which has been on the market for 10 years, is an external tissue expansion device acting through suction. The resulting short-term tissue expansion, according to its developer and proponent, results in an expanded fibrovascular scaffold, which is fertile ground for fat engraftment.¹³¹

The most significant study of breast augmentation involving the BRAVA system was a multicentre study of 81 patients, which showed promising results both visually as well as in reported data. A mean augmentation of 233 mL is reported at 12 months based on 3D calculations. The patients had a baseline MRI

preoperatively, a three-month and a second follow-up MRI at least six months postoperatively. The key findings were an approximately 90% estimated graft survival and a stable volume between the first and second postoperative MRI, indicating permanency.¹³¹

The authors have no direct experience of the BRAVA technique, but they routinely use fat for contour deformity correction, especially in reconstructive cases. Larger controlled augmentation volumes remain, for now, in the realm of promising trials.

CHAPTER 39

Breast reconstruction

Phillip Blondeel, Maria Athanasiadou and Andreas Tromaropoulos

Department of Plastic, Reconstructive and Aesthetic Surgery, Department of Plastic Surgery, University Hospital Gent, Gent, Belgium

Introduction

The presence of breasts is a defining feature of adult mammalian gender. It must therefore be considered an essential element of human femininity, and the role it plays in female psychology cannot be understated.^{1,2} The requirement for reconstruction of the female breast is almost exclusively consequent on breast surgery for breast cancer.

Providers are becoming legally bound to educate and prepare patients who require mastectomy for reconstruction, such that informed choices can be made. They are obliged to offer a multidisciplinary setting as part of a care pathway, in particular allowing for cross-specialty engagement to allow for immediate reconstruction. The surgery of reconstruction has become a recognized specialist area, which by virtue of its appreciation of three-dimensional form, and its possible call on microsurgical skills, naturally falls within the domain and skill set of the plastic surgeon.

In this chapter the techniques of breast reconstruction and the principles behind them are reviewed, and it is hoped this will offer the practitioner a ready reference for what we trust will be a meticulously if not passionately executed endeavour.

Reconstructive aims

Any attempt at reconstruction should appreciate the nuances of breast form, volume and its complex three dimensionality. Its position on the chest wall is determined by its footprint,^{3–5} a fixed entity that does not change with age, and that is set by the inframammary fold (IMF) at the 6–7th rib inferiorly, the 2nd rib superiorly, 1–2 cm behind the anterior axillary line laterally, and the lateral border of the sternum medially. The footprint sets the basic breast position on the chest, and by complementing the opposite side creates the necessary foundation for symmetry.

The breast conus represents the tissue that projects from the chest wall, a complex of skin envelope with its glandular and fatty content that falls inferiorly to a variable extent over the

IMF in a manner termed ptosis. Unlike the footprint, the conus is variable with age. Creating, therefore, a symmetrical ptotic conus precisely positioned on the breast footprint embodies the art of breast reconstructive sculpture. The skin envelope aids in determining shape and any damage or removal of skin will influence its final shape. The ultimate goal of breast reconstruction is to create symmetrical, natural-looking breasts and not necessarily a specific shape or volume.

Aesthetic and functional considerations

Breast ideals have changed over time, as depicted in art and reflecting past and existing cultural differences. There is also a potential variation between what the surgeon and the patient perceives as aesthetic. For this reason it is critical to be attentive to the patient's wishes, appreciating that simple breast symmetry rather than an idealized form may well be their preference.

However, insofar as it is possible to specify what an ideal breast should be, the following can be stated:⁶

- Breast size relates to the size and shape of the torso.
- Nipple placement is critical – ideally 19–24 cm from the suprasternal notch. The nipple is centralized over the breast mound with a ratio of volume above the nipple to below the nipple of 45:55. The nipple should ideally be oriented vertically at a 20° angle.
- The majority of breast volume should be in the lower outer quadrant – following the natural gravitational vector, with the minority in the upper inner quadrant. The line from the nipple to the clavicle, on lateral view, should be straight or slightly concave. The angle at the IMF should preferably not be too sharply defined but become sharper with age, as volume increases and therefore gravitational pull increases. The angle between the breast mound and thorax at the medial and superior border of the footprint is very obtuse. Sharp angles here create an artificial 'implant' look. The angle at the lateral border is slightly sharper but never exceeds about 60° in standing position.

- A critical measurement of the aesthetic breast is the line from the inferior margin of the areola to the IMF. This should be somewhere between 6 and 8 cm, depending on the breast volume. Any such excess of tissue below the nipple creates a 'bottoming out' appearance.
- It is not possible to create a functionally lactating breast, nor one that is necessarily erogenously responsive. However, the reconstruction should not be functionally disadvantageous. It should be pain free, without any disabling donor-site complications, protectively sensate, and have a tissue consistency and movement similar to that of normal breast tissue.

Oncology

Breast cancer is now considered to be the most common invasive cancer, and is clearly a global phenomenon of almost epidemic proportions. In the United States, approximately 232 340 new cases of female invasive breast cancer are predicted to occur in 2013.⁷ It accounts for 29% of all cancers in women and is second only to lung cancer as a cause of cancer deaths. In terms of incidence, one in nine women who reach the age of 85 in the US will develop breast cancer.⁸ Rates have steadily increased by around 1–2% per annum from the 1980s, although that has been explained by the widespread use of mammography screening. The impact on healthcare systems remains immense for treatment as well as restoration.

Risk factors

Of all risk factors, the primary one is that of gender. The additional X chromosome exposes breast tissue to the cyclical fluctuating influence of powerful hormones, with constantly changing reproductive stimuli. Any decrease of the number of cycles theoretically reduces the proliferation of breast cells and thus the risk of breast cancer. Age >30 years old at first full-term pregnancy, nulliparity, early onset of menses <12 years old, and late age at menopause beyond 55 years old are related to increased risk of breast cancer.⁹

Of equal importance to female gender is the risk factor of age. Half of all cases occur in women older than 65. In 2004–2008 95% of newly diagnosed breast cancers occurred in women 40 years old and older.¹⁰ In fact the curve is bimodal, with the first peak at 50 years and the second at 70 years.¹¹

Familial factors are associated in 20% of cases with a relative diagnosed with the disease. The risk is 4 times higher if a mother or sister is affected, and 5 times higher if two or more first-degree relatives have been diagnosed with breast cancer.

Hereditary breast cancer accounts for 5–10% of the cases.¹² In 1990 the genetic susceptibility to cancer was attributed to two specific loci, those being tumour suppressor genes or in this case *BRCA* genes. They characteristically repair damaged DNA, and reduce the likelihood of cells proliferating excessively. Mutations in the *BRCA* complex (1 and 2) were able to be identified through blood tests and genetic profiling.

Women with *BRCA1* mutations are estimated to have a 44–78% risk for developing breast cancer by the age of 70; the corresponding risk for *BRCA2* mutations is 31–56%.¹³ These women are also at increased risk of developing ovarian cancer. It is now possible to test patients with a strong family history in order to counsel them on their own susceptibility. Their assessment, follow-up and treatment should take place in the context of a multidisciplinary team composed of oncologists, radiologists, general surgeons, gynaecologists, pathologists and plastic surgeons. Once the diagnosis has been established, some of these women will opt for prophylactic bilateral mastectomies rather than chemoprevention and aggressive follow-up. Bilateral prophylactic mastectomy reduces the risk of breast cancer in these patients by 90%.^{14,15} It is of great importance to be aided into an informed decision with regard to the appropriate type of reconstruction for them.

The greater prevalence of breast cancer in developed nations suggests lifestyle factors play a significant part. Rates in the developing world such as the Far East, in Eastern and Central Europe are rising rapidly. Within the developed nations, prevalence is lower in areas of social deprivation as many of the risk factors prevail among more affluent populations.^{16,17} Within the same context, obesity increases the risk for postmenopausal breast cancer¹⁸ and alcohol consumption has a dose-related effect.¹⁹

Extensive research has taken place to establish the relationship between increased risk of breast cancer and hormone replacement treatment (HRT), which involves combination of oestrogen and progesterone for women with postmenopausal symptoms. Women on HRT have an increased risk of developing breast cancer and this risk is higher the sooner they start or the longer they continue the treatment.^{20,21} Last but not least, significant exposure to radiation at different ages also appears to increase the risk of breast cancer.

Pathophysiology

Most of the breast cancer tumours arise from ductal breast elements. Repetitive hormonal stimuli on the normal breast tissue, theoretically promote the malignant transformation of the ductal cells. Ductal carcinoma *in situ* (DCIS) is characterized by malignant cells confined into the borders of the basement membrane. Approximately 15–30% of newly diagnosed cancers are in the form of DCIS in women under a screening mammography programme. It is unknown which of those will progress into invasive carcinomas but there are histological parameters such as comedo necrosis, nuclear grading and solid growth that manifest a more malignant cytology and thus greater possibility of progression to an invasive tumour.²²

The most common histological types of breast cancer are infiltrating ductal carcinoma (75%), followed by lobular carcinoma *in situ* and infiltrating lobular carcinoma, which arise from the breast lobules. Other histological types are medullary (5%), which carries a favourable prognosis, mucinous or colloid (5%), tubular (1–2%), papillary (1–2%), metaplastic (<1%) and

mammary Paget's disease (1–4%). These have their own behavioural characteristics, which align with the presence or absence of oestrogen or progesterone receptors, or the overproduction of human epidermal growth factor receptor 2 (HER2).

Hormone and targeted treatment

Women who test positive on immunohistochemistry staining for oestrogen hormone receptors are amenable to hormone therapy such as tamoxifen, which is an antagonist of oestrogen receptors and prevents oestrogen from binding and stimulating cancer cells. When administered as adjuvant treatment it reduces the risk of recurrence and death.^{23,24} In addition, tamoxifen is proven to reduce the risk for breast cancer significantly when administered prophylactically to women with known high risk.²⁵

However, patients on tamoxifen treatment are at risk of venous thromboembolic events²⁶ and after communication with the oncology team they are advised to discontinue it approximately two weeks before a free flap reconstruction.

Another type of medication, used specifically for postmenopausal patients, with a cancer positive for hormone receptors, are the aromatase inhibitors (AIs). The AIs have the ability to inhibit the enzyme responsible for the production of oestrogens in the periphery from adrenal gland precursors. They have been found to be of benefit in the treatment of early as well as advanced breast cancers.^{27,28}

Approximately 15–30% of the breast cancers overproduce human epidermal growth factor receptor 2 (HER2). Trastuzumab (Herceptin) is a monoclonal antibody that targets the HER2 protein of breast tumours and it offers a survival benefit in metastatic cancer.²⁹ In addition, Herceptin, when administered in conjunction with chemotherapy for early-stage breast cancer, reduces the risk of recurrence by 52% and death by 33%, compared to chemotherapy alone.³⁰

Trastuzumab has been related to cardiotoxicity manifested as decreased left ventricular function and cardiac monitoring is advised for patients treated with Herceptin.³¹

Chemotherapy

The surgical and medical treatment of breast cancer is individualized. Factors that are taken into consideration in the administration of adjuvant chemotherapy are the size of the invasive component of the primary tumour, the nodal status, hormone receptor expression and HER2/neu expression. Histologic parameters that are taken into consideration as well are the lymphovascular invasion and histologic grading.

Adjuvant chemotherapy is administered for 3–6 months and it includes a combination of different medication. It has been successful in demonstrating reduction in recurrence rates and improvement of the survival outcome.³² An overview of the randomized trials on administration of adjuvant chemotherapy in early-stage breast cancer showed a substantial reduction of 5-year recurrence rate and 15-year mortality rate regardless of the oestrogen receptor status of the primary cancer.²⁴

The implications of chemotherapy on reconstruction have been comprehensively reviewed in a meta-analysis by the American Society of Plastic Surgeons. There is no consistent finding that preoperative chemotherapy is a significant risk factor for complications in expander/implant reconstructions. It is advised that adjuvant chemotherapy should be completed 4–6 weeks prior to reconstructive surgery, and that adequate white cell level should be confirmed preoperatively. There is no definite data on effects of chemotherapy on autologous reconstruction.^{33,34}

Prognosis

Prognostic factors include the status of axillary lymph nodes (number of nodes involved), tumour size, lymphatic or vascular invasion, age, histological grade, histological subtype, response to adjuvant treatment, oestrogen/progesterone receptor status and *HER2* gene amplification.

The key objective in breast cancer treatment remains that of complete local cancer tissue removal such as to prevent recurrence or wider spread, and to treat more widespread disease. Complete surgical excision with negative margins remains the principal method of treatment and can be curative in patients with early disease, with adjuvant therapy (chemotherapy and radiotherapy) used to treat micrometastases.

Oncological-surgical treatment

Mastectomy

Breast cancer surgery has its origins in an aggressive technique developed by Halsted in 1882, without reconstruction in mind, and with extensive tissue clearance and disfiguring chest wall scarring. This *en bloc* removal of all breast tissue and pectoralis major muscle, including the axillary nodes (and/or internal mammary lymph nodes), was modified by Patey to a procedure where the pectoralis major muscle was spared. A 'simple' or 'total' mastectomy is one where all breast tissue including the skin and nipple areolar complex (NAC) is removed, possibly accompanied by the ipsilateral axillary lymphatics.

In modern times, the appreciation of the wider and complex ramifications of breast cancer treatment has brought with it the now universal acceptance that the disease should be managed by an oncological team. The disfiguring consequences of the surgery, and the development of surgical techniques to reduce this, has prompted cancer surgery to evolve to facilitate reconstruction. Increasingly, the standard preservation of the IMF and superolateral fold, a useful residue of skin envelope, has been supplemented with preservation of even the areola or NAC (SSM or skin-sparing mastectomy) which confers a greater likelihood of achieving symmetry. Importantly, reviews have shown that a skin-sparing periareolar subcutaneous mastectomy does not increase the likelihood of local recurrence.^{35,36} The advantages of the SSM are the judicious use of native skin

with its preferential colour and texture match, the retention of the breast footprint and critical elements of the skin envelope. There may be less need for surgery to the contralateral breast, and a smaller reconstructive skin paddle may be required. Surgical judgement is required to ensure that the length and thickness of the undermined flaps are viable, as necrosis can compromise wound healing and result at worst in a failed reconstruction. If necessary, a Wise pattern is employed to tailor the skin flaps to an appropriately sized envelope. The reconstruction essentially involves the filling of a skin envelope with synthetic or autologous tissue, or both, and any NAC defect is replaced by a skin island from the flap.

The NAC has been shown to be free of cancer cells when there is no multifocal disease, the tumour is less than 2 cm diameter (T1), and there is greater than a 4 cm distance between the tumour and the NAC.³⁷ This therefore applies particularly to risk-reducing prophylactic mastectomy. The mastectomy may then be areola sparing, or nipple and areola sparing. The nipple itself can be removed together with the mammary gland in one single specimen. The skin of a flap that reconstructs the breast mound can later be used for the nipple reconstruction together with re-approximation of the areola.³⁸ Results of a retrospective study also show that a nipple-sparing procedure may be used in relevant clinical circumstances.³⁹

Studies have now shown that 'lumpectomy' or partial mastectomy (breast conserving surgery) with adjuvant radiotherapy is comparable to modified radical surgery not only in survival terms, but also in local recurrence rates.⁴⁰ In early cases, therefore, therapeutic mammoplasty with radiotherapy is used, where after a local excision varying local reconstructive patterns are employed to reform the breast to an aesthetic shape, with or without contralateral surgery.

The axilla, axillary dissection and sentinel lymph node biopsy

Approximately 80% of the breast's lymphatic drainage is through the axilla and the axilla is the commonest site of metastasis in breast carcinoma. Axillary node status is one of the critical indicators of prognosis. Until recently, identification of axillary lymph node spread was through clinical examination and axillary node sampling at levels 1 and 2 (axillary nodes below subclavicular vessels). More recently, at clinical assessment, the routine use of axillary ultrasound and fine needle aspiration has become commonplace. With nodal positivity, wider axillary clearance was then usually considered necessary. However the inevitable consequence of this was chronic brachial lymphoedema, possibly with chronic pain, paraesthesia, recurrent infections and seroma.

The identification preoperatively or indeed intraoperatively of sentinel nodes with contrast injections (vital dyes, radioactive tracers or combinations of the two) into the peritumour area has been introduced into the clinical pathway. These nodes are the first nodes or groups of nodes that drain from the breast to the axilla.⁴¹ If the biopsied sentinel node is disease free, no axillary

dissection is performed.^{42–45} Hereby, through a minimally invasive procedure the cancer can be staged in patients who have clinically negative nodes and who have T1 to T2 tumours.

As definitive therapy, studies have shown cancer outcomes for both approaches – axillary dissection and sentinel node biopsy with axillary sparing, similarly matched for disease free survival and local recurrence.^{46–49} Any adjunctive therapy may have been at the oncologist's discretion, and the use of axillary radiotherapy as an axillary-sparing modality has been shown also to be clinically justified.⁵¹

Radiotherapy

The breast and radiation therapy

Radiation therapy has an established role in the therapeutic management of locally advanced breast cancer in reducing the local recurrence and providing a clear overall survival advantage. This has been well established by multiple trials.^{52–54} The American Society for Therapeutic Radiology and Oncology recommend postmastectomy radiation therapy for breast cancer patients with advanced disease (T3 or T4 tumours) or at least four positive axillary nodes. The role of radiation therapy in patients with T1 or T2 tumours and one to three positive axillary nodes⁵² remains questionable. Additional to this is the controversy about which would be the correct reconstructive method for patients who received radiation.

Radiation pathophysiology and effects on tissues

There is a range of effects that can occur in irradiated skin over time. In general, radiation can damage cells by directly disrupting DNA or through free radical production. This damage results in disorganized fibroblast activity, microvascular thrombosis and inadequate tissue oxygenation. During the 3rd to 6th week of therapy, populations of basal layer stem cells become depleted in the treated area. The gross skin changes occurring with standard schedules and doses of radiotherapy to the breast are categorized as early or late effects, as determined by the time at which they present. This is covered in more detail elsewhere, but a brief account of salient features in breast treatment are discussed below.

Early effects are defined as those that occur within 90 days of the first radiation therapy. The skin reactions include dryness, epilation, pigmentation changes and erythema. Dryness and epilation are results from destruction of the dermal layer. Hyperpigmentation is a result of epidermal melanocyte stimulation. Some patients may develop hypopigmentation due to complete eradication of all melanocytes. Acute erythema is caused by cytokine-mediated inflammatory reactions.

Late effects are considered the effects that present after 90 days from the first radiotherapy. These effects are related to dermal injury. Until the moment that late effects appear the skin can appear 'normal'. Late effects can appear after months or even

up to 15 years later. These late effects are directly related to the dermal fibroblast response to radiotherapy and the resorption of collagen fibres. Telangiectasia is another effect of radiation that can manifest months or multiple years after the therapy. If necrosis appears this is associated with doses of radiation higher than those used in breast cancer treatment.^{55,56}

Patients who underwent lumpectomy and irradiation are also predisposed to an increased incidence of complications, although the extent of radiation damage may be more limited. Recent research has shown that even when a three-beam radiation has been used (a modern radiation technique), the complication rate remains high in comparison with the non-irradiated breast.⁵⁷

Radiotherapy and breast reconstruction

Evidence indicates that radiation therapy, regardless of when it is administered (before reconstruction or on a reconstructed breast), is associated with an increased risk of complications and/or reconstructive failure in patients undergoing postmastectomy expander/implant breast reconstruction. A prospective cohort study, which controlled for confounding factors in multivariate logistic regression analysis, demonstrated that postoperative radiation therapy to an implant was associated with a six-fold increase in risk of complications compared with no radiation therapy. Patients who received postoperative radiation therapy to an implant were also 5.1 times more likely than patients who received no radiation therapy to experience reconstructive failure.⁵⁸ Additionally, a 5-year follow-up retrospective cohort study found that implant patients with radiation had a 61% total complication rate compared to only 21% among patients without radiation.⁵⁹

Patients should be counselled regarding these associated complications. Complications may include early and severe capsular contracture, infections, implant displacement, skin erosion and perforation followed by implant exposure, rippling, seroma, haematoma and wound-healing problems.

Autologous breast reconstruction in an irradiated area can be performed without major risks or complications. Recipient vessels within the irradiated field are surrounded by an increased amount of fibrosis but can still be used. If there is doubt, recipient vessels from outside the irradiated field can be used. Soft tissues that have become too fibrotic or damaged by irradiation, are removed and replaced by soft, pliable and healthy tissues of the flap.

If irradiation is to be performed after ablation and reconstruction, we now recommend against performing a primary autologous reconstruction. Even though the side effects of radiotherapy on pedicled or free flaps are minimal and severe complications are rarely seen, we feel it is safer to temporarily introduce an implant or expander (depending on the amount of skin deficiency) into the mastectomy pocket to keep the skin expanded during adjuvant radiotherapy. Expanders can be deflated or inflated during the radiotherapy sessions according to the available devices and to the guidance of the radiotherapist. Once the adjuvant treatment is completed, a

delayed-primary reconstruction can be performed by autologous means by filling up the existing pocket. This way the flap is never directly irradiated, avoiding fibrosis and long-term shape and volume changes.

Implants/tissue expansion/acellular dermal matrix

Alloplastics – synthetics (implants) with acellular dermal matrix/tissue expansion

Introduction

The placement of a suitable implant under the remaining tissues on the chest wall after mastectomy would seem logically to be the simplest and indeed cost-effective way to create a breast mound. In the United States, this is the commonest type (of the order of 67%) of breast reconstruction.^{60,61} The reconstruction may involve a primary implantation, as a staged procedure with the use of a tissue expander, and with possibly further bulking or implant protection using a flap (such as the latissimus dorsi muscle with or without skin). It should be performed with an appreciation of its limitations; it is difficult if not impossible to create a ptotic breast or to match a large breast, and the best results are usually obtained with bilateral procedures. Implants carry with them specific complications, the most important being capsular contracture, which becomes more likely when used with radiotherapy. Implant failure and silicone leakage with silicone gel-filled implants are also relevant.

Technically, the implant comes to rest on the chest wall and pectoralis minor muscle, to a great extent being covered by the pectoralis major muscle (thereby providing partial robust soft tissue cover). However, the lower pole of the implant is covered only by skin and subcutaneous tissue, which renders it at risk for extrusion and failure. Solutions such as the serratus anterior coverage may blunt the IMF and result in a suboptimal shape. The use of a buried dermal flap of the breast inferior pole has been described.⁶² There has been recent promise in the use of an additional biologically engineered tissue layer over the relatively poorly covered lower pole of the implant, and for this acellular dermal matrix (ADM) has found a place in potentially improving outcomes.

Current implant materials

The first attempts to create or augment a breast mound with synthetic material began in the 1960s with silicone implants. This is covered in more detail in the breast augmentation chapter. Briefly, the implant that Cronin and Gerow developed consisted of a teardrop-shape silicone rubber envelope filled with liquid silicone.⁶³ On the back of the implant a Dacron patch was placed to prevent rotation. About 50 years were needed to develop the fifth-generation implants used today. Contemporary models are based on the characteristics of the filler, the shell, the shape and the surface configuration.

The two main types of breast implant in use today are silicone and saline filled. Regardless of the content of the implant, the

shell is made up of silicone elastomer. The majority of implants used today are silicone filled and this is due to their superior feel and durability. In the Unites States, saline-filled implants have been used because of concerns voiced in the early 1990s and the moratorium on the use of silicone implants between 1992 and 2006.^{64–66} The main reason for this was the suspected complication of systemic autoimmune disease. Worldwide studies consisting of over 25 high-level scientific studies and over 10 meta-analyses have failed to prove any such link.

Medical-grade silicone has the advantage of being one of the least bioreactive materials available for medical devices. It consists of mixtures of various chain lengths. The current fifth-generation cohesive gel, developed since the mid-1990s, is a result of the extensive cross-linking of the silicone polymer, conferring properties of greater memory and shape retention. These implants are described as form-stable, offering a consistent anatomical breast shape. They also reduce the likelihood of rippling, and folding or collapse in the upper pole. In the unlikely instance of rupture, they will not leak and give rise to silicone migration to elsewhere in the body.^{67,68} These implants have now been developed with a variety of dimensional options in relation to base-width, projection and height, all of which can be assessed and applied at the surgeon's discretion in order to optimize symmetry and the aesthetic outcome.

Attempts have been made to replace the contents of silicone implants, particularly when the health risks of silicone gel remained under question. Soya-filled (trilucent) implants appeared on the market for a short time, as did various hydrogels (Poly Implant Prostheses (PIP)) and a pure form of triacylglycerides. These two formulations were withdrawn from the market because of the inability to demonstrate safety data.^{69,70} Public confidence in silicone implants was once again undermined when poorly engineered implants with an unacceptably high failure rate and inferiorly graded silicone (PIP) were allowed medical certification.⁷¹ Under scrutiny is also an association between silicone implants and anaplastic large cell lymphoma, although to date the number of cases remain very few and any link has by no means been formally established.^{72,73}

Implant shell

The first implant shell, developed by Cronin and Gerow, was smooth surfaced and relatively fragile, and was related to higher rates of failure and capsule formation. A second technological development arose a few years later, where a polyurethane foam coating created a rough porous surface with an open cell structure. This allegedly prevented circumferential collagen deposition, thereby reducing capsular contracture and lowering rupture rates. In addition, they disguise or at least reduce rippling, and their tendency to adhere to tissues to reduce 'bottoming out' also made them potentially appealing alternatives. Polyurethane devices were briefly discontinued because of the effect of a polyurethane by-product known as 2,4-toluenediamine (TDA). It was identified as a carcinogen in rodents with unknown potential risks in humans. The US Food and Drug

Administration (FDA) has concluded that TDA-induced breast cancer was an infinitesimal health risk to women with such breast implants.^{74,75} Polyurethane-coated implants have now been reintroduced, and are favoured as a replacement implant where capsular contracture exists, or indeed even as a primary option.

Risk factors for implant and expander-based reconstruction

The American Society of Plastic Surgeons has published a comprehensive set of evidence-based guidelines for the use of implants and expanders in breast reconstruction.⁷⁶ Risk factors have been identified and weighted according to rigorous meta-analysis. These include infection, haematoma, seroma, wound dehiscence, skin flap necrosis, expander/implant deflation, capsular contracture, hypertrophic or keloid scarring, and venous thromboembolism disease. The strongest weighting, and therefore the risk factors that deserve the most caution, are smoking and obesity. Less weighted but nevertheless of significance is postoperative radiotherapy to both implants and to expanders. Diabetes and preoperative radiation are less significant, as are breast size, and hormonal therapy or chemotherapy.

Capsular contracture

The spontaneous elaboration of a deforming layer of scar tissue around an implant has been a confounding complication ever since silicone implants were introduced. Shell texturing, and lately the reintroduction of a polyurethane coating, has had a significant impact on reducing its incidence. The Benediktsson and Perbeck study⁷⁷ evaluated rates of capsular contraction (Baker classification, Table 39.1) around saline-filled textured implants, finding that the rate of capsular contraction was significantly higher for irradiated than for non-irradiated breasts. The difference in contracture rates was not evident during the first six months but was highly significant thereafter, even 5 years later. This has resulted in reconstructive strategies such as staged definitive implantation when possible adjuvant radiotherapy is anticipated (the 'delayed-immediate' approach).

Tissue expansion

The introduction of tissue expansion in 1982 by Radovan paved the way for breast skin enlargement in circumstances where skin cover might be in short supply.⁷⁸ The relative rigidity of the ribcage provides a suitably firm base for the expansion. With serial episodes of saline inflation of the silicone balloon to a point of overexpansion advised at 30–35%,⁷⁹ extra skin may be created to allow for a larger implant, if not to help to create

Table 39.1 Baker capsular contracture classification

Grade I	The breast is normally soft and appears natural in size and shape
Grade II	The breast is a little firm, but appears normal
Grade III	The breast is firm and appears abnormal
Grade IV	The breast is hard, painful to the touch and appears abnormal

ptosis. In general, it would seem that anatomically shaped, textured expanders with an integrated port are preferred. The shaped or bi-dimensional expander allows for preferential expansion of the lower pole.^{80,81} However, this necessitates at least a two-staged procedure, which the Becker double-lumen implant (a combination of saline expander and silicone implant) has endeavoured to reduce to one stage.⁸² Although the expanded skin might allow for a larger implant, however, a key disadvantage has been the inability to create significant ptosis. This seemed only feasible with the importation of additional tissue, such as with a latissimus dorsi flap.

The apparent suitability of ADM in these procedures, however, has added further support for implant placement without the need for flap reconstruction. Tissue expansion under the collagen scaffold of ADM has now found a definite place in the attempts to create an implanted ptotic breast. However, an irradiated chest is considered a relative but not absolute contraindication to tissue expansion,⁸³ with the tissue being less pliable, rendering expansion difficult and unpredictable. This results in less favourable outcomes, with more asymmetry and less projection in comparison to non-irradiated controls.

Acellular dermal matrix

Subpectoral implant placement following subcutaneous mastectomy leaves the lower pole covered by a relatively thin layer of skin and subcutaneous tissue. This can prove to be a weak support for an implant, prone to poor radiation tolerance, and with a potential for breakdown and implant exposure. It can attenuate the IMF, and allow superior migration of the inferior edge of the pectoralis muscle.⁸⁴ The raising of local muscle tissue such as rectus abdominis/serratus anterior serves only to potentially increase morbidity and deform breast shape by restricting lower pole expansion.⁸⁵

This problem has originally been addressed by the placement of an allogenic dermal sublayer attached to the inferior pectoral muscle edge superiorly, and the IMF inferiorly, and the serratus anterior muscle laterally.^{86–88} ADM is a cell-depleted biological tissue layer, usually of human or porcine dermal origin, which biologically integrates through revascularization into the tissues into which it is placed. In doing so it adds a permanent collagen scaffold or hammock to the inferior pole of the reconstructed breast. As such it allows for a greater volumetric increase and limited degree of breast ptosis, thereby potentially removing the need for a contralateral procedure. There have been improved results in terms of appearance, stability of implant position, ptosis, reduced rippling and radiotherapy tolerance, with decreased capsular contracture rates.^{84–86} The attractiveness is strengthened by there being no donor site morbidity and scar, with a single scar limited to the breast, a reconstruction with local compatible tissue, and with no preclusion of a further surgical procedure (such as autologous reconstruction) if required. Contrarily, and besides being expensive, there have been reports of greater incidences of infection, seroma and skin necrosis,

although not sufficient as to contraindicate its use.⁸⁹ Particular caution has to be exercised in attempting to reconstruct a large breast (i.e. greater than 600 g).⁹⁰ The American Society of Plastic Surgeons guidelines on the use of ADM recognize the increased reported complications in many studies, but also appreciate its potential benefits in selected cases. They advise therefore that it is subject to the clinician's discretion.⁹¹

Immediate versus delayed reconstruction

There would logically appear to be a benefit in patients having breast reconstruction as a delayed second procedure some time after their cancer surgery, in order to be more certain of the cancer clearance and to allow for adjuvant therapy. Surgeons may therefore be inclined to prefer this.⁹² It would shorten their operative time, and allow for patients to adjust to life without a breast, and give time for consideration of the reconstructive options and their risks. Immediate reconstruction, however, allows for a one-stage procedure and facilitates reconstruction when much of the breast skin envelope, and the IMF, can be preserved.

Studies have shown there to be no increased risk from an oncological standpoint, however.⁹³ An increase in complications was identified, in particular wound infections,⁹⁴ but there was a definite patient preference for, and demonstrated psychological benefit from, immediate reconstruction.^{95–97}

Nevertheless, immediate reconstruction carries with it service implications, including greater interspecialty collaborative working. Current guidelines from the American Board of Plastic Surgeons are that, in the light of incomplete evidence, the timing of reconstruction should be on an individual basis.⁷⁶

Where nodal status and indeed adequacy of resection proved uncertain, and where adjuvant radiotherapy might be expected, the M.D. Anderson Centre in Houston pioneered the concept of 'delayed-immediate' reconstruction, whereby the immediate procedure simply involved the submuscular placement of an underfilled expander. This is in view of the greater incidence of complications encountered in radiation to reconstructed breasts (whether implant-based or autologous). Here it was felt logical to perform at least a preparatory immediate procedure that might optimize later reconstruction. This would allow for later expansion once the adjuvant radiotherapy was completed, or facilitate autologous reconstruction by maintaining a suitably placed subcutaneous cavity that might accommodate a definitive soft tissue transfer at a later stage.⁹⁸

Latissimus dorsi

Historically, the latissimus dorsi musculocutaneous flap can be considered the forerunner of breast flap reconstruction, having been described originally in 1906 by Tansini,⁹⁹ with resurgence in the 1970s when Bostwick¹⁰⁰ introduced a skin island to the flap.

The proximity of its robust vascular pedicle (the thoracodorsal artery and venae comitantes) and the ready availability of suitable soft tissue placed the latissimus dorsi musculocutaneous flap in a pre-eminent position for the creation of a breast mound during the last three decades of the twentieth century. However, the volume achieved with the flap may be limited due to insufficient tissue bulk and an implant or fat grafting is sometimes required. When used with an implant it can reduce capsular contracture and rippling.

The donor site morbidity with regard to loss of function and scarring is a matter of debate in plastic surgery literature. Some studies have shown that the loss of a latissimus dorsi muscle does little to limit function¹⁰¹ and the scar can be placed transversely, to be concealed within a bra strap, or can be a short oblique scar in the relaxed skin tension lines. When extended latissimus dorsi flaps are harvested, the contour deformity of the back can be more conspicuous.

Relative technical ease and reduced operation times have made it stand the test of time. This flap is considered an alternative option when the abdomen, lumbar and gluteal areas are scarred or otherwise unsuitable as a donor choice.¹⁰²⁻¹⁰⁴

Technique

The patient is positioned in a lateral decubitus position. The preoperatively designed skin paddle is incised until the muscle fascia. The skin around the skin paddle is undermined over the muscle so that the muscle can be mobilized. Flap elevation is easier by identifying the anterior margin of the muscle. The vascular pedicle runs underneath the latissimus dorsi muscle. The thoracodorsal artery enters the latissimus dorsi muscle after giving a branch to the serratus anterior muscle. This branch should be preserved. The vessels then split into a descending and transverse branch, allowing the surgeon to harvest only the antero-lateral strip of muscle if a limited reconstruction is required.

A subcutaneous tunnel is then created and the flap is transferred without tension in its recipient site. To achieve maximal anterior transposition, the tendinous insertion can be released. It is a consideration to release only 90% so that inadvertent traction of the pedicle will be prevented.^{105,106}

Decisions regarding division of the thoracodorsal nerve remain controversial and tend to be at the surgeons discretion. Transection of the motor nerve can be performed immediately. This will lead to progressive loss of volume of the breast but will avoid inappropriate contraction of the muscle and unwanted displacement of the (breast and) implant. If left intact, it maintains the greatest muscle volume by reducing atrophy.

The flap has undergone modifications. To add further bulk, additional fat can be harvested deep to Scarpa's fascia over the muscle in the lumbar or the scapular area, leaving only 1-cm-thick overlying skin flaps. A fleur-de-lys skin

island can also be taken to maximize the skin flap area. In addition, a muscle-sparing technique of the perforator-based thoracodorsal artery perforator (TDAP) flap is used for more limited mastectomy defects, mainly in the lateral quadrants of the breast.

Complications

The major disadvantage of combining a latissimus dorsi flap with an implant is that one combines the long-term morbidity of both techniques, mainly the creation of a significant scar on the back, potential loss of function and capsular contracture around an implant.

Flap necrosis is a possible complication. Problems with flap inset and wound healing are rare. Total flap loss is exceptional and mostly due to technical problems or coagulopathies. Partial flap loss is more frequent, especially in the most distant part of the flap (infero-medial at donor site) that ends up at the supero-medial part of the breast, especially in extended flaps. These issues are more frequent in patients who have undergone irradiation.

Recent studies from Saint-Cyr *et al.*¹⁰⁶ have shown that use of the pedicle descending branch muscle-sparing latissimus dorsi flap produces minimal donor site morbidity. The tendency to seroma formation in the undermined cavity has been drastically reduced by quilting sutures.¹⁰⁷

As with any wound that is closed under tension, the donor site may tend to form hypertrophic scars. Breast-shaping problems are often seen, mainly in the long run. Fullness of the sub-axillary region, where the proximal part of the muscle passes, is predominantly seen when the tendon has not been transected completely. For the same reason it is very difficult to create a well-defined lateral breast crease in a single procedure. Prolonged contraction of the latissimus dorsi muscle (especially when the latissimus dorsi motor nerve is left intact) will pull the breast and the underlying implant laterally resulting in asymmetry and insufficient definition and fullness of the medial breast mound.

The skin texture and thickness is very different from the breast skin and if incisions are not well positioned over the breast, a pincushion effect can disfigure the shape of the breast.

Pedicled transverse rectus abdominis myocutaneous flap

One of the most popular and most frequently performed autologous tissue flaps in breast reconstruction is the transverse rectus abdominis myocutaneous flap (TRAM flap). The flap was first described by Holmström,¹⁰⁸ was popularized in 1982 by Hartrampf *et al.*,¹⁰² and has been modified to minimize abdominal wall morbidity by harvesting only the muscle surrounding the perforators (the muscle-sparing TRAM flap).¹⁰⁹

The rectus abdominis muscle has a dual blood supply – the superior epigastric artery and the deep inferior epigastric artery. In the pedicled TRAM flap operation, the superior epigastric arterial system is utilized, with a horizontal lower abdominal skin paddle. Skin and subcutaneous tissue perfusion is via para-umbilical perforating vessels that originate from an intramuscular network nourished by the superior as well as the deep inferior epigastric vessels. The size and location of these vessels are variable. Venous drainage can be either from the comitant veins of the deep perforators or through the superficial system. The perforating arteries and veins supply a random cutaneous vascular network or plexus.

Historically, four perfusion zones have been recognized, with zone IV being the most distant part from the perforator vessels. Blood flow and, thereby, tissue survival will depend on antero-grade flow of arterial blood to the most distant parts and sufficient retrograde venous pressure to pump the blood back to the perforators or the superficial venous plexus. Blood pressure and cardiac output are therefore just as important to distant blood flow as vascular anatomy. The old concept of delineated zones is therefore considered historical and obsolete and should be abandoned.

As the pedicled TRAM flap relies on a very long pedicle that is subject to anatomical variations on top of unfavourable flow physiology, along with the possibility of a dominant superficial venous plexus, the incidence of partial necrosis is high. Attempts to augment vascularization by harvesting a second rectus muscle lead to an unacceptable high rate of donor site morbidity and should be avoided.

Technique

Technical details

A midline mark is made from above the umbilicus, through the TRAM skin island to the pubis. This line can be used as a guide in placing the midline of the upper abdominal flap to the midline of the pubic area when closing the abdominal donor site. The transverse skin island of the TRAM flap is marked over the lower abdomen and approximates the same tissue that is removed in a cosmetic abdominoplasty.

The flap can be designed on one or both rectus abdominis muscles, with most surgeons electing to perform a unilateral flap to minimize donor site morbidity. In cases of a unilateral reconstruction the contralateral muscle is used due to better flap rotation and manipulation. When a bilateral reconstruction is needed, both rectus abdominis muscles can be used with each muscle being used for the ipsilateral side. Donor site morbidity is once again relatively high.

A first incision is made along the upper edge of the skin island until the fascia of the rectus abdominis muscle is reached. The chosen muscle is identified to the level of the costal margin. The anterior rectus fascia is then incised medially and laterally over the muscle.

The inferior part of the flap is then incised to the level of the rectus muscle. After identifying the medial and the lateral

border of the muscle, the inferior margin of the rectus is divided with electrocautery and the entire posterior surface of rectus muscle is raised from the posterior sheet up to its costal margin attachments. At that point a costal vessel is ligated to give a more tension-free transposition.

Once the dissection is completed a subcutaneous interconnection (tunnel) must be created between the costal attachments of the rectus abdominis muscle and the mastectomy defect. Once the flap has been passed through the tunnel to the defect, the skin island must be checked for venous congestion and arterial perfusion. The most distal part of the skin paddle needs to be systematically removed to avoid high rates of partial flap necrosis.

The donor site defect is usually repaired with large non-absorbable sutures. Some surgeons recommend reinforcement of the fascial repair with a mesh overlay. This can, however, lead to additional complications of chronic discomfort or pain. The abdominal wall skin defect and replacement of the umbilicus is performed as in an aesthetic abdominoplasty.¹¹⁰

Pedicled or Free TRAM flap

When patient and surgeon have decided that the breast should be reconstructed with abdominal donor tissue, the surgeon then has to decide whether a pedicled or a free TRAM flap is appropriate for the clinical circumstances that exist.

The advantage of the free TRAM flap technique compared to its pedicled sibling is improved blood supply to the skin island by virtue of its vascular pedicle being the larger deep inferior epigastric artery. The free flap, therefore, is used in patients at higher risk for partial flap loss with the pedicled technique. Such high-risk patients include smokers, the obese and patients with prior abdominal surgery. Patients without these risk factors can be expected to achieve good results with either the pedicled or free flap technique.¹¹⁰

Complications

The most common complications are fat necrosis followed by infection, seroma, abdominal hernia, partial flap loss, and deep vein thrombosis.

Removal of the entire or a full-width part of the rectus abdominis muscle will lead to irreversible loss of abdominal wall competence and force, resulting in abdominal wall hernia or bulging, a decreased ability to perform daily activities in work and sports, decreased mobility, chronic abdominal wall pain and imbalanced muscle forces around the lumbar spine, resulting in chronic back pain. Complications are more frequent in patients who have undergone a bilateral TRAM flap.¹¹¹ The denervation of the rectus muscle will lead to loss of breast volume several months after surgery. Additionally, epigastric bulging is often seen as a result of subcutaneous tunnelling of the muscle, leading to poor definition of the medial IMF.

Free TRAM

The free TRAM flap involves the use of abdominal excessive tissue composed of skin, subcutaneous fat and variable amount of rectus abdominis muscle as a free tissue transfer mound. It is with no doubt the flap that has undergone the most extensive evolution throughout the last 30 years.

Since 1982, when it was popularized by Carl Hartrampf¹⁰² for breast reconstruction in the pedicled form, several other versions have emerged in the process of improvement. Although aesthetically pleasing results have been demonstrated with the pedicled technique, the need to offer patients a reconstructive option with the least donor site morbidity possible has focused interest in muscle-sparing techniques and more specifically muscle-sparing free flaps. Holmstrom and Robbins^{108,112} described the free rectus abdominis myocutaneous flap for breast reconstruction even before it was described in a pedicled form.

Indications and contraindications

Patient-, surgeon- and unit-related factors are the salient points in an individualized reconstructive approach. This type of autologous reconstruction demands adequate, redundant abdominal tissue that can replace in volume the original breast. Preoperative physical examination will also reveal previous scarring which will be critical in deciding the appropriate type of reconstruction. Before the implementation of the CT angiogram, patient selection was dependent on the medical history and physical examination (presence of adequate panniculus, scars, smoking, obesity). The assessment of the abdominal perforators in terms of their calibre, numbers and flow was done intraoperatively.

Recent implementation of the CT angiogram of the abdominal perforators has become routine practice because it assists in patient selection and reduces operative time.^{113,114}

High-risk patients who are obese, heavy smokers (>10 cigarettes/day) and those with significant comorbidities such as diabetes mellitus will benefit from the free muscle-sparing TRAM flap.^{115,116} In addition to the excellent vascularity, studies have shown that it involves less immediate postoperative pain, faster abdominal recovery and shorter inpatient hospital stay^{117,118} when compared to the pedicled TRAM flap.

Contraindications to a free TRAM reconstruction related to patient factors are highlighted in the initial patient consultation when there is inadequacy of abdominal tissue, abdominal scarring and general patient comorbidities that forbid a long general anaesthetic. A CT angiogram for the assessment of the abdominal wall perforators is essential in patient selection. In addition to the above, the surgeon's experience and microsurgical expertise and the availability of a qualified team that will provide postoperative monitoring and support are necessary prerequisites for this type of reconstruction.

Advantages

One of the fundamental differences between the free TRAM flap and the pedicled one is the dominant blood supply. The free TRAM is based on the deep inferior epigastric artery which has been shown to have higher pressure and total blood flow compared to the superior epigastric artery, which is the dominant blood supply to the pedicled TRAM flap.¹¹⁹

Another fundamental difference is that the free flap, although initially introduced as a non-muscle-sparing technique, has evolved into a muscle-sparing technique which nevertheless involves harvesting of a small segment of the rectus abdominis muscle and anterior rectus sheath. This muscle segment safeguards the musculocutaneous perforators in the effort to maintain a robust blood supply in addition to reducing the functional muscle sacrifice. The muscle-sparing technique does not, however, spare the motor nerves of the rectus abdominis muscle as they pass from lateral to medial and from proximal to distal. In that way, large parts of the remaining muscle are denervated and left non-functional. The impact of this denervation is unclear, however, as muscle continuity seems to be more important.

Free tissue transfer combines large volumes of donor tissue, good vascularity, easier inset and elimination of the contour epigastric deformities associated with the subcutaneous tunnelling and the medial IMF breach seen in the pedicled TRAM flap.

The free TRAM flap can be used in immediate or delayed reconstruction and can be anastomosed to either the internal mammary vessels or the thoracodorsal vessels according to the surgeon's preference or special circumstances, such as patients with sentinel biopsy and previous axillary dissection.

The internal mammary vessels are favoured for the well-documented advantages of more medial positioning of the flap, better venous drainage¹²⁰ good arterial flow and unscarred tissue in comparison to the axilla after axillary surgery. Irradiation to the internal mammary lymphatic chain has not shown significant changes to the internal mammary vessel parameters.¹²¹ Last but not least, anastomosis to the internal mammary vessels allows for easier assistance positioning and training opportunity.

In unilateral cases, direct closure of the anterior rectus sheath is always possible in muscle-sparing-free TRAMs, but in bilateral reconstructions closure is not always possible without the use of a mesh.

Complications

Complications can be classified into flap and donor site complications.

Fat necrosis has the potential to occur with every kind of free abdominal flap reconstruction. In theory this is related to the size and position of the perforators, the size of the panniculus, and patient risk factors such as smoking and obesity. The free muscle-sparing TRAM has shown a reduced rate of fat necrosis compared to its precursor, the pedicled form.¹²² Partial flap loss

and complete flap loss are possible complications of both pedicled and free TRAM.

Kroll *et al.*¹²³ and Mizgala *et al.*¹²⁴ have reported that the degree of abdominal wall weakening is proportional to the amount of sacrificed rectus abdominis muscle. This means that the muscle-sparing technique, if performed correctly, by maintaining the nerve supply and vascularity to the remaining rectus abdominis muscle carries reduced risk of abdominal bulging, strength and contour deformity complications.^{115,126} There is no difference in abdominal morbidity between pedicled TRAM flaps and full-width free TRAM flaps.

Flap complications as well as donor site complications have been shown to be significantly higher in obese patients, whereas donor site abdominal flap necrosis and hernias are significantly higher in smokers.^{127,128}

Deep inferior epigastric artery perforator flap

The deep inferior epigastric artery perforator (DIEAP) flap represents the most evolved version of abdominal flap technique for breast reconstruction. Its unique difference from the TRAM flap is the complete preservation of the rectus abdominis muscle with the usage of skin and subcutaneous fat only, based on musculocutaneous perforators of the deep inferior epigastric artery.

Koshima and Soeda¹²⁹ pioneered the deep inferior epigastric artery skin flaps for pedicled groin reconstruction and later Koshima *et al.*¹³⁰ described 13 free thin paraumbilical perforator-based flaps for intraoral defects. The use of the DIEAP free flap for breast reconstruction was reported for the first time by Allen and Treece.¹³¹

Indications

Selection of patients utilizes the same criteria as a TRAM flap. Initial consultation of a patient seeking autologous breast reconstruction should focus on the present comorbidities and previous operations, physical examination to assess the size of the abdominal skin excess and abdominal scarring and the pre- or postoperative cancer treatment, such as chemotherapy and radiotherapy. The ideal patient is free of comorbidities, not overweight or obese, non-smoker and has not had a previous abdominoplasty or abdominal liposuction. Abdominal suction-assisted lipectomy is considered a relative contraindication but preoperative radiological imaging can safely depict the intact abdominal perforators and allow for a successful DIEAP reconstruction.¹³²

For patients who have a diagnosed prothrombotic condition in addition to the breast cancer, an individualized antithrombotic regime should be decided in conjunction with the haematology team.

Preoperative CT angiogram (CTA) of the abdominal wall perforators is now routinely used in microsurgical centres as it benefits both patient and surgeon.^{113,114} This is performed in the

process of the patient selection as it assists in the assessment of the perforator location, their size and intramuscular course which, on some rare occasions, can render a patient a poor candidate for this type of reconstruction (Figure 39.1). The CTA is reported by a specialist radiologist who displays the perforators on a reproducible X to Y axis centred to the umbilicus. These measurements are reproduced in theatre before the operation and the perforators are marked on the abdomen and checked with a handheld Doppler.

The flap is centred over the location of the perforators that are estimated to be the best by CTA, however, the design should be symmetrical over the midline to allow an aesthetic donor site closure.¹³³

Technique

A few technical points on raising a DIEAP flap should be highlighted.

When the distal incision of the flap is performed in the suprapubic crease, the superficial inferior epigastric vein should be preserved and taken with the flap in the maximum length possible. In the event of inadequate venous flow, these vessels will take the role of a 'lifeboat'.

Raising the flap usually starts from lateral to medial until the lateral perforators are visualized. If a CTA has been performed then dissection is faster until this point. All the perforators must be visualized and preserved before the best one is chosen and the rest are ligated. Often the deep inferior epigastric artery (DIEA) separates into a medial and a lateral branch in the middle third of the rectus abdominis muscle. The lateral branch is the dominant one in 54% of the cases.¹³⁴ In general, lateral

Figure 39.1 Preoperative CT angio image at the level of the umbilicus showing two important perforators on the right side connecting through a subdermal vascular plexus that drains immediately into the superficial epigastric vein (yellow arrow). The intramuscular course of the branches of the deep inferior epigastric artery can also be seen (blue arrows).

perforators are used for bilateral cases (hemi-abdomen flaps) or in obese patients, whereas medial perforators are chosen when a maximum of tissue over the midline needs to be vascularized. The most distant part of the flap is always sacrificed to limit the risk of partial necrosis.

When more than one perforator is located on the same longitudinal row then they can be preserved. On these occasions muscle fibres in between these perforators might have to be divided but the success and the uniqueness of the DIEAP technique relies on strict muscle and fascia preservation and maintenance of the motor nerve supply to rectus abdominis muscle. Division of muscle fibres or motor nerves is to be avoided in all circumstances unless absolutely necessary. If a motor nerve is divided it should be repaired.

The anterior rectus sheath fascia is divided longitudinally distally and 3–4 cm proximally once the perforators have been selected. The main pedicle is identified and dissected off its muscle branches safely by staying close to the vessel and under complete muscle relaxation (Figure 39.2). The pedicle is dissected almost until its origin, providing a length of 10.3 cm and average calibre 3.6 mm.¹³⁵ The thoracodorsal or internal mammary vessels can be used for the anastomosis. The flap skin paddle, which can measure 12–15 cm in height and 30–45 cm in width, can be fashioned in an oblique or horizontal orientation, but it is of great importance to avoid torsion or kinking of the pedicle in this process.

For very large DIEAP flaps one must anticipate inadequate arterial supply and use the ipsi- or contralateral superficial epigastric artery or the contralateral DIEA to supercharge the flap.

Donor site closure is fairly straightforward. The anterior rectus sheath is closed primarily with a continuous mattress

absorbable suture. The abdominal closure is performed in the standard abdominoplasty technique (Figure 39.3).

Complications

The complications of a DIEAP technique are similar in nature to the TRAM flap and are related to fat necrosis, which ranges from 6 to 13%, partial flap loss 7%, and complete flap loss 0–2%.^{136–139} Incidence of abdominal bulging is much lower than TRAM flaps and abdominal hernias are avoided with DIEAP flaps. In addition, the trunk flexion capacity and abdominal strength was found to be reduced in patients who underwent TRAM reconstruction compared to DIEAP.¹⁴⁰ It has been well documented that obese patients and smokers have increased risks of flap and donor site complications.^{127,128}

Superior gluteal artery perforator flap

The gluteus maximus muscle flap is a type III flap according to Mathes and Nahai classification. The main vascular pedicles supplying this muscle are the superior and inferior gluteal arteries. Perforators of either of these vessels are used to raise skin and subcutaneous tissue flaps for autologous breast reconstruction.

Taking in to account that the free DIEAP flap is now the gold standard technique, the superior gluteal artery perforator (SGAP) flap is an alternative method of breast reconstruction. In 1983 Shaw¹⁴¹ popularized the myocutaneous free flap for breast reconstruction but in the process of evolution into the new era of perforator flaps Allen and Tucker¹⁴² reported the muscle-sparing SGAP flap breast reconstruction. Similar to the TRAM flap, the muscle-sparing technique has reduced donor site morbidity.¹⁴³

Indications and contraindications

The natural tendency for fat deposition in the gluteal area and the concealed scars under normal underwear render this area a good candidate for donor site in patients who have extensive abdominal scarring or minimal abdominal redundancy. Patients with previously failed free TRAM or DIEAP flaps, preference on donor site scarring, and adequate gluteal soft tissues for small breast replacements are the main reasons why patient and surgeon would choose this technique over the abdominal type of reconstruction.

Contraindications to this technique are related to poor patient general health, smoking and previous surgery in the region, such as suction-assisted lipectomy.

Technique

This technique involves harvesting a fusiform shape of tissue composed of skin and subcutaneous fat based on the perforators of the superior gluteal artery (SGA). Markings are performed in a standing and prone position and it is very important to orient the skin paddle in the best possible cosmetic position, which is in a horizontal and slightly oblique orientation.¹⁴⁴

The surface anatomy landmarks used to localize the supra-piriform exit point of the SGA are the posterior superior iliac

Figure 39.2 Typical intraoperative view of a deep inferior epigastric artery perforator (white arrows) dissection on the left side. Motor and sensory (right vessel loop) are freed and retracted by blue vessel loops. The main deep inferior epigastric vessels are highlighted by the green background. A tiny strip of muscle can be transected to allow harvesting of both perforators.

Figure 39.3 A 42-year-old woman after invasive ductal carcinoma at the right breast and confirmed *BRCA1* mutation. Status nine months after right skin-sparing and left areola-sparing mastectomy and bilateral immediate DIEAP flap reconstruction (a, b, c). The skin islands are used to reconstruct the nipples. The entire nipple–areolar complex is then tattooed in a third step to create a uniform colour over the scars (d, e, f).

spine and the lateral point of the greater trochanter. A line is drawn connecting these landmarks and the junction point of the middle and proximal third of this line marks the SGA. The perforators are located lateral and distal to this point along this line, by a handheld Doppler preoperatively.

The average skin paddle measures 10 cm in width and 20–26 cm in length. Elevation of the flap starts laterally to medially, making sure that the fascia of the gluteus maximus is identified and raised with the flap. One perforator is enough to supply the flap. Dissection must proceed with good exposure by separating the muscle fibres along their orientation. When the sacral fascia is

encountered and divided, dissection continues until the SGA and vein are reached, at which point the length of the pedicle is 7–12 cm and the diameter appropriate for anastomosis.¹⁴⁴

The recipient vessels can be either the internal mammary (IM) vessels or the thoracodorsal vessels, but due to the short pedicle compared to a DIEAP flap, the IM vessels are favoured. A two-team approach is possible in this type of technique, with the patient in a lateral decubitus position until the teams are ready to perform the anastomosis. At this point the donor site is closed primarily and the patient is turned into a supine position.

The SGAP flap can be performed as a sensate flap by harvesting one of the nervi clunii superiores along the superior incision of the flap. These are dorsal branches of the thoracic and lumbar segmental nerves, which can be coapted to the anterior ramus of the lateral branch of the 4th intercostal nerve at the mastectomy site.¹⁴⁵

Complications and implications

The intramuscular dissection can be tedious and time consuming but it secures adequate length of pedicle. For the same reason, good exposure is important but aggressive retraction can apply pressure on the sciatic nerve. Especially in the inferior

gluteal artery perforator technique patients may complain about long-term irritation-type symptoms.

In some cases, vessel discrepancy is encountered, most commonly involving the superior gluteal vein (SGV) which has a larger diameter than the SGA.

Despite the fact that it can be a two-team procedure, the positional changes are always time consuming.

Flap shaping into a breast mound is considered easy, but the quality of the subcutaneous tissue of the SGAP flap has less of a ptotic effect compared to a DIEAP flap and initially might look overprojected (Figure 39.4).

Figure 39.4 Preoperative (a) and postoperative images of a 39-year-old woman diagnosed with a *BRCA2* mutation who underwent bilateral areola-sparing mastectomies and immediate breast reconstruction with a DIEAP flap on the right side and a SGAP flap on the left side. (b) The shortcomings and difficulties in shaping an SGAP flap during the first procedure are clearly shown. Lipofilling and selected liposuction will finally provide the same aesthetic outcome as a DIEAP flap reconstruction (right breast) but additional surgery is always necessary (c, d, e).

Contour deformity of the donor site must be emphasized in the preoperative consultation with the patient. A large amount of bevelling might be needed to achieve the desirable size of breast, leaving a disappointingly hollow contour. Secondary procedures for the correction of the deformity in the form of liposuction and lipomodelling can be performed at the same time as nipple reconstruction.

Inferior gluteal artery perforator flap

The gluteal flaps in the breast reconstruction domain were championed by Shaw¹⁴¹ and Boustred and Nahai.¹⁴⁶ Initial descriptions were of musculocutaneous flaps until the breakthrough of the perforator-based flaps and muscle-sparing concept. The vascular pedicle of the inferior gluteal artery perforator flap (IGAP) exits the pelvis through the greater sciatic foramen in the company of the sciatic nerve, the internal pudendal vessels and the posterior femoral cutaneous nerve.

Indications

The gluteal flaps are used as an alternative type of breast reconstruction in patients who are poor candidates for an abdominal free flap by transferring only skin and subcutaneous fat from the gluteal region. Previously failed free TRAM or DIEAP flaps, inadequate abdominal tissue, abdominal scarring, patient's preference on donor site scarring, adequate gluteal soft tissues in small-breasted women are the main reasons why patient and surgeon would choose this technique over the abdominal type of reconstruction.

Technique

The infrapiriform exit point of the inferior gluteal artery is located halfway between the posterior superior iliac spine and the ischial tuberosity.

Markings are performed in a standing and prone position, and it is very important to design the skin paddle in the best possible aesthetic position, most commonly in horizontal and slightly oblique orientation.

The inferior margin of the flap can be either positioned 4 cm above the inferior gluteal crease or just above the crease in order to utilize excessive saggy tissue in that area. In the former case the scar is hidden in the underwear and in the latter it is disguised by the gluteal fold.¹⁴⁷

The size of the flap that can be harvested is similar to the SGAP flap, measuring 10 cm in width and 20–26 cm in length, but the pedicle is longer, reaching 10–14 cm.

The more lateral the perforators are located on the skin paddle, the longer the pedicle they will provide compared to the more medial perforators.

The muscle-sparing dissection is similar to the SGAP flap and good exposure is achieved by separation of the muscle fibres along their direction. Special caution must be taken to

avoid exposure and damage to the sciatic nerve. In addition, the internal pudendal vessels and posterior thigh nerve must be preserved.

Primary closure of the donor site is achieved with undermining of the skin flaps and by placing a suture to approximate the superficial fascial system.

Complications and implications are similar to the SGAP flap. If excessive tissue harvesting is performed and incisions are not planned correctly, unsightly scars may result.

Transverse upper gracilis flap

Another option in breast reconstruction is the transverse upper gracilis (TUG) flap. It has been used for more than two decades for immediate or delayed reconstruction. The inclusion of a transversely oriented skin paddle along with the gracilis muscle has been described and termed the TUG or transverse myocutaneous gracilis (TMG) flap.^{148–150}

Indications

This kind of flap can provide very good results when a small size of breast is required. In the large series of Schoeller *et al.*, flap weight averaged 330 g, similar to that of other authors.^{151,152}

This flap is ideal for women who have had an abdominoplasty in the past or women who do not want an oblique scar on their gluteal area or back referring to a latissimus dorsi flap for breast reconstruction. One of the advantages of this flap is the thigh lift in bilateral breast reconstructions.

Flap design

The flap is marked with a semilunar skin paddle centred over the longitudinal axis of the gracilis muscle. Tension on the perineal area is reduced by placing the skin island more posterior. By using the pinch technique the borders of the skin paddle can be defined to ensure that the donor site will close free of tension. In this step of the preoperative design, one must take in to account the amount of skin and soft tissue needed to achieve the desired breast volume. The average width of the island is 8–10 cm, or 12 cm in patients with marked weight loss, to ensure that the donor site will close immediately.

Surgical technique

The designed skin paddle has to be harvested with the underlying fascia. Once the edges of the island are incised the tendon of the adductor longus muscle attached on the pubic bone can easily be palpated. The vascular pedicle can be found on the dorsal border of this muscle. Along the axis of the gracilis muscle a minor pedicle is found. This pedicle must be clipped or ligated. When the entire muscle is dissected, first the distal tendon is cut and then its origin from the pubic bone. Care must be taken to preserve the saphenous nerve while dissecting. Once the skin island and the muscle is completely released, the whole complex is transferred to the recipient site. A breast form

can be easily created by folding and suturing together the tips of the paddle. After this step a cone is formed. The apex of that cone can be used to create a nipple as it is on the most projected part of the flap. The transported gracilis muscle can be folded to form the lower pole volume of the new breast after the anastomosis of the vessels has been done. In skin-sparing mastectomy the flap can be totally or partially de-epithelialized.^{153,154}

Complications

The TUG flap has minimal donor site morbidity compared to other free flaps. The TUG flap is not coupled that much with complications as with minor aesthetic results. It has to be said that few authors have focused on the complications of the flap and their management. Shape changes at the level of the inner thighs and donor site scars descending below the groin area may be a problem.

Assuming that the surgeon's experience and microsurgical expertise allows this technique, the downside of this kind of breast reconstruction is the aesthetic outcome due to its small volume. This may not be considered as a complication but it is considered by many authors to be a negative outcome. If volume loss persists then this can be corrected by the classic lipofilling technique to achieve the desired breast volume.¹⁵⁵

CHAPTER 40

Gynaecomastia and tuberous breast

Afshin Mosahebi and Amir Sadri

Department of Plastic Surgery, Royal Free Hospital, London, UK

Gynaecomastia

Gynaecomastia is commonly described as a benign proliferation of male breast tissue.¹ The incidence of gynaecomastia is reported to be between 32 and 36%^{2,3} of men, and as high as 65% in adolescent boys.⁴ Bilateral disease is reported to occur in 25–75% of cases.⁴ From a surgical point of view it is best to define gynaecomastia as a *persistent* enlargement of male breast tissue. It is this permanent enlargement that motivates patients to seek surgical correction of the condition. From a management perspective, gynaecomastia can be classified as idiopathic, physiologic, pathologic or pharmacologic.

Aetiology

Idiopathic gynaecomastia

Most cases of gynaecomastia are idiopathic.⁵ Oestrogens, androgens and their respective receptors are thought to play a major role in the development of the condition. An imbalance in the concentrations of these hormones, with a relative increase in oestrogens, is thought to bring about breast tissue proliferation.

Physiologic gynaecomastia

This can be further subclassified into neonatal, pubertal and elderly gynaecomastia.

Maternal oestrogens transferred across the placenta into the fetal circulation are thought to contribute to the development of breast tissue in neonates. Treatment is rarely indicated as this usually last weeks to months and is a self-limiting condition. Parental reassurance is usually all that is required.

Transient development of breast tissue is common in adolescent boys. It is usually a failure of this breast tissue to regress that results in emotional distress, motivating surgical correction. Regression is usually seen over a period of months to years. A relative increase in plasma oestradiol compared with testosterone is thought to cause pubertal gynaecomastia. Obesity during teenage years compounds the issue. Increased levels of adipose tissue on the chest add to the problem of enlarged breasts. In addition, obesity results in increased

aromatization of androgens to oestrogens, which further increases breast glandular tissue growth.⁶ These changes in serum oestrogens levels are not usually detectable. As puberty advances, testicular development results in increased androgen levels. This results in regression of breast tissue back to normal in 90% of cases.⁷

With advancing age (>60 years) older men can develop breast tissue as plasma testosterone levels begin to decline. In addition to this, any associated weight gain results in conversion of testosterone to oestrogen (peripheral aromatization). This increased oestrogen-to-androgen ratio results in breast tissue growth.⁵

Pathologic gynaecomastia

Gynaecomastia occurring at the extremes of life is not an unusual finding, however, gynaecomastia occurring suddenly between these two extremes warrants further investigation. Pathologic gynaecomastia occurs as a result of various metabolic and endocrine disorders and acquired and congenital hypogonadal states, leading to an increased overall oestrogen state (Table 40.1).

Pharmacologic gynaecomastia

Drugs are a major aetiological factor in gynaecomastia. There are over one hundred compounds that have been associated with gynaecomastia.⁸ Pharmacologic gynaecomastia is thought to occur by several mechanisms. Increased direct oestrogen activity, decreased testosterone synthesis and decreased androgen sensitivity. In addition, some drugs are also thought to cause gynaecomastia through a prolactin-increasing state (Table 40.2).⁹

Classification

Clinical classifications of gynaecomastia in common use are either based on examination findings or the type of surgical correction required.

Webster¹¹ first proposed a classification for gynaecomastia in 1944. This system grouped patients into three groups:

Table 40.1 Pathologic causes of gynaecomastia

Causes	Examples
Hypogonadism	Primary (trauma, torsion, radiotherapy, infection) Secondary (Kallman syndrome, pituitary failure, hypogonadotrophic hypogonadism)
Tumours	Testicular, adrenal, bronchial
Organ failure	Renal, liver, adrenal, thyroid
Congenital	Klinefelter's syndrome, anorchia
Infective	HIV, herpes zoster
Others	Cystic fibrosis, alcoholism, malnutrition

Table 40.2 Drug-induced gynaecomastia

Class	Examples
Hormones	Oestrogen agonist, anabolic steroids, hCG
Anti-androgens	Bicalutamide, flutamide, nilutamide, cyproterone, goserelin, leuprolide
Antimicrobials	Metronidazole, ketonazole, isoniazid, minocycline
Chemotherapeutic agents	Methotrexate, alkaloids
Cardiovascular drugs	Digoxin, ACE inhibitors, calcium channel blockers, amiodarone, spironolactone, minoxidil
Gastrointestinal agents	Cimetidine, ranitidine, omeprazole
Psychoactive agents	Anxiolytic agents, tricyclic antidepressants, phenothiazines
Others	Metoclopramide, penicillamine, phenytoin, antiretroviral agents

- Glandular
- Fatty-glandular
- Fatty.

Bannayan and Hajdu¹² histologically identified three patterns of gynaecomastia according to the varying amounts of stromal and ductal proliferation:

- Florid – increased number of ducts
- Intermediate – overlap of florid and fibrous types
- Fibrous type – extensive stromal fibrosis with minimal ducts.

Simon's classification of gynaecomastia, described in 1973, is based on subjective assessment of breast volume and skin excess¹⁰ and is the most commonly used system. It is as follows:

- Grade 1: Small enlargement, no skin excess (Figure 40.1)
- Grade 2a: Moderate enlargement, no skin excess (Figure 40.2)
- Grade 2b: Moderate enlargement with skin excess
- Grade 3: Marked enlargement with skin excess (Figure 40.3)

In 2003 Rhorich *et al.*⁴ described another classification system based on the degree of breast hypertrophy, breast ptosis and subtyped them into glandular and fibrous:

- Grade I – Minimal hypertrophy (<250 g of breast) without ptosis
- Grade II – Moderate hypertrophy (250–500 g of breast tissue) without ptosis
- Grade III – Severe hypertrophy (>500 g of breast tissue) with grade I ptosis

- Grade IV – Severe hypertrophy with grade II or III ptosis. Each grade is further subdivided into (A) primarily glandular and (B) primarily fibrous. Glandular and fibrous subtypes are determined using the 'pinch test' medially and laterally and below the nipple–areola complex (NAC).

More recently Cordova and Moschella¹³ have described their own classification system (Figure 40.4). This system takes into account the different structural components of the breast and the relationship with the inframammary fold (IMF) and the NAC:

- Grade I – Increase in diameter and protrusion limited to the areolar
- Grade II – Hypertrophy of all the components of the breast. The NAC is above the IMF
- Grade III – Hypertrophy of all the components, NAC at the same height as or 1 cm below the IMF
- Grade IV – Hypertrophy of all the components, NAC more than 1 cm below the IMF.

Assessment

History

The age of onset, time span of breast growth, pain and any regression or involution should be noted in the patient's history. Alteration in patient weight and its effect on breast growth should also be documented. An enquiry should be made of any systemic symptoms such as weight loss, night sweats and anorexia, which may be signs of pathologic or pharmacologic gynaecomastia. In particular, changes in olfaction or vision should be enquired about as this may suggest a pituitary tumour. Specific questions about medications should include drugs that cause gynaecomastia, including therapeutic and recreational.

Clinical examination

Inspection from the front and side allow the surgeon to appreciate the extent of the disease globally, asymmetry of the breasts and to note any areolar widening and herniation.

The character of the breast tissue is documented by palpating for the presence of any discrete masses. Estimation is made as to the consistency and amount of fibrous subareolar tissue compared to the fibrofatty component. The degree of glandular tissues extension in the subareolar plane is also noted.

It is also important to note how much of the breast contour is due to fatty tissue, and where this fat distribution is most pronounced. Extension of fat under the arm or onto the chest wall must be noted, as this will need to be addressed to create a smooth contour to the chest wall. The chest is also assessed for skin excess.

A testicular examination completes the assessment to exclude possible hormonally active tumours.

Investigations

It is rarely inappropriate to refer a patient with gynaecomastia to an endocrinologist for further investigation. Although pathologic gynaecomastia is uncommonly seen, ruling out underlying

Figure 40.1 Clinical examples of gynaecomastia: Grade 1.

(a)

(b)

Figure 40.2 Clinical examples of gynaecomastia: (a) Grade 2a; (b) Grade 2b.

pathology is paramount to patient care. Investigations should be guided by the examination findings.

General investigations may include evaluation of liver, renal and thyroid function (blood tests), as failure of these organs may cause gynaecomastia. Specific haematological markers may be investigated such as the beta unit of human

chorionic gonadotrophin (β hCG) (testicular tumours), alpha fetoprotein (testicular tumours) and basal serum prolactin levels (prolactinoma).

Imaging can include a chest radiograph to exclude carcinoma of the lung, mammography of the breast to rule out breast cancer and CT head to exclude pituitary tumours.

Management

When a recent diagnosis of idiopathic gynaecomastia has been made, it is reasonable to delay definitive surgical management, as spontaneous regression is likely. This is particularly so in adolescent gynaecomastia.

It is also prudent to delay surgical management in those with a body mass index greater than 28 kg/m². Obesity will not only exaggerate the degree of breast enlargement and lead to increased ptosis, but circulating levels of oestrogen are higher

due to adipose tissue aromatization. In addition to this, obesity will increase perioperative risk with regards to infection, wound breakdown and thromboembolic events.

Non-operative treatment

Once a pathological cause of gynaecomastia has been excluded (either clinically or through further investigations) a watch and wait policy is always prudent as some cases may resolve.

The anti-oestrogen tamoxifen has been reported to be effective in some cases of physiological gynaecomastia.^{17–20} Tamoxifen competes with endogenous oestrogen for the oestrogen receptors and inhibits transcription of growth genes. Other pharmacological agents used in the management of gynaecomastia include clomiphene and danazol.

Clomiphene, a non-steroidal agent with a weak oestrogenic activity, acts on the hypothalamic–pituitary axis to increase gonadotrophin-releasing hormone and therefore luteinizing hormone (LH)-releasing hormone and follicle-stimulating hormone (FSH) release. The results of clomiphene treatment however, are disappointing.

Danazol decreases oestrogen production by suppressing the pituitary–ovarian axis by inhibition of the output of both FSH and LH from the pituitary gland. It also has androgenic side effects. It has proved effective in the management of gynaecomastia compared with placebo.²¹ Adverse effects such as weight gain have prevented its general use.

Operative treatment

The aims of surgical treatment are volume reduction with or without retailoring of redundant skin. These aims can be achieved in either a single modal or multimodal treatment strategy. The main surgical options are resection (breast tissue and/or skin) or liposuction (power assisted or ultrasound assisted), or a combination of the two. Again this can be done in a single or staged manner.

Liposuction

Liposuction contouring is indicated in those patients with a predominant fibro-fatty accumulation of tissue. Obese adolescent and elderly gynaecomastia patients are those that benefit the most from liposuction alone. Despite the presence of subareolar parenchymal tissue, liposuction can still reduce its projection and thus yield a satisfactory chest wall contour.

Liposuction can be performed under general anaesthesia or tumescent local anaesthesia and sedation.

Cannula access points can be periareolar, inframammary or laterally on the chest wall. It is important to mark the areas for liposuction preoperatively to ensure a feathered removal of fat and smooth contour to the chest is achieved.

There are several options in terms of type of liposuction technique which can be deployed in gynaecomastia cases.

- *Suction-assisted lipoplasty (SAL)* – Traditional SAL uses blunt tip cannulas with varying diameter attached to tubing with a vacuum as a source of suction. This effectively ‘vacuums’ fat through the cannula. SAL is effective for removal of small volumes of soft fat. It requires considerable effort from the surgeon. Cross-tunnelling must be performed to avoid contour deformities. Bruising is another common sequel of SAL.
- *Ultrasound-assisted lipoplasty (UAL)* – This technique uses ultrasonic waves emitted from the cannula tip to cause micro-mechanical and thermal effects and cavitation on subcutaneous fat. This allows easier removal of the emulsified fat without excess damage to the fibrous septae. This results in greater skin retraction postoperatively. UAL is indicated in areas of fibrous fatty tissue, particularly the breast. Cross-tunnelling may be not be required with UAL as ultrasound energy dissipation at the cannula tip is thought to produce a smooth contour. Bruising is also thought to be reduced with UAL. Thermal injuries and seroma formation can occur with UAL, particularly during prolonged application.
- *Power-assisted lipoplasty (PAL)* – This is similar to SAL but with the addition of an oscillating cannula tip. The cannula tip mechanically breaks down fat and fibrous tissue similar to UAL without the rise in temperature. Cross-tunnelling is required similar to SAL with comparable skin retraction and bruising rates.

Excisional surgery

Patients may present with an isolated fibrous mass beneath the NAC, this may be in addition to diffuse stromal hyperplasia associated with obesity, and there may be excess parenchymal

and skin present. These patients generally require some excisional surgery to address the gynaecomastia. This may be direct excision alone or in concert with liposuction or skin excision (dermoglandular resection).

- *Excision only* – This is indicated in slim individuals with a discrete subareolar mass without any excess skin or fat. It can be performed under general or local anaesthetic. Access is gained through subperiareolar incision at the junction between normal and pigmented areolar skin. The subareolar mass of breast tissue is dissected free from the surrounding breast tissue and NAC. The excision should be tapered peripherally and a small amount of fat should be left behind to avoid a depressed contour deformity beneath the nipple. Postoperatively, a compression support garment should be worn for three weeks to achieve a smooth contour to the chest and prevent haematoma formation.
- *Excision and liposuction* – A combined approach may be required in those individuals where the overdeveloped breast bud is associated with surrounding diffuse stromal fat excess. This can be addressed with excision for the subareolar breast bud and liposuction to the peripheral fatty excess. The combined technique is particularly valuable in those with mild to moderate gynaecomastia. Two strategies can be employed. The patient can undergo a *staged procedure*, which involves liposuction initially, and then removal of subareolar breast bud. Alternatively both procedures can be combined in a *single procedure*. The advantage of the former is that some patients may be satisfied with the postoperative outcome with liposuction alone. This is particularly so when using UAL, as penetration of the breast bud with the cannula can significantly reduce the projection of the breast bud. In addition, the periareolar incision may be avoided. If liposuction alone does not significantly decrease the breast bud intraoperatively, the operation can proceed to direct excision. By then the passage of the cannula through the subareolar breast bud leads to its fragmentation. These can then be removed piecemeal, this has been described by Morselli as the pull-through technique.^{14–16}

Skin excess

In those patients in whom there is excess skin laxity that does not retract after liposuction or excision, or in those with excessive ptosis, then a skin excision is required. It is prudent to wait as long as possible (approximately 6–12 months) to allow as much skin retraction as possible to occur, thus minimizing scars.

Skin excision can be direct, periareolar, circumvertical or horizontal in pattern. Each option is dependent on the degree of skin laxity. In patients with lateral skin excess after liposuction, direct skin excision can be performed with the scar placed in the same line as the lower edge of the pectoralis muscle. This usually leaves a satisfactory scar and addresses the skin excess.

If the NAC requires elevation with excision of skin then a periareolar skin resection can be performed. The NAC position should be between 2 and 3 cm above the IMF. A periareolar doughnut of skin is then de-epithelialized and the defect closed to reduce the skin excess.

Figure 40.5 Unilateral and bilateral tuberous breast deformity. (a) Unilateral. (b) Bilateral. Source: Shiffman, 2009.²² Reproduced with permission of Springer.

Patients with skin laxity requiring excision in the horizontal and vertical planes would be better suited with a circumvertical pattern of skin excision. The redundant skin in the vertical and periareolar regions can be plicated temporarily to gauge contour correction. Once excess skin has been taken up with plication, excision and definitive closure can be performed.

Horizontal skin pattern excision is used in cases of severe skin redundancy. Blood supply to the NAC is maintained through an inferior pedicle dermoglandular pedicle. Once the skin excess has been removed and the incision closed, the nipple is brought out onto the chest wall in its new position. The resulting scar is placed in the IMF.

Tuberous breast

This rare breast deformity is characterized by a deficiency in the vertical and/or horizontal dimensions of the breast, underdevelopment of the breast and frequently pseudoherniation of breast tissue into the NAC. These characteristics give rise to a breast with a high IMF, constricted base and herniation of the NAC. It can be unilateral or bilateral (Figure 40.5) with its true incidence unreported.^{23,24}

Pathoanatomy

To better understand the mechanism behind tuberous breast formation it is important to appreciate the breast's embryology, described in the breast development chapter. Briefly, the breasts originate from the mammary ridge, an ectoderm derivative, during the fifth week of gestation. The area of the mammary ridge around the thoracic region begins to invaginate into the underlying mesoderm between weeks 7 and 14. Until puberty no further development occurs.

During the invagination of the ectoderm into the mesoderm, the breast tissue is surrounded by superficial fascia. Synonymous with the abdomen the superficial fascia is composed of two layers. A fatty layer superficial to the breast parenchyma, and deeper fascial layer posterior to the breast exists throughout. This fascial layer is absent in the subareolar region.

Histological studies have demonstrated that there is thickening of the deep fascial layer around the areolar in the form of a 'fibrous ring'. This fibrous ring prevents the breast tissue from spreading out onto the chest wall. Therefore, instead of growth posteriorly the breast parenchyma grows anteriorly. Since there is no fascia beneath the NAC, we see pseudo herniation of breast tissue through it.

The severity of the deformity depends on the constricting effect of the fibrous ring. This can range from slight underdevelopment of the inferior and medial quadrants to major hypoplasia.

Classification of tuberous breast

There are two major classification systems in use for tuberous breast. In 1996 von Heimberg described four types of tuberous breast (Figure 40.6) deformity based on a study of 68 tuberous breasts in 40 women.²⁵

- Type I – Hypoplasia of lower medial quadrant
- Type II – Hypoplasia of lower medial and lateral quadrant
- Type III – Hypoplasia of the lower medial and lateral quadrant with skin deficiency in the subareolar region
- Type IV – Severe breast constriction with a minimal breast base.

In 1999 Grolleau²⁶ introduced another classification (Figure 40.7). He modified von Heimberg's classification by arguing that the difference between a type II and III tuberous breast was not clinically or anatomically objective when planning therapeutic options. Therefore, Grolleau's classification consisted of three types:

- Type I – Lower medial quadrant deficiency
- Type II – Both lower quadrants are deficient; areolar points downwards with a short subareolar skin segment
- Type III – All breast quadrants are deficient with a breast base that is constricted in the horizontal and vertical axis.

Assessment

History

Patients may present with either unilateral or bilateral breast deformity. This may have both a functional and psychological impact, such as difficulty wearing certain clothing or relationship issues. The patient with unilateral tuberous breast will have noticed her problem post puberty as breast development occurs.

It is important to ascertain whether the patient has breastfed or plans to breastfeed and counsel then on the potential impact on breastfeeding post surgical correction.

Examination

The breasts should be examined to ascertain the presence of bilateral or unilateral deformity. The key clinical findings are as follows:

- superiorly malpositioned IMF;
- constricted lower pole skin envelope; and
- widened areolar with herniation of breast tissue.

An assessment must be made as to whether or not the constricted lower pole skin can be expanded to allow primary placement of an implant to create a natural lower pole contour. One should also determine whether the old IMF could be overcome by the primary implant once the new lower IMF has been created. In a fully developed tuberous breast a flattened lower pole with breast skin adherent to the chest wall will mean that a primary implant may not correct the deformity adequately.

A general examination of breast for masses and axillary palpation for lymphadenopathy should be performed routinely to exclude malignancy.

Management

The principles in correcting tuberous breast are: (a) the constricted skin envelope and malpositioned IMF should be corrected as much as possible, (b) areolar pseudo herniation must be addressed and the areolar size reduced to normal range, and (c) aesthetic breast volume and symmetry should be achieved.

Figure 40.6 von Heimburg classification of tuberous breast. Source: von Heimburg *et al.*, 1996.²⁵ Reproduced with permission of Elsevier.

Constricted skin envelope

Correction of the tight skin envelope and high IMF play a large part in the final aesthetic outcome following surgery for tuberous breasts. A constricted skin envelope will limit the final volume of the breast. Therefore a tight skin envelope will limit the size of any potential implant used to add volume to the breast. This tight skin envelope also means that the IMF is abnormally high.

The constricted skin envelope in mild forms of tuberous breast can be managed with primary placement of a breast implant. However, this is difficult decision to make as a persistent IMF skin crease may be source of patient dissatisfaction and may not soften and relax with time.

A tight skin envelope and high IMF can be stretched and lowered over time using a tissue expander. This can be followed at a second stage with exchange of the expander for an implant.

Areolar size and pseudoherniation

Reducing the areolar size in cases with areolar pseudoherniation has the effect of evenly distributing the forces of the underlying breast tissue on the entire skin as well as adding symmetry to the breast appearance. Areolar size can be matched to the contralateral normal side if possible or in cases of bilateral disease an areolar diameter of 4–4.5 cm can be created depending on patient choice.

Breast volume and symmetry

If bilateral disease exists then both breasts are treated with skin envelope expansion, lowering of the IMF, correction of areolar diameter and the addition of volume. However, many patients present with asymmetry. They usually have a hypoplastic tuberous breast and ptotic contralateral breast (Figure 40.5). In addition to this, the contralateral ptotic breast may also display tuberous characteristics with a high IMF.

It is prudent to treat the more severe side first, usually the tuberous side, followed by symmetrization at a later stage. It is important to counsel patients appropriately that although perfect symmetry is the ultimate goal, realistic expectations are that perfect symmetry cannot be achieved in many patients.

Immediate reconstruction

Periareolar technique

In this approach, using a standard mastopexy technique, the NAC can be reduced in size, the constricting ring divided and the remaining breast parenchyma rearranged and positioned in the breast envelope to achieve a more pleasing aesthetic shape. Additional volume can also be achieved with an appropriate implant. This single-stage approach is appropriate in those patients with adequate skin envelope with mild to moderate (grade I–II) tuberous breast. Adequate breast volume is highly

Figure 40.7 Grolleau's classification of tuberous breast. Source: Grolleau *et al.*, 1999.²⁶ Reproduced with permission of Lippincott, Williams & Wilkins.

desirable to allow breast tissue reshaping. When severe skin inadequacy is an issue with a tight lower pole contour then a tissue expander is indicated.

A periareolar ring of skin is de-epithelialized to reduce the size of the areolar (Figure 40.8). The inferior half of the breast is dissected to the IMF and continued behind the breast

Figure 40.8 Areolar reduction technique. Source: Mandrekas and Zambacos, 2010.²⁷ Reproduced with permission of Elsevier.

parenchyma superficial to the pectoralis fascia. This manoeuvre dissects the breast off the chest wall. The breast is then exteriorized through the periareolar incision (Figure 40.9).

Once the breast parenchyma is exteriorized it can be transected radially or bisected up to the dermis if required or vertically divided in its lower pole (Figure 40.9). This releases the constricting ring and increases the breast width. However, this manoeuvre may result in loss of projection. The two pillars of breast tissue can be loosely approximated or folded onto themselves to create a more desirable breast shape and an implant used if required. Next the IMF can be lowered to the desired position and the periareolar incision closed in layers.

A disadvantage of the periareolar single-stage technique includes a stubborn old inframammary crease that may or may not improve with time. Placing the implant in a subglandular as opposed to a submuscular plane will help counteract this by placing direct pressure on the inframammary crease and lower pole skin.

The technique described above utilizes a superior pedicle to the NAC. An inferior pedicle technique can also be used to achieve the same goals. This is in the form of the short scar periareolar inferior pedicle reduction (SPAIR) technique. This again allows internal release of the constricted breast base. Once the breast is reshaped the widened areolar is reduced and a circumvertical pattern used to reduce the skin envelope.

Figure 40.9 Dissection of breast parenchyma off the chest wall and creation of breast pillars. Source: Mandrekas and Zambacos, 2010.²⁷ Reproduced with permission of Elsevier.

Implant technique

If there is inadequate breast parenchyma, and the skin envelope is compliant enough to accept an implant, then a primary breast augmentation can be utilized. A subglandular pocket is ideal as this would better fill out the skin envelope. Access incisions

depend on whether there is areolar herniation and enlargement. If this exists then the previously described periareolar technique can be utilized. If the areolar is a normal size an inframammary incision will allow pocket creation and soft tissue release. This is the case in patients with hypoplastic breasts.

Staged reconstruction

Staged reconstruction is indicated in those patient who require additional volume yet the soft tissue envelope is inadequate to accept a suitably size implant (grade III and IV tuberous breasts). In these patients a staged reconstruction with tissue expansion is required to prepare a sufficiently sized implant pocket.

The optimal plane for expander placement is the same as that for an implant – a subglandular pocket. It is important to select an expander with suitably broad base to fill out the width of tuberous breast and to match the contralateral normal side, or in bilateral tuberous breast the desired breast width.

Expander placement is through a mammary fold incision. The constricted base of the breast can be divided to provide soft tissue release. The expander is placed with its inferior pole at the position of the new IMF. Tissue expansion can begin two weeks after surgery and be continued until the desired volume is achieved.

Definitive implant placement is dependent on the outcome once full expansion has been achieved. In some cases an implant expander may be sufficient to correct the deformity. If areolar reduction is required then this may be the only procedure that is subsequently required to achieve breast symmetry.

CHAPTER 41

Mastopexy and breast reduction

Elizabeth J. Hall-Findlay

The Banff Plastic Surgery Centre, Banff, Alberta, Canada

The best way to approach breast reduction, mastopexy, mastopexy–augmentation and augmentation is to remove tissue where it is in excess and add tissue where it is deficient. Although this sounds simplistic, it forms the basis of the principles of aesthetic breast surgery.¹ Although in some cases the skin brassiere can be used to shape the breast, it is better to rely on parenchymal reshaping for a consistent, long-lasting result. The parenchyma can be reshaped most easily by following this ‘excess/deficiency’ principle.

The surgeon needs to understand what various surgical manoeuvres can achieve and what our limitations are as surgeons. With that knowledge, we can then manage surgical results (and therefore patient expectations) more appropriately (Figure 41.1).

Because the upper breast border will not change with either a breast reduction or mastopexy, the result can be predictable (but not always what either the surgeon or the patient desires).² Adding an implant will raise the upper breast border on average 2 cm, which has the effect of making the breast footprint look higher on the chest wall. Some patients are high breasted and some are low breasted. Once the patient (and the surgeon) understands this concept, it becomes clear what can be ‘removed’ in a breast reduction or ‘moved’ in a mastopexy.

The surgeon can transpose the drawings in Figure 41.1 onto the patient’s photographs and the decision-making process becomes simplified. Remove (or move) any ptotic gland below the ideal breast shape. Determining the ideal nipple position then becomes simple once the shape is outlined.

This involves an understanding of the inferior wedge principle.^{3,4} The inferior ptotic gland needs to be removed in a breast reduction. It can be separated and moved up to the centre of the breast (not the upper pole) with a mastopexy. Filling the upper pole usually requires either an implant or the addition of tissue (e.g. fat injections). The inferior wedge is that tissue below the Wise pattern. When Robert Wise⁵ deconstructed a brassiere and developed the ‘Wise pattern’, it was designed to be used for the skin to shape and hold up the breast (Figure 41.2). Unfortunately,

skin is often not a good brassiere and it stretches with tension (as it does with skin expansion procedures). If the surgeon, on the other hand, uses the Wise pattern for the parenchyma and leaves behind a Wise pattern (with no tension on either the parenchyma or the skin), the result will be predictable and long-lasting. The Wise pattern shown in Figure 41.2 starts flat but then develops a nice conical shape when put together with the inferior wedge removed.

Because the upper breast border is the more stable (and predictable) landmark, the inframammary fold (IMF) becomes less important. In the past, I marked the new nipple position at the level of the IMF until I realized how variable it can be. Some patients not only have a variable footprint location on the chest wall, the distance between the upper breast border and the lower breast border (IMF) can vary from a few centimetres to over 15 cm.²

Because of the variability of the IMF, the Regnault classification of ptosis can be misleading. Paule Regnault⁶ classified breast ptosis based on the relationship of the nipple to the IMF and breast parenchyma into three grades (Table 41.1). If the nipple was well below the level of the fold, then a mastopexy would be required. Unfortunately, sometimes the nipple is in a good position on the breast mound, but the fold is abnormally high (especially in tuberous breasts) and the approach should instead be to fill the lower pole of the breast and give a better breast shape by centralizing an implant behind the existing nipple position. If the breast is large and the nipple is high then the best approach would be to remove some of the ptotic gland. The nipple should only be moved if it is too low on what will be the final breast mound.

We should instead look at the amount of glandular ptosis or nipple ptosis in relation to the upper breast border and upper pole of the breast. Once the inferior wedge of glandular ptosis is removed, the new nipple position can be easily determined. The ideal nipple position on an average ‘C’ cup breast is about 10 cm down from the upper breast border and about 10 cm from the chest midline (drawn straight – not around the breast).

Figure 41.1 Principles. (a) The upper breast border does not change in a breast reduction or mastopexy. The key to a good result is for the surgeon to understand that the excess in the lower pole needs to be 'removed' in a breast reduction or 'moved' in a mastopexy. (b) The surgeon can visualize the shape of the final result by marking what is desired. The excess beyond that shape needs to be removed in a breast reduction. The ideal nipple position should be determined at about 10 cm below the upper breast border (since this remains unchanged) in an average 'C' cup breast. The new breast meridian should be drawn where it 'should' be, not where it exists and the ideal breast meridian is about 10 cm from the chest midline (straight, not around the curve of the breast) in the 'average' patient. Source: Hall-Findlay et al., 2010.¹ Reproduced with permission of Taylor & Francis.

The upper breast border remains at the preoperative level with a breast reduction or mastopexy but it can be elevated on average 2 cm with an augmentation or mastopexy–augmentation.²

It is easier to plan surgery if the surgeon first assesses glandular ptosis and then nipple ptosis. The level of the IMF is the least important landmark. Sometimes it is better to fill the lower pole of the breast (and lower the IMF) with an implant to centralize the breast mound behind the existing nipple position than it is to move the nipple.

Macromastia

Assessment

History

It is important for the surgeon to first assess patient desires in terms of size. Any previous biopsies, mammogram results, and personal and family breast history should be outlined. The patient should be asked about past experience and wishes related to pregnancy and breastfeeding.

Then details of other patient requests, such as shape and upper pole fullness, should be determined.

Examination and photographs

The consultation is far easier if photographs are taken. The surgeon can then mark on the photos to illustrate what kind of result can be achieved. The upper breast border is marked (dotted line in Figure 41.3a). The distance of 'flat' chest wall is marked with the vertical arrow on both frontal and lateral views.

Note that the drawing shows removal of the glandular ptosis – removal of both inferior and lateral breast tissue where it is in excess. Once the desired inferior border of the breast is determined, the new nipple is placed about one-third up the breast mound. Note that the IMF is not marked – and not needed.

There is still a bit of overhang in the final result because it is difficult to lift the breast completely up onto the footprint without some overhang. Having the breast shape completely confined to the breast footprint is difficult without lowering the IMF (as often happens with an inverted T inferior pedicle breast reduction).

Patients need to be warned that they will not achieve the 'double push-up brassiere effect' without clothes. There is normally a vertical distance of flat chest wall (this can vary from about 9 cm to 16 cm in an average height patient) between the clavicles and the upper breast border. The breasts do not normally come up close to the clavicle and the upper breast border should never be higher than the preaxillary crease. This has become an important part of managing patient expectations over the last few years with the new fashions in brassieres.

If a patient has very poor upper pole fullness, some of the inferior wedge can be moved up^{7,8} (separated from all surrounding breast tissue but left attached as a chest wall-based flap) to provide better projection, but any attempt to try to fill the upper pole is usually doomed to failure. The tissue that is mistakenly pushed up will inevitably fall down, resulting in unattractive glandular ptosis.

Patients often see more in the photographs than they do in the mirror and they can then understand the limitations of the

Table 41.1 Regnault's ptosis classification

Grade	Description
I	NAC at the level of IMF
II	NAC below the level of IMF but above the most dependent part of the breast parenchyma
III	NAC well below the IMF as well as the most dependent part of the breast parenchyma
Pseudoptosis	NAC is at or above IMF but the majority of the breast parenchyma has descended below the IMF

procedure. Patients need to understand that they cannot achieve either a higher footprint or more upper pole fullness. They can, however, achieve better projection.

Management principles and operative options

Reduction/mastopexy

There are numerous designs and labels for various breast reduction and mastopexy techniques. The design should be divided into two categories: pedicle design and skin resection pattern.

Pedicle design

Pedicle design is based on blood supply. If the surgeon does not believe that there is a safe pedicle available, then a free nipple graft may be an option. Usually, however, there are good pedicle designs that can be used. The main choices are inferior (and central), superior, medial, lateral or a combination (Figure 41.4).^{9,10}

The breast is a superficial structure attached to the skin at the nipple. Most of the blood supply to the breast is superficial. It starts out in a deep location around the periphery of the breast and then both the arteries and veins travel around the breast in the subcutaneous tissue.

Most of the blood supply to the breast comes from the internal mammary system. The inferior or central pedicle is supplied by the deep artery and vein that penetrates through the intercostal muscles and the pectoralis muscle from the fourth interspace. That this artery (and venae comitantes) comes from the fourth interspace makes sense because the breast is a fourth interspace structure.¹

The superior pedicle is supplied by the internal mammary system by the descending branch of the artery from the second interspace and the medial pedicle is supplied by the third interspace. There is clearly some variability but a true superomedial pedicle can be designed to include these two axial arteries.

There is also some blood supply from the superficial branch of the lateral thoracic system and this artery supplies a lateral pedicle.

Most of the arteries are within the first centimetre deep to the skin surface at the level of the areola. The veins travel separately from the arteries and they are more superficial – just under the dermis. They can often be seen through the skin when examining

Figure 41.3 Managing patient expectations through consultation photographs. Patient photographs taken at consultation can be used to manage patient expectations. Once the surgeon understands that the upper breast border will not change, the expected result can be drawn on the preoperative photograph. More projection can be achieved by coning the breast tissue after the inferior wedge is removed. The breast cannot be elevated on the chest wall and the upper pole cannot be filled, but the angle (projection) can be increased. The surgeon will also know if tissue needs to be removed in the upper pole in the occasional patient where reduced projection is desired. (a) Preoperative frontal breast reduction candidate showing the desired final breast shape with inferior and lateral tissue removed. (b) Preoperative lateral of same breast reduction candidate showing the patient that the upper breast does not change but the lower pole is removed. (c) Postoperative view of same patient showing the postoperative result. The frontal view matches the preoperative drawing. (d) The lateral postoperative view matches the preoperative drawing. The breast footprint remains unchanged but the glandular ptosis is corrected and the nipple repositioned to the most projecting part of the breast. Source: Elizabeth Hall-Findlay. Reproduced with permission.

the patient and they can be seen to drain mainly superomedially (Figure 41.5).

Because the blood supply to an inferior or central pedicle comes up through the chest wall, the pedicle must be full thickness. Because the blood supply to the superior, lateral and medial pedicles is in the subcutaneous tissue, the pedicles can be created as dermoglandular pedicles. The pedicle should be thick where the vessels are deep at the breast periphery and then can be thinned out closer to the areola where the vessels are found

usually within the first centimetre of tissue depth beneath the skin. Figure 41.6 shows the artery and vein to the inferior wedge that is about to be removed in a vertical breast reduction using a superomedial pedicle.

Innervation to the nipple comes from various sources.¹¹ There are nerves that come from all directions. There are several medial branches but also a major nerve from the lateral fourth intercostal nerve. This nerve splits with a superficial branch that courses up in the subcutaneous tissue and a deep branch that

Figure 41.4 The various pedicle designs for the nipple and areolar complex. A true superomedial pedicle combines both superior and medial pedicles to include two axial arteries. The majority of the venous drainage is superomedial. Source: Elizabeth Hall-Findlay. Reproduced with permission.

travels along the pectoralis fascia. The deep nerve branch then turns upward at the breast meridian and can be included in a full-thickness pedicle. Evaluation of my patients has shown that the medial pedicle actually has better return of sensation than either lateral or superior pedicles.¹ Other studies have shown that there is not much difference in sensation recovery among the various pedicles.

Skin resection pattern

The pedicle design determines the design of the parenchymal resection pattern, but the skin pattern can vary. The classic inverted T (Wise pattern) skin resection pattern^{12,13} was designed to use the skin brassiere to hold up the remaining breast parenchyma. In those cases where the skin has good elasticity, it can be used to shape the breast.

Unfortunately, skin tends to stretch under tension and many surgeons are now using the inferior wedge resection principle to remove the heavy inferior breast tissue, then closing the pillars together following the Wise pattern⁵ for the parenchymal resection and closure instead of using the Wise pattern for the skin resection pattern. The skin resection pattern will then depend

on how much skin redundancy there is because it is used to redrape around the breast parenchyma instead of being used as a handle or support.

Not all 'vertical' (or 'inverted T') breast reductions are the same. They can be designed with various pedicles. Usually, however, the term 'vertical' is associated with the superiorly (superior, medial or lateral) based pedicles and the term 'inverted T' is associated with inferior or central pedicles.^{14–26} The excess breast tissue is removed inferiorly (and laterally) with the superiorly based pedicles and the excess breast tissue is removed superiorly (and laterally and medially) with the inferiorly based pedicles.

Periareolar skin resections patterns (where the outer doughnut skin edge is sutured to the inner doughnut hole skin edge) are only used rarely because there is not much skin resected. If the patient has a significant amount of redundant skin, then more skin needs to be resected along either a vertical or inverted T pattern. The breast is not well reshaped when the skin alone is tightened – surgeons need to be aware that Benelli's description²⁷ of a periareolar mastopexy did not just tighten the skin; he reshaped the underlying breast parenchyma as well. Failure to follow this advice has resulted in unsatisfactory results.

Figure 41.5 The major blood supply to the breast comes from the internal mammary system. There is also some contribution from the superficial branch of the lateral thoracic artery. (a) The arteries penetrate up from the chest wall around the periphery of the breast and then they pass around the breast parenchyma itself up in the subcutaneous tissue. The arteries are superficial as they course toward the areola. The veins are even more superficial as they course just under the dermis (and are often visible through pale skin) with the majority draining superomedially. (b) The branch of the internal mammary artery from the fourth interspace actually penetrates directly up into the breast parenchyma just medial to the breast meridian just above the fifth rib. This artery has accompanying venae comitantes. This makes sense because the breast is a fourth interspace structure attached to the skin at the nipple and sliding loosely over the pectoralis fascia. The breast is held in place by skin–fascial structures at the inframammary fold and over the sternum. The superior and lateral aspects of the breast slide freely over the underlying tissues. Figure 41.6 This photo shows the artery and vein to the inferior wedge that is about to be removed in a vertical breast reduction using a superomedial pedicle. Source: Elizabeth Hall-Findlay. Reproduced with permission.

Indications

Some surgeons believe that the inferior pedicle is a safer pedicle for the very large breast reduction. I personally believe that the true superomedial pedicle has the best blood supply because it includes two axial arteries. I have pencil dopplered over 85 patients and the descending artery from the second interspace is usually just medial and occasionally just lateral to the breast meridian.

When the breast enlarges, the blood vessels also enlarge and travel down with the nipple. The risk in a longer pedicle is not that the blood vessels do not travel to the nipple but that creation of the pedicle might not actually include those particular vessels.

An inferior pedicle (using the inverted T skin resection technique) is the easiest to inset but the weight of the breast is left inferiorly. The medial and lateral pedicles are easy to inset because they rotate into position. The superior pedicle can be harder to inset because it needs to be folded or forced up. Superior pedicles often need to be thinned in order to allow an easier inset without compression and this leaves an empty concave lower pole.

Figure 41.7 Markings for a vertical breast reduction using a superomedial pedicle. (a) The upper breast border and desired breast meridian are marked. The new nipple position is marked about 10 cm below the upper breast border. The inframammary fold is marked at the chest midline (it is often different from one side to the other) but it is not used to determine the new nipple position because it is often too high or too low. Because the upper breast border remains unchanged from the preoperative position to the postoperative result, it is the better landmark to use to determine the new nipple position. (b) The areolar opening is drawn freehand about 2 cm above the new nipple position. The drawing should be performed so that the final result is a circle. A large paperclip is 16 cm long and it can be folded out and used as a template if desired. The skin opening will determine the new areolar diameter because the areolar skin is so elastic that it will stretch to fit the skin pattern. A 16-cm-circumference matches a 5-cm-diameter areola and a 14-cm-circumference matches a 4.5-cm-diameter areola. (c) A true superomedial pedicle is drawn. A pure medial pedicle has a base that is about 4 cm up into the areolar opening and about 4 cm below along the vertical limb. A true superomedial pedicle has an extension of the base up and slightly across the breast meridian to capture the descending artery from the second interspace. A true superomedial pedicle contains the arteries from both the second and third interspaces and still allows the lower border of the pedicle to become the medial pillar (giving an elegant shape to the lower pole) while avoiding some of the difficulties inherent in inseting a superior pedicle. (d) The lower skin resection pattern is drawn while rotating the breast medially and then laterally to match the desired breast meridian drawn on the breast and continued down onto the chest wall. The pattern should be joined usually about 4 cm above the inframammary fold to take into account the fact that the fold often rises but also to avoid the scar extending onto the chest wall. Closure of an ellipse ends up with a longer scar at each end. The pattern should be designed only to remove the excess, not to use the skin as a handle or brassiere. The key is to reshape the parenchyma (by removing the inferior wedge) and then allowing the skin to redrape. Source: Elizabeth Hall-Findlay. Reproduced with permission.

The true superomedial pedicle (with the main base medial but extending upward and across just lateral to the breast meridian) can be harder to inset than a true medial pedicle. But

if the surgeon understands that the blood supply is superior, debulking deep tissue which is causing the restriction can be performed safely. This not only provides a good reliable blood

supply but it also gives a nice elegant curve to the lower pole of the breast on the table because the inferior border of the medial pedicle becomes the medial pillar.

The lateral pedicle can be a good pedicle but it is often difficult to remove some of the lateral bulk in a breast reduction because the tissue that is in excess (laterally) forms the base of the lateral pedicle. Although there are some veins that drain superolaterally, the majority of the venous drainage is superomedial.

With a mastopexy, breast tissue needs to be rearranged because tightening the skin brassiere alone is not effective. Patients who have developed ptosis have already demonstrated that their skin envelope cannot hold up the breast parenchyma. A small breast reduction is the easiest mastopexy, especially when an inferior wedge of breast tissue is removed. When the patient wants to maintain their volume, then an inferior flap can be created, moved up and the pillars closed around caudal to the flap.^{7,8} When this method of a mastopexy is used, the pedicle is therefore based superiorly (superior, superomedial or superolateral). This method of 'moving' breast tissue (that is 'removed' in a breast reduction) is a good way of reshaping the breast when the skin brassiere has lost elasticity.

Operative technique for superomedial vertical breast reduction

Assessment

The surgeon needs to assess the footprint – whether the patient is high or low breasted. Then he or she needs to visualize what needs to be removed – usually inferiorly and laterally. The patient needs to be consulted on their preferred breast size (and of course warned that an exact size and shape cannot be achieved).

The superomedial pedicle can be used with either the vertical or inverted T skin resection pattern.²⁸ This will depend on the desired final size of the breast and the elasticity and amount of excess skin. A vertical distance from the lower border of the areola to the IMF is usually about 7 cm in a 'B' cup breast, 9 cm in a 'C' cup breast and 11 cm in a 'D' cup breast. Surgeons are often warned to keep the vertical scar length at 5–7 cm in an inferior pedicle inverted T breast reduction because the weight of the breast stretches out the skin. In a vertical type of breast reduction, however, the extra vertical length is needed to accommodate projection.

Markings

First the surgeon should mark the *upper breast border* because this is a landmark that does not change. This is best determined by finding the preaxillary indentation laterally and marking the upper breast border medial to that indentation (Figure 41.7). The breast can be pushed up to see where the fold between the breast and the chest wall occurs.

Next the surgeon should draw the *chest midline* and *breast meridian*. The 'ideal' breast meridian should be marked and not the 'existing' breast meridian. The surgeon can then draw what

the resultant breast shape would be (see Figure 41.3). This can help to mark the new nipple position.

The *ideal nipple position* on an average 'C' cup breast on an average patient should be about 10 cm below the upper breast border and 10 cm from the chest midline (not drawn around the curve of the breast but with a straight ruler on a line parallel to the chest wall). If a surgeon places the new nipple (for example) at 24 cm from the suprasternal notch (SSN), that distance will not change postoperatively. It will remain at 24 cm. An arbitrary SSN–nipple distance can be misleading, leading to too high a nipple placement. The surgeon needs to understand that the footprint cannot be changed and a low-breasted patient will remain low breasted.

The *new areolar opening* should be marked about 2 cm above the new nipple position. The opening can be drawn freehand to be about 14–16 cm in length. A 14 cm circumference matches a 4.5 cm diameter areola and a 16 cm circumference matches a 5 cm diameter areola. A large paperclip is 16 cm long and can serve as a good template when unfolded. There is no need to draw out the opening laterally in a mosque-type shape. It is in fact better to take out length vertically rather than horizontally.

In order to mark the *skin resection pattern* the breast can then be rotated laterally and the vertical meridian marked to match the breast and chest wall meridians. The breast is then rotated medially and the lateral meridian marked. The breast can be held up with the surgeon's thumb of the opposite hand and the two lines can be joined in a 'U' or 'V' shape, but the bottom of the design should remain at least 2–4 cm above the IMF. The surgeon can then test the skin resection pattern by pinching the skin.

A vertical breast reduction using the superomedial pedicle does not rely on the skin brassiere so there is no need to design a wide skin resection pattern. There should be no tension on the vertical skin closure. If an inverted T design is needed, the medial and lateral extensions are drawn about 7 cm down the vertical limbs. These extensions are then drawn to meet the IMF both medially and laterally. The skin resection pattern should not result in a tight closure in any direction; it is used only to allow the skin to redrape loosely.

A pure *medial pedicle* is designed with the base about 4 cm below the areolar opening along the vertical skin resection pattern and 4 cm above into the areolar opening. A true *superomedial pedicle* takes the medial pedicle base and extends it up and across the breast meridian. This allows it to include two axial arteries (as opposed to one artery in a medial pedicle) but it does make it a bit harder to inset occasionally. If it does prove to be too stiff to inset easily then excess tissue can be safely debulked deep to the pedicle because the blood supply is superficial.

Finally the areas that may need to be liposuctioned (preaxillary fullness and lateral chest wall areas) are marked.

Positioning

The patient is supine on the operating table with the arms outstretched to the sides.

Infiltration

It is not a good idea to infiltrate along the incisions because the veins can be damaged. Lidocaine with adrenaline is used in the areas to be suctioned. If the patient has a higher body mass index, then tumescent type of infiltration may be indicated for the lateral chest wall in particular.

Operative technique²⁹

De-epithelialization

The incision lines are incised around the areola and vertically, making sure that the vertical skin resection pattern remains about 4 cm above the IMF. A lap pad is then placed around the base of the breast and held with a Kocher clamp to tighten the breast skin and facilitate de-epithelialization.

The veins are just deep to the dermis, so whatever method is used, the surgeon should keep the dermis intact during de-epithelialization. The skin is easier to remove in a superomedial pedicle than in an inferior pedicle (Figure 41.8a).

Pedicle creation

The pedicle is created initially as a full thickness pedicle cutting straight down toward the chest wall. Most of the bleeding occurs in the first few centimetres as initially the veins are encountered just under the dermis and then the arteries are severed in the subcutaneous tissue. There is not much bleeding from the breast parenchyma itself (Figure 41.8b).

No alteration is made at this stage for inseting the pedicle. If the pedicle is stiff then deep tissue can be debulked later to allow for an easier inset.

Parenchymal resection

The inferior wedge of parenchyma is then removed, cutting straight down to the chest wall. Once a surgeon is more familiar with the technique an en bloc resection including lateral tissue can be performed but a 2-cm-thick lateral pillar should be created before undermining the lateral flap. It is important to remove tissue down toward the pectoralis fascia, but there will be less bleeding if the fascia itself is left undisturbed. The surgeon will encounter the deep perforators coming just up above the fifth rib (fourth interspace) just medial to breast meridian. There are some branches that perforate more laterally as well but all from the internal mammary system (Figure 41.8c).

The excess parenchyma in a breast reduction is inferior and lateral. Once the inferior wedge of breast tissue is removed, then more tissue can be bevelled out under the lateral flap. The lateral parenchymal pillar should be about 2 cm thick and about 7 cm in length. If the tissue is thick glandular tissue (as in a teenager) the surgeon needs to carefully carve out all tissue until a good Wise pattern is left behind. If the lateral excess tissue is composed mainly of fat, it can be removed later with liposuction, but any 'white' glandular tissue needs to be directly excised (Figure 41.8d).

Rarely does any parenchyma need to be removed medially except just above the IMF. It is good to leave behind some parenchyma in the lateral aspect of the areolar opening to serve as a platform so that the areola does not retract once it is inset. Even a full-thickness pedicle will appear to be undermined once it is created.

The surgeon should consciously leave behind a Wise pattern of parenchyma. This will mean not only removing the inferior wedge of tissue and tissue under the lateral flap but also tissue caudal to the Wise pattern above the IMF. This will result in some elevation of the IMF – another reason to keep the lower border of the vertical skin resection pattern about 4 cm above the original IMF.

The surgeon who is less familiar with the vertical approach will initially remove less parenchyma than required – the breast looks smaller on the table than it is when sitting.

Pillar closure

It is best to close the areolar opening first to best assess the shape and to effectively close the pillars. The dermis does not need to be undermined or released for this suture (usually a 3–0 Monocryl). Once the areola is closed, the pedicle can be easily rotated up into the opening. If there is any resistance, the deep tissue of the pedicle can be debulked because the blood supply is superficial (Figure 41.8e).

If the pedicle is pulled up in a cephalad direction, the pillars will automatically come together. The inferior border of the medial pedicle becomes the medial pillar and the first suture should be placed at the caudal end of the lateral pillar (about 7 cm down from the areolar opening as shown by the arrows on the photograph) and where the inferior border of the medial pedicle meets the skin (i.e. at the caudal end of what is now the medial pillar) (Figure 41.8f).

Deep bites are not necessary (and can actually lead to tissue necrosis). It is only necessary to make sure that parenchyma (not fat) is apposed on each side so that healing can occur. I usually use only 3–4 sutures of 3–0 Monocryl to hold the pillars in contact with each other. Any tension on parenchyma (which I mistakenly tried with lateral pedicles in a vain attempt to pull lateral tissue inward) will eventually release and the tissue will return toward its original position (Figure 41.8g).

Skin closure

The deep dermis is then closed with interrupted 3–0 Monocryl sutures again with the goal of only achieving dermis-to-dermis contact so that the circulation to the skin edges is not compromised. The vertical skin is then closed with a subcuticular 3–0 or 4–0 Monocryl but it is important not to 'cinch' or 'gather' the vertical incision. It was initially thought that it was important to shorten the vertical incision because of the fear of bottoming-out that occurred when the skin stretched with the inferior pedicle, inverted T breast reduction.

Not only does the gathering compromise blood supply to the skin edges, but it is ineffective in shortening the vertical skin

Figure 41.8 Operative technique for superomedial vertical breast reduction. (a) De-epithelialization of a superomedial pedicle. Note that the base of the pedicle extends along the vertical limb but that the upper base extends across to just lateral to the breast meridian. This allows the pedicle to include two axial arteries (from the second and third interspaces). (b) The superomedial pedicle is created as a full-thickness pedicle to include the ascending branch of the fourth intercostal nerve that travels above the pectoralis fascia and then turns upward toward the areola at the breast meridian.¹¹ (c) Resection of the parenchyma is performed initially around the pedicle but mainly as an inferior wedge resection. An initial *en bloc* resection is performed while leaving a 2-cm-thick lateral pillar (about 7 cm long). The medial pillar will be formed by the inferior border of the medial pedicle. (d) Extra breast tissue is removed inferiorly above the IMF and below the Wise pattern (which is marked in blue on the skin). This is performed to prevent bottoming-out and to prevent an inferior pucker (which is usually a problem of lack of subcutaneous tissue excision rather than a skin redundancy problem). Aggressively removing this tissue will result in a higher IMF level. The blue forceps are pointing to the excess parenchyma that needs to be removed under the lateral flap. In a very glandular breast (young women) this tissue needs to be carved out under the flap but also to remove any tissue lateral to the desired Wise pattern. In older patients, this excess can be liposuctioned but it must be completely removed or else the breast will end up too wide and full laterally. Tissue needs to be removed where it is in excess. (e) The lower border of the areola is closed first to allow the surgeon to assess the extent of resection. No dermal undermining is needed for this closure. (f) The superomedial pedicle is easily rotated up into position. This manoeuvre of pulling the areola cephalad allows the medial and lateral pillars to fall together. The arrows marked on the skin show the lower edges of the pillars. This is usually about half way up the vertical

Figure 41.8 (Continued) skin resection with tissue removed inferiorly. The pillars do not extend as far down as the skin opening or as far down as the IMF. The pillars are closed with a few relatively superficial sutures with no tension. The pillars should be sutured only enough to allow them to stay together during the postoperative period so that they can heal together. Deep bites are not necessary and may lead to tissue necrosis. Tension should not be relied upon to shape the breast because it will inevitably fail over time. The key is to remove all tissue where it is in excess. (g) The dermis is closed loosely both vertically and around the areola. Note the shape of the right breast. Good projection is achieved along with narrowing of the breast base as compared with the unoperated left breast. (h) The photograph shows that the breast does not settle by dropping as shown. (i) The final breast shape and extent of excess skin can be shown by using this manoeuvre where the breast is elevated and pushed down so that it slides down the chest wall to its original position. This allows the surgeon to determine if any more subcutaneous tissue or parenchyma needs to be removed but also to assess whether a horizontal skin excision needs to be added. The excess inferior skin in this example will just curve up under the parenchyma around the pillars and does not need to be modified. (j) Final closure. The cross-hatched area shows where the liposuction has been performed (usually after deep dermal closure before subcuticular closure). Liposuction is also performed along the lateral chest wall and (not to excess) in the preaxillary areas. (k, l, m, n) Postoperative photographs at five months of the patient shown above. She was 41 years old, 180 cm tall, weighed 82 kg and wore a 34G brassiere. She had 346 g removed from the right breast and 325 g from the left breast. She had 400 mL of fat suctioned from the inferior breast along the IMF as well as along the lateral chest wall and in the preaxillary areas. Source: Elizabeth Hall-Findlay. Reproduced with permission.

length. It is important for surgeons to change their thinking and realize that a longer vertical length is actually needed to accommodate the increased projection that occurs with the vertical approach. Bottoming-out occurs with the inferior pedicle procedures because the weight of the tissue is left in the lower pole and the skin brassiere stretches; bottoming-out occurs with vertical procedures with inadequate resection of the lower pole (inferior wedge). The skin is allowed to redrape with a vertical approach it is not used as a handle to hold the breast up. Any procedures that use skin (or dermis) as slings tend to fail over time because skin (and dermis) stretches.

There is some tissue overhang in a vertical breast reduction and the vertical length from the lower border of the areola to the IMF is usually about 7 cm in a 'B' cup breast, about 9 cm in a 'C' cup breast and about 11 cm in a 'D' cup breast. It is important to warn patients that they will still be able to 'hold a pencil' underneath their breasts.

The decision to add a 'T', a 'J' or and 'L' can be a difficult one. It will depend on the quality and amount of excess skin. As a guideline, a vertical incision length of up to 12 cm can be tolerated in patients with poor-quality skin and up to 15 cm with good-quality skin for an average 'C' to 'D' cup breast. The way to test to see if the inferior end of the incision will tuck up underneath the breast is to hold the breast up and push it down by lifting and sliding (see Figure 41.8h,i) and if the end of the incision tucks up under the pillars, no further correction is necessary.

Areolar closure

The pedicle is allowed to sit comfortably in the areolar opening and it is usually rotated slightly to fit. Debulking of deep tissue in the superomedial pedicle to allow unrestricted inset can be performed at any time during the procedure.

Four deep 3–0 Monocryl sutures are used to close the dermis and the skin is closed with a subcuticular 3–0 or 4–0 Monocryl. If the skin opening is not completely circular, the skin can be trimmed prior to closure.

The areola will eventually stretch out to match the skin opening circumference. A 16 cm circumference (of the skin opening, not the areola) will match a 5 cm diameter areola. A 14 cm circumference matches a 4.5 cm diameter areola. Areolar skin is quite elastic and will stretch to fit the skin opening. A permanent Goretex type of suture can be used in a circumvertical type of breast reduction (which is used to shorten the vertical length) but at the expense of some stretching that can occur beyond the Goretex pursestring.

Liposuction for tailoring

After the deep dermis is closed, liposuction is easier to perform because there is some resistance to the tissues and because it is easier to visualize the final Wise pattern. Liposuction is performed beyond the Wise pattern to remove any excess tissue (this must be carved out and excised directly in young patients who have more parenchyma and less fat). Liposuction can also

be used to reduce fat in the lateral chest wall and preaxillary areas (Figure 41.8j).

Drains

Drains can be used if desired. If a patient has a large lateral dead space or had an unusual amount of bleeding during surgery then drains might be indicated. Seromas do occur and drains would need to be left in for a long time to prevent seroma formation. The advantage of the vertical approach is that seroma fluid can easily work its way through the tissues with gravity without being blocked by an inframammary incision.

Antibiotics

The breast is often considered 'clean' surgery, but it is well known that breast ducts contain bacteria and it may be best to give a prophylactic dose of antibiotics before surgery (usually a cephalosporin). When I gave patients a full week of postoperative antibiotics, almost all my problems with suture spitting disappeared. Some of those problems recurred when I began using only a single prophylactic dose. The use of triclosan (an antibacterial, not an antibiotic)-impregnated sutures also helped reduce the incidence of suture spitting.

Taping and garments

The incisions are best managed by covering them with paper tape. Steristrips can be used but if placed across the incision, blisters can occur from the shear forces as the breast swells. Tape should be placed along the incision and glue is not necessary. The incisions are then covered with gauze and the patient is placed in a non-compressive surgical brassiere. It is unnecessary (and ineffective) to tape all the breast skin in an attempt to shape the breast.

Patients are allowed to shower the next day. The paper tape will stay in place (without being changed) for 3–4 weeks.

The pucker at the lower end of the vertical incision may swell and protrude for a few weeks and then it will tuck in under the pillars. Some patients may need a revision but this should not be performed for at least six months. Because the parenchyma (and skin) is removed as a vertical ellipse, there is a dog-ear that disappears into the areola and one that can be a nuisance inferiorly. The inverted T, inferior pedicle type of breast reduction results in a horizontal type of excision of skin and parenchyma with a medial and lateral dog-ear – both of which can be a nuisance.

Another example of vertical breast reduction in a 16-year-old patient is shown in Figure 41.9.

Operative technique for vertical mastopexy

It is important to understand that the skin will not act as a good brassiere in a patient who has already developed breast ptosis. An inferior wedge of breast tissue needs to be removed in a breast reduction or small mastopexy. If a patient likes her breast size, then the inferior wedge of breast tissue needs to 'moved'

Figure 41.9 Vertical breast reduction. (a, b, c, d) A 16-year-old patient who was 170 cm tall, weighed 61 kg and wore a 32FF brassiere. (e) She had a true superomedial pedicle vertical breast reduction with 398 g removed from the right breast and 388 g removed from the left breast. She only had a minimal amount of fat removed with liposuction. (f, g, h) She is shown just over a year after the surgery. Source: Elizabeth Hall-Findlay. Reproduced with permission.

Figure 41.10 The inferior wedge that is normally removed in a breast reduction is shown as an inferior flap left attached to its chest wall-based blood supply but separated from breast and skin on all four sides to allow good mobilization. Source: Elizabeth Hall-Findlay. Reproduced with permission.

rather than 'removed'. Any attempt to push and hold up the parenchyma with the skin will be doomed to failure.

Ribeiro^{7,8} describes an inferior flap along with a superior pedicle. The flap needs to be separated on all four sides and left as a chest wall-based flap. The flap can be easily mobilized and moved up the chest wall and the medial and lateral pillars can then be closed caudal to the flap to hold it up. The flap is sutured up to the chest wall long enough that breast tissue will heal to breast tissue. The flap does not heal to pectoralis fascia even when sutured up but it will heal to the overlying breast tissue (Figure 41.10).

Any attempt to suture breast tissue to pectoralis fascia will either fail or result in scar contracture that will cause the breast to move unnaturally every time the muscle is contracted. In normal circumstances, this flap can provide extra breast projection and can prevent recurrent glandular ptosis but it will not result in increased upper pole fullness.¹

The blood supply to this inferior flap is the deep artery and vein from the internal mammary system at the fourth interspace. It is important to create the flap while being careful to preserve the attachments to the chest wall just above the fifth rib and just medial to the breast meridian. The flap is de-epithelialized not to maintain blood supply but to serve as a something somewhat substantial to help suture the flap upwards. Either a superior or superomedial pedicle can be used with this inferior flap.

A superior pedicle is often used because a concave inferior aspect to the breast will not occur because the central aspect of the breast is filled with the flap (Figure 41.11). A superomedial pedicle can be used if the nipple and areola have a long distance to travel – where rotation is better than folding.

Graf³⁰ has described a similar mastopexy but using a strip of pectoralis muscle to act as a handle to hold the flap up higher on the chest wall. This does attach the flap to the chest wall but the remaining breast will still tend to drop down around the flap

back into its original position. This flap can improve upper pole fullness to some degree but it can cause a problem in weight-loss patients when the flap stays up and the breast drops down. Some surgeons complain that this procedure puts breast tissue behind the pectoralis muscle, but in reality all that happens is that a strip of muscle acts as a handle over the breast tissue.

Operative technique for vertical augmentation–mastopexy (Figure 41.12)

The problem with the inferior flap in a mastopexy–augmentation is that the blood supply to the inferior flap is damaged when the implant is placed in either a subglandular or subpectoral location. The artery and vein to this flap comes up through the intercostal muscles just above the fifth rib and they are cauterized with insertion of the implant. The procedure can be performed while preserving the flap but it is difficult and skin closure can be a problem.

It is best to perform a 'reduction–augmentation' or 'plus–minus' procedure^{31,32} when both a mastopexy and an augmentation are desired. Some surgeons believe that the mastopexy and the augmentation involve opposing forces, but that is not really the best way to approach the problem.^{33–35} The implant is used to add volume to the upper and central poles of the breast and the inferior wedge resection is used to take care of the glandular ptosis.

A superior pedicle is often used because a concave inferior aspect to the breast will not occur because the central aspect of the breast is filled with the implant. A superomedial pedicle can be used if the nipple and areola have a long distance to travel, where rotation is better than folding.

Closing the skin under tension is not only unnecessary but can lead to wound-healing problems. The skin will not act as a good brassiere and skin tension should not be relied upon to hold the implant up. Even a subfascial inferior sling fails to hold up the implant in the long term.¹ The ptotic gland needs to be removed and patients need to understand that a large implant will be subject to gravity.

Some surgeons will insert an implant into the subpectoral pocket, first keeping inferior muscle and fascia intact to close up the pocket completely. They then perform the mastopexy so that there is no contact between the implant and the bacteria present in the breast ducts.

Complications

The potential complications are basically the same for all breast procedures: blood loss, infection, necrosis, hematoma, seroma, dehiscence and unsatisfactory aesthetic results.

Blood loss

It is unusual to need a transfusion or even an autologous transfusion for most aesthetic breast surgery. Blood loss is higher for the inverted T inferior pedicle breast reductions (about 300–400 cm³) than a vertical reduction (about 100–200 cm³). A vertical

mastopexy as described here has a blood loss of about 100 cm³ and a vertical mastopexy–augmentation rarely exceeds 100 cm³.

Infection

The breast ducts contain bacteria and breast surgery should not be considered completely ‘clean’. A single dose of prophylactic antibiotics is indicated but postoperative antibiotics should probably only be considered when an implant is used. Even this is controversial. In my experience, suture spitting (festering) is a low-grade infection and it can be prevented to some degree by using antibacterial-impregnated sutures such as Monocryl Plus.

It appears that larger breast reductions and a higher BMI may lead to a higher infection rate.

Necrosis

Nipple necrosis is a definite risk inherent in all breast procedures that involve a transposition of the nipple and areola complex (Figure 41.13). The rate is usually less than 1%. A

good understanding of the blood supply to the breast will help minimize the risk but it is probably inevitable in any large-volume practice. Although there are many recommendations on what to do with incipient necrosis, it is probably best to only intervene if it is possible that there is compression causing obstruction on either arterial inflow or venous outflow. The latter may develop obvious venous congestion. Once it is clear that some necrosis is likely, it is best to leave things alone and let the extent of necrosis declare itself. The NAC seems to be a ‘privileged’ construct and it often recovers far better than expected with no intervention.¹ There are recommendations to remove the nipple–areola and apply it as a free nipple graft but this is probably not indicated in most cases. Removing sutures or taking the patient back to the operating room to inspect the pedicle for compression may be indicated but the surgeon needs to weigh the potential consequences of action versus inaction. Inaction is often a good choice.

Figure 41.14 Dehiscence. Sometimes a dehiscence is best left alone for healing by secondary intention. Source: Elizabeth Hall-Findlay. Reproduced with permission.

Haematoma

All plastic surgery procedures have a risk of hematoma. The rate is probably close to 1% of cases. The best way to prevent a haematoma is to understand the main arterial supply and to check those areas for secure haemostasis before closure. There is an artery that comes up at the fourth interspace just medial to breast meridian along with some branches appearing laterally as well at the fourth interspace. There are some vessels coming up in the subcutaneous tissue at the level of the IMF and there is the superficial branch of the lateral thoracic artery that enters the breast laterally and courses up into the breast, initially deep peripherally and then in the subcutaneous tissue. The veins are even more superficial and usually lie just beneath the dermis. Drains do not prevent or treat haematomas but they may be indicated if there is an unusual amount of 'ooze' that is evident during surgery.

Seroma

Seromas occur where there is a lot of dead space and where there is some friction between the overlying flap and underlying chest wall. Drains are needed for as long as shearing movement allows friction to occur. This can range from several days to

weeks. Quilting sutures are very effective in the abdomen but somewhat harder to use along the lateral chest wall.

Dehiscence

This can occur when sutures fail to hold. More frequently the problem is excess tension on the closure, which leads to constriction of blood supply to the skin edges (Figure 41.14).

CHAPTER 42

Chest wall reconstruction

Anatomy and physiology of the thoracic cage

The thoracic cage consists of 12 pairs of ribs articulating with the facet joints of the 12 thoracic vertebrae posteriorly and, via their respective costal cartilages, to the manubrium and sternum anteriorly. The costal cartilages of ribs 1–7 ('true' ribs) articulate directly with the manubrium/sternum, whereas those from ribs 8, 9 and 10 ('false' ribs) unite as a synchondrosis joining the 7th costal cartilage to articulate with the inferior part of the sternum. Ribs 11 and 12 have no anterior articulation and are known as 'floating' ribs. Between the ribs are three layers of intercostal muscles, external, internal and innermost, with a neurovascular bundle running just below each rib between the internal and innermost layers. The thorax is bounded inferiorly by the diaphragm and superiorly by the clavicle.

This arrangement of the thoracic cage confers both strength, to provide protection for the thoracic and upper abdominal viscera, and flexibility, to allow the movements required for ventilation. During inspiration, contraction of the external intercostal muscles elevates the ribs, which, given their curved shape and fixed points anteriorly and posteriorly, allows the thoracic cage to swing up and out (analogous to the oft-quoted movement of a bucket handle). This, together with depression of the diaphragm, increases the thoracic volume, thus creating the negative pressure to draw air in. As the diaphragm and the external intercostals relax, thoracic volume decreases and air is expelled. The internal intercostals, which actively depress the ribs, are only used during forced expiration.

CONGENITAL DEFECTS

Mazyar Kanani and Martin J. Elliott

Cardiothoracic Unit, Great Ormond Street Hospital, London, UK

Congenital chest wall anomalies may present at any age up to adolescence and may occur in isolation, or represent one marker in a spectrum of defects.

Pectus deformities

In this spectrum of malformations, there is an abnormal contour of the anterior chest wall. It is thought the underlying problem lies with the relative rate of growth of the costal cartilages in relation to the growth of the ribs and sternum. If the elongated cartilages cause the anterior chest wall to buckle inwards, pectus excavatum results. If there is buckling outwards, the result is pectus carinatum.^{1,2} However, some have proposed that the defects arise from abnormal growth of the diaphragm.³

Both conditions may be symmetric or asymmetric in nature, with a varying composite of anomalies, such as sternal angulation, tilt and rotation about the long axis – all of which need to be taken into account during cosmetic correction. Within the broad spectrum, some patients may even have a mixed defect.

Pectus excavatum

In this condition, there is a depression in the anterior of the chest wall of varying shape and severity (Figure 42.1).

Morphologic varieties

In most cases, the depression is symmetrical on either side of the midline and limited to the lower half of the sternum. More severe forms are deeper and extend further upwards toward the manubrium. At the more severe end of the scale is the so-called 'Grand Canyon' variety, where there is a deep and long depression. It can be a challenge to treat successfully, particularly since many of these are asymmetrical. In about 5% of cases, there is a combined excavatum/carinatum deformity.

Epidemiology

The incidence of the defect is 1 in 150–1000 live births.¹ Although the defect may present any time after birth, most patients present around the time of puberty during their phase of rapid body growth. There is also an association with connective tissue disorders such as Marfan's and Ehlers–Danlos syndromes, where scoliosis is also more frequent.⁴

Figure 42.1 Transverse section of a CT scan of a patient with pectus excavatum, before (a) and after (b) Nuss correction. Note the cardiac compression seen before correction.

Clinical evaluation

Prior to surgical correction, we undertake a number of investigations to determine the severity and extent of morphology, as well as impact on physiology.

Imaging

We routinely perform a plain chest radiograph that demonstrates the overall shape of the thoracic cavity. This is followed by CT imaging, which can be used to construct the 3D anatomy of the thoracic cavity.⁵ The Haller⁶ index of severity can be calculated from this. This is the ratio of the transverse diameter and the anteroposterior diameter of the rib cage. A normal ratio is 2.5. Of special importance is the shape and axis of the body of the sternum. Sternal torsion and asymmetry have an impact on the type of surgery. Imaging can also show the extent of cardiac compression.

We also routinely perform transthoracic echocardiography to assess overall ventricular function. There is also an association with mitral valve prolapse, which may be seen with connective tissue disorders.⁴

Functional assessment

As part of our initial evaluation, we also perform exercise testing of the patient. This is following some reports of a modestly reduced functional capacity arising from the combination of right ventricular compression and reduced pulmonary capacity in some patients.^{7,8}

Surgery for pectus excavatum

Timing

There are advantages and disadvantages to both early and late repair.⁹ Each case is considered individually. Important factors to consider include the age at presentation, symptoms, severity of the deformity and type of surgical approach. As a general rule, younger patients have a more malleable chest, which will make the minimally invasive Nuss procedure an attractive

option here. However, this has to be tempered with the fact that some of these children will outgrow their bar and need further bar insertion. Also, early bar removal in younger patients may result in recurrence as the chest continues to remodel with age. Nevertheless, the severity will reduce the age at intervention.

In the literature, surgery has been performed successfully from the ages of 1 year to 50.^{10,11} In our experience, for the reasons noted above, the ideal is around the age of puberty.

Influence of morphology

We reserve the minimally invasive Nuss procedure for symmetric cases.¹² If the symmetry extends to a so-called Grand Canyon type deformity,¹³ we may either use two Nuss bars, or elect to perform an open sternochondroplasty.¹⁴ If it is likely that any second bar needs to be inserted high up, we favour an open approach due to the risk of placement over the great arteries in the mediastinum. In some cases with mild asymmetry, the Nuss bar can be moulded appropriately.

Nuss procedure

The patient is usually positioned supine on the operating table with the arms abducted following induction of anaesthesia and epidural catheter placement.

Once positioned, necessary landmarks are drawn on the chest: the deepest part of the chest which indicates the level where the bar will lie, the point beneath the nipples at the level of where the bar will lie, and the two lateral points where the vertical skin incisions are made for the introduction of the bar and stabilizers.

The two lateral skin incisions are made, and the subcutaneous plane is developed to the marked point beneath the nipples at the level of where the bar will lie. These will be the points at which the bar will exit the chest wall on either side. Then, the thoracoscope is introduced into the right pleura through a port placed either just beneath or into the lateral skin incision. Carbon dioxide insufflation permits exposure. Next, the bar

Figure 42.2 (a) STRATOS bars in place for stability following repair of pectus carinatum. (b) Two Nuss bars *in situ* following repair of pectus excavatum.

introducer creates a subcutaneous tunnel from the skin incision to the point of entry into the chest. Entry through the chest wall is observed via thoracoscopy. The introducer is passed to the pleural cavity on the other side, anterior to the pericardium under direct vision. It is guided through the chest wall. Once safely out of the skin, it is tied by umbilical tape to a moulded Nuss bar of appropriate size. As the introducer is removed, the bar is carried with it into the chest. The bar is then finally flipped with a specially designed flipper and secured to the chest wall by bilateral stabilizers secured to it by steel wire (Figure 42.2b).

Following the procedure, the patient is extubated on table and a chest radiograph is taken immediately to check for pneumothoraces and bar position.

Once on the ward, the patient is observed in the high-dependency unit for the duration of the epidural catheter – usually 4–5 days. Adequate analgesia is very important here once the epidural is removed. Mobilization aided by physiotherapy is the final step before discharge. A final PA and lateral chest radiograph check the bar position.

Bar removal

We elect to remove the bar after 3 years. Although the bar can be left in for 4 years without problems, the longer it is left, the greater the degree of calcification around the bar, which can make removal more challenging. Removal is performed as a day-case procedure under general anaesthesia. The greatest risk comes from pneumothorax, and there are also isolated reports of injury to great vessels.¹⁵

Pectus carinatum

This is also known as pigeon or keel chest. In this condition there is variable protrusion of the chest.¹⁶ It is less common than pectus excavatum, being seen in about 0.06% of all live births¹⁷ (Figure 42.3).

Morphologic varieties

Depending on the exact extent of the protrusion, there are a number of variations:

- Symmetrical – The sternum is arched forwards. If there is some depression of the costal cartilages, the sternal prominence is exaggerated. In some cases, the body of the sternum fuses with the xiphoid at a 90° angle.
- Symmetrical deformity with a normal sternum – Here, the anterior prominence comes from protrusion of the costal cartilages with a relatively normal sternal contour.
- Asymmetry with combined carinatum and excavatum – Protrusion of costal cartilages on one side only causes rotation of the sternum about its long axis, causing a relative excavatum on the contralateral side.
- Pouter pigeon chest – There is prominence of a thickened maubrium so that the deformity is limited to the upper sternum only.

Timing of operations

This deformity becomes most apparent during adolescence, when the infantile potbelly recedes to make the anterior chest more prominent during the period of rapid body growth.

Figure 42.3 Pectus carinatum as seen on 3D CT reconstruction (a) and transverse CT scan (b). Note the 90° angulation between the body of the sternum and xiphisternum.

Although we do not have a distinct cut-off age, surgery is mainly reserved after this final adolescent growth-spurt has begun and chest wall natural chest wall modelling is complete.¹⁸

Reconstructive aims

The main aim of surgery is to remodel the anterior chest wall to the normal contour through trimming the elongated costal cartilages and returning the sternum to its natural alignment. Surgery will provide an immediate result, but in order for the remodelling to be complete, we encourage physiotherapy and muscle-building exercises to enhance the muscular contribution to chest wall shape.

Technique of repair

Our method of repair is based on that of Ravitch¹⁴ but with the addition of chest wall stabilization using the Strasbourg Thorax Osteosyntheses System, MedXpertGmbH, Heitersheim, Germany (STRATOS™) system of costal bars^{19,20} (Figure 42.2a).

The patient is positioned in the supine position, with the arms by the side. We prefer to mark the skin first – indicating both the line of incision and the most prominent areas of cartilage/sternum. The incision is horizontal at the level of the xiphisternal junction, being some 10 cm with a gentle upwards curve. The subcutaneous plane is developed, at first superiorly to the highest cartilage involved then inferiorly to the xiphisternum. This is seldom above the 3rd rib. Then the pectoralis major muscles are detached, sparing their clavicular origins. Care must be taken not to enter the intercostal spaces, especially in thin patients. Next, the plane inferior to the incision is developed. The uppermost origins of the rectus abdominis muscles

may have to be detached if the underlying cartilages are involved. At this point, the xiphisternum is also detached from the body of the sternum with diathermy.

Once the underlying involved costal cartilages and ribs are exposed, resection can begin. The cartilages are initially detached at the sternocostal joints through a combination of diathermy and sharp dissection. Care must be taken not to damage the underlying internal thoracic vessels, or parietal pleura. In order to preserve growth potential in the juvenile sternum, we try to preserve the underlying perichondrium when shelling out the exuberant cartilage. Generally, the lower the cartilage level, the greater the lateral extent of resection required. The lateral extent of resection will be determined by the final position of the sternum.

A sternal osteotomy is performed at a level determined by the angle and position of protrusion. This allows the sternum not only to be straightened, but also rotated appropriately to the normal anatomic plane. The sternum is fixed in the correct position using absorbable suture, or stainless steel wires depending on the size of the patient.

Next, the free ends of ribs are fixed to the lateral edge of the sternum with a figure-of-eight absorbable suture, making sure that they lie flat without protrusion. The xiphisternum is also reattached to the body of sternum with absorbable suture.

If there has been multilevel involvement with the risk of chest wall instability, we add STRATOS titanium rib bridges to provide final stability.

The muscles are reapproximated, ensuring that the two pectoralis major muscles on either side are brought together in the midline. This will help determine the final contour of the

chest, and allow better healing of the bone beneath. Two drains are inserted and placed in the subcutaneous plane. If the pleural cavity has been entered, a suction catheter is placed at the end of the case to evacuate air. The rest of the tissues are closed in layers and dressing applied. Once in the recovery room, a chest radiograph is taken to ensure there is no pneumo- or haemothorax.

Poland's syndrome

Poland's syndrome is a rare congenital anomaly characterized by hypoplasia of the breast and nipple, absence of the costosternal portion of the pectoralis major muscle, absent pectoralis minor, aplasia or deformity of the costal cartilages and ribs 2–4 or 3–5, alopecia of the axillary and mammary region, and unilateral brachysyndactyly.²¹

Epidemiology and aetiology

The incidence of Poland's syndrome ranges from 1 in 7000 to 1 in 100 000 live births. Males are affected more frequently with a 2:1 to 3:1 ratio. The right side of the body is involved in 60–75% of patients.²²

There are a number of theories as to why it develops. One suggests that there is hypoplasia and interruption of the subclavian artery during the 6th week of development.²³ Another theory suggests a disruption of the lateral plate mesoderm affecting the development of the upper limb girdle.²⁴ There is an association with Klippel–Feil syndrome²³ and Möbius syndrome, with bilateral congenital facial nerve palsy and paralysis of the eye abductors.²⁵

Clinical manifestations

Although there is some variation upon the theme, the most consistent feature is the absence of the sternocostal head of the pectoralis major muscle. The underlying pectoralis minor may be absent altogether. Other chest wall muscles, such as the latissimus dorsi and serratus anterior, may also be absent – which is important when considering surgical soft tissue coverage. In up to a third of females there is absence of breast development.

Absence of underlying ribs and costal cartilages causes the ipsilateral chest to be sunken. The most frequently absent or hypoplastic ribs are 2–4 or 3–5. As a result, upwards of 10% of patients may also have lung herniation and chest wall instability, leading to paradoxical movements during respiration.²¹ Hand abnormalities in Poland's syndrome include shortness of the middle phalanges with cutaneous webbing (or even full syndactyly), to complete absence of the hand (ectrodactyly). These tend to be ipsilateral to the chest wall anomalies.

Reconstructive aims and indications for surgery

Surgical intervention may be indicated for the following reasons:¹⁷

- unilateral depression of the chest wall with cosmetic implications;
- lack of adequate protection of the heart and lung with lung herniation;

- chest wall instability with resulting paradoxical chest movement;
- hypoplasia or aplasia of the female breast.

Surgical management

This will be influenced by the age and sex of the patient, as well as pattern of involvement. Both the chest wall contiguity and muscular coverage need to be addressed. Many have advocated a two-stage approach in children – first repairing the chest wall defect, followed by a second procedure, which provides chest wall soft tissue coverage and sculpting of the absent anterior axillary fold.^{26,27} A single-stage approach may be reserved for older children and adolescents.

The approach is via a transverse incision, which will provide excellent access not only to the rib defects, but also to the sternum, which may be rotated as part of the constellation of defects.¹⁷ A subperichondral resection of the costal cartilages is performed of the affected rib ends. A sternal osteotomy is performed to allow it to be rotated to the corrected plane. Where there is rib aplasia, rib grafts may be used to bridge the defect. Synthetic mesh has also been used to provide a wider coverage.²⁷ We have, however, in more recent cases been using artificial bone or STRATOSTM bars to bridge the defect and provide chest wall stability.

A musculocutaneous flap of the latissimus dorsi can be used for coverage and provide reconstruction of the absent axillary fold. In our centre, such cases are performed as joint procedure between the thoracic and plastic surgeons.

Sternal cleft

This is a rare malformation characterized by failure of fusion of the sternum in the midline. It may be partial, where there is a U-shaped dip at the upper end of the manubrium, to a more extensive defect extending all the way to the xiphisternum, where there are two bars of bone to which attach the costal cartilages.²⁸

This defect in the sternum may occur in isolation, but it may also herald associated anomalies, such as cardiac malformations.²⁹

Surgical approach and timing

Our preference is to repair this defect in the neonatal period, or at least as early as possible, as the more pliable tissues allow for a better chance for primary repair with autologous tissues.

The repair is carried out via a midline vertical incision and the subcutaneous plane developed over the sternum and adjoining costal cartilages. A wedge osteotomy is performed of the bony bridge between the two sternal bars. This will allow better mobilization when bringing the two sides together without tension.

If the two sides of bone can be brought together, they may be sutured together with either stainless steel wire, or else a heavy absorbable suture. If there is tension laterally, the sternocostal joints may have to be released and resutured or bridged with STRATOS bars.

We close the soft tissues over the bone by suturing the pectoralis major, rectus abdominis and sternocleidomastoids to their counterparts in the midline. The subcutaneous tissues and skin are then closed primarily to complete the operation.

Jeune syndrome: asphyxiating thoracic dystrophy

This autosomal recessive condition leads to characteristic skeletal abnormalities in the form of generalized chondrodysplasia, limb defects, mild dwarfism and, importantly, a constricted chest. This latter feature makes the resulting physiological problems particularly difficult to manage.³⁰

Epidemiology and clinical features

The incidence is 1:100 000 to 1:130 000 live births. Since 2006,³¹ this has been classified under the umbrella of short rib skeletal dysplasias with or without polydactyly. The natural history of the condition is that the majority of patients do not live beyond the age of 10, mainly from the complications of respiratory or renal failure, which are some of the extraskeletal manifestations of the disease.³²

Chest wall morphology

Failure of normal costal cartilaginous growth leads to cessation of normal chest wall expansion and a persistently narrowed, bell-shaped rib cage. The result of the defect is that the ribs and costal cartilages are shortened, with a fixed horizontal orientation. This results in failure of normal lung development with resulting respiratory failure and pulmonary hypertension, recurrent chest infections and restrictive lung disease.³³

Chest wall surgery

There is no easy surgical solution to the chest wall defects seen in this condition. A number of approaches have been attempted, often through staged interventions.

Lateral thoracic expansion was first outlined in 1995 by Davis *et al.*³⁴ as a staged approach for patients who are older than 12 months. Dissection is carried down to the beds of the 4th to 9th ribs. Those ribs are divided along their shaft, and their adjoining intercostal muscle released. This will permit the rib to be connected to the rib below by a titanium plate in order to expand the chest. Additional chest wall support is obtained by uniting the subperiosteal tissue of rib bed to its counterpart below. In those in whom this technique has been used, new bone formation has been demonstrated.³⁵

Less frequently, there are reports of the modified Nuss technique being used to provide expansion. In the former technique, two bars are implanted bilaterally to provide expansion in the lateral plate. It has been reserved for older children and is limited by the need for a bar change.³⁶

More recently, thoracoplasty using the vertical expandable titanium rib technique has been described.^{37,38} A vertical titanium device is anchored bilaterally to ribs 2 and 10. Ribs 3–8 are then transected and pulled laterally, and finally connected to the titanium device. Growth is allowed by progressively adjusting the device.³⁸

ACQUIRED DEFECTS

Simon Withey¹ and Robert Pearl²

¹Consultant Plastic Surgeon, Department of Plastic Surgery, Royal Free Hospital, London, UK

²Department of Plastic Surgery, Queen Victoria Hospital, East Grinstead, UK

Pathology of chest wall defects

A 'flail segment' or paradoxical chest movement occurs when a segment of chest wall is discontinuous with the remainder of the thoracic cage (classically two or more ribs fractured in two or more places). As the rib cage swings up and out during inspiration, this segment will be 'sucked in' by the increasing negative pressure in the thorax. A similar effect is produced with larger chest wall defects as the overlying soft tissues move paradoxically in comparison with the rest of the chest, compromising ventilation.

Acquired defects of the chest wall invariably result from one of four pathologies: sternal dehiscence following cardiac surgery, tumours, radiation necrosis or trauma. The aetiology has important reconstructive implications both locally in terms of resection margins and quality of local tissue, and in terms of the patient's general health and planned adjuvant treatments.

Sternal dehiscence following median sternotomy Background

Fifty years ago it was the high mortality rate of sternal wound dehiscence, over 50% in early series, that contributed to a delay in the midline sternotomy incision³⁹ gaining universal acceptance amongst cardiac surgeons. At that time, treatment involved debridement and packing, leaving the sternal wound open to granulate. These patients required prolonged mechanical ventilation as a result, with large numbers succumbing to bypass graft failure due to exposure.

The advent of early, aggressive wound debridement and obliteration of the dead space by importing fresh, well-vascularized tissue was introduced by in 1976 by Lee *et al.*,⁴⁰ who transposed greater omentum into the sternal defect. In 1980, Jurkiewicz reported the successful use of muscle flaps in a small series of sternal dehiscences where closed catheter irrigation had been unsuccessful.⁴¹ This became the basis for modern-day treatment and has resulted in the attendant mortality falling to 8–15%.⁴²

Aetiology and classifications

Wound dehiscence occurs in 1–3% of median sternotomies and, although often attributed to an infective aetiology, the underlying problem is devascularization of a hemisternum secondary to the harvest of the internal mammary artery (IMA). Bilateral IMA harvest increases the risk of sternal wound complications significantly up to 7%.⁴³ Those patients with concurrent vascular compromise, such as diabetes, are the least tolerant of the reduction of hemisternal blood supply as a result of IMA harvest. Conditions such as obesity, immunosuppression, previous chest wall irradiation, chronic obstructive airways

disease, congestive cardiac failure and smoking all elevate the risk of sternal wound dehiscence.

The commonest organisms cultured in infected sternal dehiscences are *Staphylococcus epidermidis* and *Staphylococcus aureus*, although a range of gram-negative bacteria have also been isolated.

The two most widely used classifications of sternal defects are outlined in Table 42.1. Like most classifications that attempt to rigidly categorize clinical presentation, neither is perfect, but both can aid management decisions. Although it supplies useful clinical information, a drawback of Pairolero and Arnold's classification⁴⁴ is it fails to specifically identify those early wounds where there is a significant degree of devascularization, or those that are longstanding but with reasonable vascularity.

Starzynski's classification⁴⁵ is anatomical, defined by the location of the sternal defect and thus can only be made after intraoperative assessment. The authors use the classification to predict the degree of physiological compromise in terms of loss of mechanical integrity of the thoracic cage, though it can also be useful in guiding the choice of flap for reconstruction.

Management principles – planning

When assessing a patient with sternal wound problems the reconstructive surgeon should have a clear understanding of the cardiac procedure performed and the implications of that procedure for chest wall vascularity, subsequent debridement and reconstruction requirements. A full history of any thoraco-abdominal procedures that might influence the reconstructive options should be taken. It is particularly important to carefully assess the general wellbeing of the patient with formal anaesthetic consultation. On occasion, patients will not be fit enough for immediate reconstruction, or even for radical debridement, and immediate washout and period of optimization may be the only option.

Patients with sternal wound breakdown will have many complex medical requirements and many will have been hospitalized for prolonged periods of time, so an assessment of the patient's nutritional status and haemoglobin level is vital.

Table 42.1 Pairolero's classification and Starzynski's classification of sternal defects

Pairolero	Presentation	Timing
Type I	Serosanguinous discharge only	0–3 days
Type II	Cellulitis and purulent mediastinitis	3 days–3 weeks
Type III	Chronic sinus and osteomyelitis	Months–years
Starzynski	Anatomical involvement	Physiological deficit
1	Upper sternal body and adjacent ribs (2–5)	Mild
2	Entire sternal body and adjacent ribs (2–7)	Moderate
3	Manubrium, upper sternal body and ribs (1–5)	Severe

In septic patients, specimens of wound fluid and pus should be sent for assessment at the earliest opportunity. Patients should also be carefully screened for coexisting sepsis with appropriate culture of sputum, urine and blood. Plain chest radiographs, while giving limited information about the state of the sternum, can identify a coexisting empyema or pneumonia. In patients where an extensive debridement and reconstruction is contemplated, the benefits and implications of the ongoing use of anticoagulant therapy should be considered and discussed with the cardiac surgeons and the anaesthetists.

CT scans can provide useful information in selected cases, especially those of a chronic nature, with regard to extent of bony necrosis.

Management principles – debridement

Following a washout the state of the tissues should be carefully assessed. The pathophysiology of this condition is reflected in the relative health of the two hemisternums in cases where one side has lost its internal mammary vessel while the other retains its blood supply. While the vascularized segment remains healthy and supports the sternal wires, the devascularized segment will frequently be soft and fragmented; there is often evidence of pus in the tissues and the wires will easily cheesewire through the bone. A thorough debridement of all devascularized tissue should be performed. This will typically involve removing the involved segments of the sternum and associated costal cartilages. It is very rare that there is a need to undertake any soft tissue debridement, although in cases where fat sutures have been used to close the original sternotomy it may be necessary to remove small areas of fat necrosis.

When undertaking a debridement, the reconstructive surgeon must be aware of the position of any grafts and should take great care when mobilizing the sternum. At the completion of debridement it is important that the bone edges should be assessed for sharp spicules that would have the potential to cause damages to the underlying tissues. If a negative pressure suction dressing is to be used, the surgeon must be aware that once suction is applied the bony edges are stabilized by the dressing and that any reorientation of the leading edge has the potential to cause damage to the underlying pericardium and myocardium. Care should be taken to protect the myocardium from the edges of the debrided bone by careful orientation of the sponge. During debridement, multiple soft tissue and bone samples should be sent for microbiological culture.

Surgical tip: Healthy sternum is difficult to debride, any bone that is removed with relative ease or crumbles in the jaws of a pair of bone nibblers is not healthy.

The patient's physiological state at the time of surgery, the extent of the debridement and the surgeon's confidence of its completeness will all influence whether reconstruction is undertaken immediately or whether it is felt wise to delay. In patients who are deemed too unfit for an extensive reconstructive procedure or in cases where there is some doubt as to the extent of devascularization (often the case of those on large doses of pressor support), the introduction of the negative pressure

vacuum dressing has transformed management. If used with care, this dressing allows those patients to be optimized while the wound is mechanically stabilized and oedema and bacterial loads are reduced. When used in open chest wounds, vacuum dressings should only be used by those with experience and an understanding of the risks involved.^{46,47}

Management principles – negative pressure therapy

Negative pressure therapy, in addition to its wound management properties, also serves as a remarkably effective splint for the sternal defect, restoring some degree of mechanical integrity to the thoracic cage and allowing early mobilization and physiotherapy.

If negative pressure therapy is employed, a suitable foam (e.g. Whitefoam (polyvinyl alcohol, KCI)) or an interface dressing, such as Mepitel (Molnlycke Healthcare, Sweden), should be used. This reduces the direct pressure on the thin-walled right ventricle and helps to prevent adherence of the sternum to the exposed myocardium (implicated as a causative factor in the rare instance of myocardial rupture). Following cardiac surgery, adhesions will develop between the myocardium in areas where the pericardium has been reflected and the anterior mediastinum, it is important to be aware that when suction pressures are applied, shearing forces are introduced to the tethered areas. To minimize the resultant damage we free as many of the adhesions as possible, and typically limit suction pressure to 75 mmHg.

Chest wall tumours

Tumours account for a large proportion of cases of chest wall defects, and can be broadly split into primary chest wall neoplasms, invading adjacent tumours (e.g. lung, breast, skin) and metastatic lesions. Advances in medical therapies for these cancers in both the adjuvant and neoadjuvant setting has led surgeons to undertake increasingly large surgical resections. These extensive procedures are only possible with adequately robust chest wall reconstruction.⁴⁸

Management principles – planning

Patients with complex chest wall tumours are best managed in a multidisciplinary team (MDT) setting. Prior to reconstruction it is important to consider the prognosis of the disease and plans for the use of adjuvant therapy. The medical fitness of the patient and the state of the local tissues, particularly following previous surgery or radiotherapy, will all influence reconstructive options.

Management principles – resection

Whether the resection is performed by the thoracic surgeon or the reconstructive surgeon, it is helpful if the surgeon planning to undertake the reconstruction is closely involved with this process to ensure that the flap and its vascular supply are protected.

Osteoradionecrosis

Advances in oncological management, in particular in the treatment of breast cancer, have led to an increasing number of patients undergoing irradiation of the chest wall. Although

more sophisticated techniques have improved therapeutic targeting, radiotherapy still damages surrounding bone and soft tissues, both through direct cellular effects (particularly damaging fibroblasts and osteocytes) and through impairment of tissue vascularity. It is worth noting that osteoradionecrosis can present years after radiotherapy, often as non-healing ulcers or pathological rib fractures.

Chest wall reconstruction associated with radiation necrosis provides considerable challenges as both the compliance and vascularity of local tissues is compromised. The extent of radiation injury is often extensive and good judgement is required to determine how to balance the need to resect compromised tissue and yet maintain stability and minimize reconstructive requirements. The quality of both local flaps and local blood vessels for free tissue transfer should be carefully assessed prior to the procedure.

Trauma

High-energy injuries involving blunt trauma to the chest wall can lead to a flail segment that may require stabilization, however it is relatively rare that a segment of chest wall requires formal reconstruction. The priorities in these patients are the assessment and treatment of life-threatening injuries, in particular any concomitant lung or mediastinal injury, but the reconstructive principles remain the same.

Reconstruction of chest wall defects

When planning reconstruction the surgeon should consider the following:

- Is the thoracic cage stable, does it require support to restore mechanical integrity?
- Which flap (or combination of flaps) will best achieve obliteration of dead space and durable soft tissue coverage for the least donor site morbidity?

Thoracic cage stability – restoring mechanical integrity

Classical teaching states that resection of four or more ribs or the creation of a defect >5 cm diameter will require bony support to prevent a flail segment and preserve pulmonary compliance. In these large defects, bony reconstruction has the added advantage of protecting the underlying viscera. This principle has been successfully applied in most major series⁴⁸ and has stood the test of time, although there are certain anatomical areas that require specific consideration. The scapula stabilizes the upper part of the posterior chest wall and larger defects (up to 10 cm) in this area may not necessarily need further rigid support. Defects in the anterior chest wall in the region of the first three ribs are splinted by the sternum, clavicle and surrounding musculature, so larger resections may likewise be tolerated without the need for stabilization. An example is a defect resulting from partial or complete sternectomy, where infection typically contraindicates

Table 42.2 Prosthetic materials used to restore thoracic cage mechanical stability

Synthetic meshes/composites	Prolene (polypropylene)
	Marlex (polypropylene and high-density polyethylene)
	Gore-tex (expanded polytetrafluoroethylene)
	Vicryl mesh (polyglactin 910)
	Composite Merlex/Prolene and methylmethacrylate sandwich
Biomaterials	Alloderm (allograft)
	Strattice (porcine xenograft)
	Permacol (porcine xenograft)
	Surgimend (bovine xenograft)

the introduction of support with prosthetic materials or grafts. In these cases, the mechanical integrity of the chest wall is rarely permanently affected, although the patient respiratory capacity is frequently, but temporarily, compromised until a fibrous union has re-established stability.

Choice of bony support

It is the re-establishment of the mechanical integrity of the thoracic cage that is pivotal for chest wall reconstruction. The use of prosthetic materials aptly demonstrates this and the development of these products has transformed the reconstruction of the chest wall skeleton. These prosthetic implants conform well to the contour of the chest wall defect, avoid the additional morbidity of a donor site and enable reconstruction of much larger composite defects than could be achieved with autologous material alone. They can be broadly split into synthetic meshes/composites and biomaterials and are outlined in Table 42.2.

Both Prolene and Marlex are non-absorbable, synthetic meshes with good tissue incorporation. For added rigidity, two layers can be combined with methylmethacrylate cement to form a composite 'sandwich'. This can be moulded to the contour of the chest wall defect as the cement sets. Gore-tex mesh is another permanent implant which provides less tissue ingrowth due to its limited porosity, but contours well and obtains a better water-tight seal. The rate of complications, such as infection and seroma, along with long-term outcome, are similar for the different synthetic meshes and use generally comes down to surgeon preference. If infected, these implants invariably need removal. Metallic support, in the form of transverse titanium plates, has been used (normally in combination with a synthetic mesh) for some anterior defects where additional rigidity is required (Figure 42.4).⁴⁹

Biomaterials – acellular dermis

The use of acellular dermis for chest wall reconstruction is relatively new. These dermal matrices can be either allograft (Alloderm) or xenograft (Strattice, Permacol) and have been denuded of their cellular components to prevent an antigenic response from the patient. Their structure allows cellular

**Figure 42.4** Composite Prolene and methylmethacrylate 'sandwich'.

infiltration and, more importantly, vascularization, which makes them more resistant to infection. A small series of acellular dermis in chest wall reconstruction has shown promising results.⁵⁰ These materials lack rigidity but they help to stabilize tissues and reduce paradoxical movement.

Autogenous

Following the development and increased use of prosthetic materials, autologous bone grafts are now seldom used. In situations where autologous bone is necessary it may be harvested as split rib grafts or taken from the iliac crest. However autogenous bone is limited in the size of defect it can reconstruct as there must be a large degree of cancellous bone overlap at the wound edge to enable the graft to survive.

Soft tissue coverage

Flap reconstruction

There are a variety of flaps that can be used for chest wall reconstruction, but familiarity with the following four flaps will enable the plastic surgeon to tackle the majority of chest wall defects: pectoralis major, omentum, rectus abdominis and latissimus dorsi.

Pectoralis major

Pectoralis major flaps are the workhorses for reconstruction of sternal wound dehiscence following median sternotomy. As a type V muscle,⁵¹ pectoralis major can be advanced and rotated on the thoracoacromial axis or raised on its secondary segmental pedicles, the perforators of the internal mammary artery (provided this vessel has not been harvested) and used as a 'turnover' flap. Combining one pectoralis turnover flap (Figure 42.5) with one pectoralis advancement flap (Figure 42.6) is an effective way of obliterating the dead space and providing adequate coverage of the inferior part of a sternal defect. Once the musculotendinous insertion is divided, the muscle is 'turned

Figure 42.5 Pectoralis major raised as a turnover flap based on IMA perforators. The turnover flap obliterates the dead space of the sternal defect, allowing the advancement flap to double breast over the top.

Figure 42.6 Pectoralis major raised as muscle only advancement flap based on thoracoacromial axis.

over' into the defect, and provides useful bulk that effectively fills the dead space and covers vulnerable tissues.

We would suggest that the post-sternotomy wound breakdown should be termed the 'IMA harvest sternal necrosis', as significant problems that require reconstruction are rare if the IMA has not been harvested. If the IMA is used to revascularize a coronary artery the pectoralis major muscle would not typically be raised on its medial blood supply. The left IMA is frequently used in bypass operations and, in these cases, the left pectoralis major is typically mobilized on the thoracoacromial axis. Cardiac revascularization with bilateral IMAs is rare and so it is usually possible to mobilize the right pectoralis major muscle on its mammary perforators.

The pectoralis major flap may also cover anterior and central defects following tumour resection. However, in cases of

osteoradionecrosis the flap has frequently been involved in the irradiated field.

Surgeons should be cautious of mobilizing the pectoralis major in a female patient with a large breast volume, particularly those patients who perfusion pressures are compromised by sepsis or organ failure. In extreme circumstances the combined removal of mammary perforators and the thoracoacromial axis supply will devascularize the fat of the breast and patients may experience considerable fat necrosis.

Omentum

Although not a muscle, the greater omentum can be classified as having a type III blood supply, with two codominant pedicles (left and right gastroepiploic arteries). Previous abdominal surgery or episodes of peritonitis may complicate or preclude its use.

Omentum is well suited to reconstruct large sternal defects; it is richly vascularized tissue and its bulk is effective at obliterating dead space. It also appears to be highly effective at encouraging the firm fibrous union that is important for the ventilatory rehabilitation of patients with large defects. The benefits and versatility of the omental flap make it particularly useful in reconstruction of osteoradionecrosis defects. The omentum provides volume, vascularity and, crucially, is derived from a non-irradiated area.

The greater omentum is accessed via an upper midline incision, although laparoscopic techniques have been described.⁵² The flap is usually raised on the larger right gastroepiploic artery and can be delivered into the sternal defect through the anterior tendinous portion of the diaphragm or through the wound and over the costal margin via a subcutaneous tunnel. Care must be taken with both of these approaches to ensure that the defect created is of adequate size so that the pedicle is not compressed, however it is also important to fashion the defect to minimize the risk of herniation of abdominal viscera. The concept of a tight defect compressing the pedicle is, in most cases, a theoretical one as the omental flaps tend to be very bulky and a generous defect is usually required to allow flap transposition. The greater risk is therefore of gastrointestinal herniation through a relatively large defect.

We would suggest the use of a technique that enables the surgeon to create a generous transdiaphragmatic window while minimizing the risk of herniation. Our preferred technique involves creating a secondary omental flap which can be wrapped around the pedicle and tacked to the edges of the diaphragmatic defect on the abdominal side (Figures 42.7 and 42.8). The flap acts as a plug that softly obliterates the defect and helps prevent the herniation of abdominal viscera into the chest.⁵³

Surgical tip: Transillumination helps identify the gastroepiploic vessels that lie close to the greater curvature of the stomach.

Rectus abdominis

A type III muscle, rectus abdominis is raised on its superior pedicle, the superior epigastric vessels (a continuation of the internal mammary vessels), when used in chest wall reconstruction.

Figure 42.7 The 'omental wrap'. Source: Tansley *et al.*, 2006.⁵³ Reproduced with permission of Lippincott, Williams & Wilkins.

Figure 42.8 The omental flap raised with secondary flap isolated.

A myocutaneous or muscle-only flap, it is transposed into the defect with a pivot point at the costal margin and provides coverage for lower chest wall defects. As a myocutaneous flap the skin paddle can be orientated vertically (VRAM) or transversely (TRAM).

The rectus abdominis flap has been reported in cases where both IMAs have been harvested. Here the residual IMA is perfused through communication with intercostal vessels, however, clearly in these instances flap reliability is unpredictable.

Surgical tip: Preserving a length of the deep inferior epigastric artery and vein enables supercharging of the flap if rectus perfusion is inadequate.

Latissimus dorsi

The latissimus dorsi (LD) flap provides robust and reliable coverage for most anterolateral and lateral chest wall defects. It has a type V blood supply, the main pedicle being the thoracodorsal vessels, a branch of the subscapular system.

As with pectoralis, the humeral attachment of the LD can be divided to aid mobilization. The thoracodorsal vessels leave the subscapular axis and run anterior to the LD for about 5–6 cm before entering the underside of the muscle. The tendinous portion must be divided above this point to avoid injuring the pedicle.

The LD muscle can also be advanced or transposed postero-medially to cover central defects on the back. The LD can be raised on its secondary segmental lumbar perforators, and mobilized as a turnover flap.

Summary – flaps

This is by no means an exhaustive list and there are a number of other flaps that may be used for specific chest wall defects in specific situations (trapezius, external oblique, serratus anterior), although for the majority of cases one of the aforementioned flaps will be applicable. For very large defects a combination of flaps may be employed, or in some instances free tissue transfer may be required.

Adult presentation of congenital chest wall defects

Although congenital defects have been covered in the previous section, it is worth highlighting that patients with congenital chest wall deformities may present in adulthood. Concerns are generally aesthetic, as severe symptomatic cases have usually been addressed earlier. A detailed history to identify the patient's concerns, and careful examination of the chest wall are essential. The treatment modalities used to camouflage the defect include custom-made silicone prosthesis and autologous fat transfer.

CHAPTER 43

Abdominal wall reconstruction

William A. Townley¹ and Stefan O.P. Hofer²

¹Guy's and St. Thomas' NHS Foundation Trust, London, UK

²Department of Surgery and Department of Surgical Oncology, Princess Margaret Hospital, University Health Network, Toronto, ON, Canada

Anatomy

The abdominal wall is a multilayered structure that wraps around and protects the abdominal viscera. In addition, it is involved in numerous other functions including trunk movement, respiratory effort (active expiration) and an adjunctive force in micturition and defecation. Anatomically, it is bound by the xiphoid process and costal margin superiorly and the iliac crests and pubis inferiorly.

The abdominal wall consists of skin, superficial fat, muscles, transversalis fascia and parietal peritoneum.

Skin, subcutaneous fat and fascia

The skin envelope of the abdomen is compliant and of intermediate thickness. Traditionally, two distinct layers of fascia are recognized – Camper's fascia and Scarpa's fascia. Camper's fascia represents the superficial layer, which contains variable amounts of fat. In males it is continuous with dartos fascia in the penis. Scarpa's fascia is deeper and more fibrous. It merges with the deep thigh fascia and superficial perineal fascia to contribute to fascia lata and Colles' fascia, respectively. In reality, it is more practical to think of three layers between the skin and abdominal musculature – superficial fat, membranous fascial layer (Scarpa's) and deep fat. The superficial fat layer is evenly distributed throughout the abdomen and the more vascular of the two. The deeper fat layer is of variable thickness, being thicker in the upper abdomen compared with the lower abdomen.¹

Muscles

The central abdominal wall is formed by the two paired rectus abdominis muscles and pyramidalis muscles inferiorly.

The paired rectus abdominis muscles are long, flat muscles involved in trunk flexion, forced expiration and in creating increased abdominal pressure such as in coughing. They originate from the pubic symphysis and pubic crest and insert into the xiphoid process and costal cartilages 5–7, interdigitating with the inferior fibres of pectoralis major. The two paired muscles are enclosed within the rectus sheath and separated from

each other by a midline band of connective tissue, the linea alba. The vertical muscle fibres are separated by three or four tendinous interconnections, which are horizontal bands of connective tissue. It is a type III muscle with a dual codominant blood supply (deep inferior and superior epigastric arteries). It is segmentally innervated from the 7th–11th intercostal nerves.

The pyramidalis muscles originate from the pubis and insert into the linea alba.

The lateral abdominal wall muscles include three sets of paired muscles – external oblique, internal oblique and transversus abdominis, which all contribute to the rectus sheath medially (Figure 43.1).

The external oblique is the most superficial and largest of the three lateral muscles. It originates from ribs 5–12 and runs in an inferomedial direction to insert into the linea semilunaris, where it contributes to the anterior rectus sheath, and iliac crest. The aponeurosis of external oblique forms the inguinal ligament inferiorly. It is innervated and nourished by the intercostal neurovascular bundles (5–12).

The internal oblique muscles originate from the thoracolumbar fascia and iliac crest and run in a superomedial direction, perpendicular to the external oblique fibres. It becomes aponeurotic medially, contributing to both anterior and posterior rectus sheath before inserting into the linea alba and ribs 10–12. It is innervated by the lower intercostal nerves and the first lumbar spinal nerve. There are multiple source vessels feeding the muscle including the deep circumflex iliac artery, deep inferior epigastric artery and lower intercostal vessels.

The transversus abdominis is the deepest of the three lateral muscles and runs transversely towards the midline from the iliac crest and thoracolumbar fascia. The transversalis fascia is a continuous fascial sheet that lies on the deep surface of transversus abdominis.

Blood supply

The blood supply of the abdominal wall is robust, with multiple independent sources and much collateralization. Huger considered the skin and subcutaneous components of the

Figure 43.1 Anteroposterior view of abdominal wall muscles (lateral and central components). Source: <http://lyndseydesjardins.com/>

abdominal wall in terms of three zones of perfusion as illustrated in Figure 43.2.²

Zone I encompasses the central abdominal tissue overlying the paired rectus abdominis muscles. It is bound by the xyphoid process, pubic symphysis and lateral edges of the rectus sheath. The skin and subcutaneous tissue of zone I is perfused by musculocutaneous perforators from the deep inferior epigastric (branch of external iliac artery) and to a lesser extent the superior epigastric arteries (branch of internal mammary artery). The perforators are predominantly arranged in two rows – medial and lateral. The highest concentration of perforators is within 3 cm of the umbilicus. The medial row perforators perfuse across the midline to a greater extent than the lateral row perforators, a feature that is important in deep inferior epigastric perforators (DIEP) flap breast reconstruction.⁴

Zone II refers to the lower abdominal wall lying below the line of the anterior superior iliac spines. It is perfused by three different branches of the common femoral artery – superficial circumflex femoral artery, superficial inferior epigastric artery and the external pudendal artery. Zone III refers to the flank and abdominal wall lateral to the rectus muscles. It is supplied by the lower intercostal arteries and first lumbar artery – a

robust blood supply that is able to perfuse the entire abdominal wall after division of Huger's zone I and II as demonstrated after an abdominoplasty.

Innervation

The motor and sensory innervation of the anterior abdominal wall is derived from the anterior rami of the 7th–12th intercostals and first lumbar root. The intercostal neurovascular abdominal bundles pierce the transversus abdominis and travel in a plane deep to internal oblique. Preservation of the motor supply is essential for maintaining the integrity of the abdominal wall to prevent hernia formation or bulging.

Fascia

A detailed understanding of the fascia of the abdominal wall muscles is essential in abdominal wall surgery (Figure 43.3). The rectus sheath is formed laterally at the linea semilunaris by the condensation of the aponeuroses of external oblique, internal oblique and transversus abdominis. The anterior rectus abdominis is covered by sheath throughout its course. Posteriorly, the rectus is covered by sheath only above the arcuate line, a transverse line at the level of the anterior superior

Figure 43.2 Huger's abdominal skin perfusion zones. Source: Karthikesalingam *et al.*, 2011.³ Reproduced with permission of Elsevier.

iliac spine. Below the arcuate line, only transversalis fascia and parietal peritoneum lie deep to the rectus.

Above the arcuate line, the anterior rectus sheath is composed of external oblique and the superficial leaf of the internal oblique fascia, whereas the posterior rectus sheath is formed by the condensation of deep leaf of internal oblique and transversus abdominis fascia. Below the arcuate line, the transversus abdominis fascia and deep leaf of the internal oblique fascia also contribute to the anterior rectus sheath, whereas the posterior rectus sheath is devoid of muscular aponeurosis. The rectus abdominis muscle is tightly adherent to the sheath at the tendinous intersections.

Aetiology and classification of abdominal wall hernia defects

Abdominal wall hernias can be congenital or acquired. Congenital causes include umbilical hernias, periumbilical hernias, Spigelian hernias (between rectus and linea semilunaris), lumbar hernias and epigastric hernias. Gastroschisis and omphalocele represent two severe types of congenital abdominal wall defects that are commonly associated with other

developmental anomalies. In gastroschisis, the abdominal wall defect is usually smaller and the abdominal wall contents freely protrude through the defect without being maintained in a sac of peritoneum, whereas in omphalocele, the defect is usually much larger and the abdominal contents are maintained in a sac of visceral peritoneum outside of the abdomen, protruding through the umbilicus. Both conditions occur infrequently (1 in 5000 births) but are often detected antenatally by ultrasound.⁵

Acquired hernias are usually iatrogenic, arising in a previous surgical incision. Other acquired causes of abdominal wall defects include trauma, infection (necrotizing fasciitis) and tumour. Common predisposing factors for incisional hernias include both systemic (poor intrinsic wound healing, obesity, age, malignancy) and local factors (inadequate surgical closure, infection, ischaemia, increased intra-abdominal pressure, prolonged ventilation). In terms of technique, evidence suggests that low dehiscence rates are best achieved by taking wide tissue bites (>1 cm from the fascia margin), short stitch intervals (1 cm) and non-strangulating tension on the suture. Even in the absence of identified risk factors, incisional hernias develop in 11% of primary laparotomies and may be as high as 33% in obese patients. Recurrent incisional hernias are especially challenging and the incidence of recurrent herniation after repair increases with each subsequent hernia repair operation.

Recently, the European Hernia Society has developed a classification system of abdominal hernias to deliver conformity and allow ease of comparison in published clinical studies.⁶ This classification system distinguishes between primary and incisional ventral hernias. For primary ventral hernias, the two parameters are location and size (hernia diameter) as illustrated in Table 43.1. The location is subdivided into midline defects (epigastric, umbilical) and lateral defects (Spigelian, lumbar). For incisional hernias, there are additional criteria including whether or not the hernia is recurrent.

Assessment of the abdominal wound

Clinical

An appropriately directed history and examination are an essential facet of the initial assessment. It is important to note whether the wound is acute or chronic and previous operations including use of mesh. Local and systemic risk factors for poor wound healing should be identified. The aim of the examination is to determine the wound characteristics and identify potential flap donor sites. On inspection, the presence of abdominal scars, fistulas, sinuses, exposed mesh and infection should be actively looked for. In addition, in long-standing wounds, there is a potential for malignant transformation. The wound is examined to determine which components are missing – skin, muscle, fascia. Adjunctive measures include an assessment of respiratory function as

Figure 43.3 Formation of rectus sheath above and below arcuate line. Source: Anatomical considerations of body contouring, In Hunstad & Repta, *Atlas of Abdominoplasty*, Elsevier 2009. Reproduced with permission.

abdominal wall restoration can affect total lung capacity and respiratory effort.

Imaging

Preoperative imaging is very helpful in defining the pathology and in preoperative planning. Both abdominal CT and MRI can successfully identify the extent of the abdominal wall defect and the integrity of adjacent musculofascial structures. However, CT angiography (i.e. with intravenous contrast) is superior at delineating the vascular anatomy, especially when planning pedicled flaps or free tissue transfer (Figure 43.4). An abdominal and pelvic CT scan with oral contrast enables detailed understanding of the wound and intra-abdominal contents.

Figure 43.4 CT image demonstrating a musculocutaneous perforator (blue arrow) traversing through the rectus abdominis muscle from the right deep inferior epigastric artery (red arrow) at the level of the umbilicus.

Goals of reconstruction

The goal of abdominal wall reconstruction is twofold. The first goal is to restore function and integrity of the musculofascial abdominal wall to prevent visceral eventration and provide dynamic muscle support. The second is to provide skin resurfacing.

Management of abdominal wounds

Acute wounds

Acute abdominal wounds may be the result of dehiscence post laparotomy, infection, trauma or neoplasms.

Most acute abdominal wounds following laparotomy can be managed with local wound care, including bedside debridement of necrotic tissue and daily dressing changes or application of negative pressure wound therapy (NPWT). In select cases, secondary closure following wound excision may be feasible and has been shown to be superior to healing by secondary intention.⁷

Fascial dehiscence post laparotomy may occur in the acute setting without a skin defect. The typical history involves persistent drainage of serous fluid through the wound after one week. Fluid cultures are often positive. Fascial reclosure has a high chance of failure. Ideally, tension-free fascial closure is achieved and this may require use of a biologic or synthetic mesh with skin closure or NPWT.

In the trauma setting, the decision must be made between performing an immediate and a staged repair. Immediate reconstruction is preferred as it is more cost-effective and less time-consuming. However, reconstructive options are limited in unstable patients, contaminated wounds or where further procedures are planned. In these circumstances, the patient may be better served by a staged repair involving initial closure by mesh repair and skin grafting once sufficient granulation tissue has developed. The second stage involves excision of the skin graft and definitive repair of the associated ventral hernia.

There is an increasing vogue for leaving the abdomen open in severe abdominal trauma. This so-called open abdomen technique prevents abdominal compartment syndrome and allows early identification of complications such as bowel ischaemia. Managing patients with an open abdomen is also appropriate where primary fascial closure is not feasible such as from oedematous bowel in a patient with peritonitis. A recent systematic review concluded that NPWT is more successful than other methods, including a staged repair, in achieving fascial closure and reducing mortality in the open abdomen.⁸

Chronic wounds

Chronic uncomplicated wounds without fistula can be managed in a number of ways. Small wounds may be managed with simple dressings and closed directly at the time of hernia repair. Moderate to large wounds are probably best skin grafted initially to allow a temporizing wound closure. The skin graft can be excised at the time of definitive hernia repair. In cases where there is exposed mesh, the mesh should be removed if grossly contaminated. However, exposed mesh can be readily salvaged with application of NPWT and subsequent split-thickness skin grafting once sufficient granulation tissue has developed.

Small sinuses with retained foreign material but no fistula (e.g. stitch abscess) should be managed by removal of the foreign body. Healing by secondary intention usually follows.

The presence of an enterocutaneous fistula, defined as an epithelial-lined connection between the skin and internal organ, poses an immense clinical challenge. Treatment must be individualized and despite involvement of experienced multidisciplinary teams, outcomes are often poor with a high morbidity, mortality and psychosocial dysfunction.⁹

Prevention is key. Enterocutaneous fistulas most commonly develop in patients who have suffered a postoperative anastomotic leak. In wounds with exposed abdominal viscera, wet-to-dry dressings should be avoided as they can cause mechanical debridement of friable bowel mucosa and subsequent fistula development. Instead, the bowel should be covered with omentum where possible or absorbable mesh if omentum is unavailable.

Once a fistula is established, initial therapy should be directed at systemic measures to facilitate wound healing and maintain bowel function. These include aggressive treatment of sepsis, nutritional supplementation and attention to fluid and electrolyte disturbances. Patients have high caloric and metabolic needs. In addition, vitamins and trace elements such as copper and zinc can be rapidly depleted through fistula-related losses. Total parenteral nutrition (TPN) can reduce enteric losses by as much as 50% although enteral may also be used to provide trickle feeds.¹⁰ Reduction of fistula output may increase the chance of spontaneous closure.

Once systemic factors have been addressed adequately, a surgical closure should be carefully planned. Imaging is critical to determine the anatomy of the fistula. This may include CT, MRI, fistulograms and small bowel imaging. In the early stages, the wound may be skin grafted to convert the fistula into an ostomy, which can be managed more easily with a pouch system. Other techniques have been used to divert the fistula effluent from the wound bed in the early stages, such as NPWT and bridging dressings, which isolate the fistula. In either case, the periwound skin should be adequately protected with topical barrier ointments (containing zinc oxide, petrolatum, dimethicone or a combination) to prevent chemical denudation. A pouch system is used to collect the effluent and in addition may suppress odour.

The fistula can then be allowed to close spontaneously or be closed secondarily. Secondary fistula closure is best achieved by bowel resection and re-anastomosis with abdominal wall reconstruction using acellular dermal matrices or components separation.

Management of fascial defects

Mesh repair

Use of mesh has been conclusively demonstrated to reduce recurrence of both primary and incisional hernias.¹¹ Surgical mesh must provide sufficient biomechanical strength to meet

Figure 43.5 Cross-sectional image of abdominal wall above arcuate line demonstrating different positions of mesh placement – overlay, inlay, underlay.

physiological requirements in order to permanently protect the fascial defect. The tension on the abdominal wall and therefore the required tensile strength of the fascia closure is a function of the intra-abdominal pressure, which ranges from 1.55 mmHg in patients lying supine up to 150 mmHg maximum peak pressure in coughing patients.^{12,13}

There are many varieties of synthetic meshes, which are broadly similar in structure to suture materials. They can be classified according to absorbability, tensile strength, porosity and filament structure. Traditionally, non-absorbable meshes such as Prolene (polypropylene) have been favoured in view of their strength, superior handling and stability. However, concerns about mesh extrusion, pain, bowel adhesions and development of fistulas have led to the development of new absorbable meshes. The current trend is for lightweight composite meshes that have an absorbable component such as Vypro II and Ultrapro (Johnson & Johnson, India). They consist of thin filaments of Vicryl and Prolene (Johnson & Johnson, India) or Monocryl (Johnson & Johnson, India) and Prolene (Johnson & Johnson, India). Such composite meshes provide sufficient tensile to withstand high intra-abdominal pressures but reduce complications such as bowel adhesions. The results of long-term randomized controlled trials comparing non-absorbable heavyweight meshes with newer composite meshes are awaited to determine if there is a significant difference in outcome.

The general principles of a successful mesh repair technique involve wide coverage with adequate overlap and secure suture fixation to the fascia. The mesh may be inserted above the fascia

Figure 43.6 Illustration of inlay mesh technique for repair of DIEP donor site hernia.

(onlay or overlay), underneath the fascia (inlay) or deep to the rectus (underlay, Figure 43.5).

Mesh can be used to reinforce a fascial repair or as an interpositional strut where a fascial defect exists. Figure 43.6 demonstrates an inlay mesh placement of a donor site hernia post DIEP flap breast reconstruction.

Both inlay and onlay mesh repair techniques are popular methods of bridging fascial defects and seem to be equally effective.¹⁴ However, with inlay mesh placement, the mesh is in direct contact with the abdominal viscera over a greater surface area than onlay placement, increasing the theoretical risk of erosion into the bowel and fistula formation. The key component is ensuring there is sufficient overlap between the margins of the fascia and the mesh.

Acellular dermal matrices

Certain fascial defects are not suitable for mesh repair, particularly in cases complicated by gross contamination, scarring, radiotherapy and absence of local tissues for reconstruction. These challenging cases have provided the impetus for development of acellular dermal matrices (ADM), which have many theoretical advantages over synthetic meshes, mostly due to their enhanced biocompatibility. It is suggested that these biologic matrices have an increased capacity for integration with surrounding tissues, while demonstrating resistance to infection, extrusion, erosion and adhesion formation.¹⁵ They are particularly advantageous in abdominal wall reconstruction, as they can be placed directly on exposed viscera and applied in contaminated fields.

Dermal matrices are classified according to the species of origin (allogenic – human, xenogenic – porcine, bovine) and the source of the collagen matrix (dermis, intestinal submucosa, pericardium). Similar to mesh techniques, they can be applied

as onlay or inlay sheets, or both as in the sandwich technique. Where fascial defects exist, they can be used as interpositional bridging grafts.

In terms of efficacy, the reported success of ADMs in reducing hernia recurrence is mixed. The incidence varies widely among published series from 0 to 80%.¹⁵ In select groups such as transplant patients, human dermal matrices have been shown to reduce hernia recurrence compared with synthetic mesh and have a lower rate of infection.¹⁶ However, other authors have reported high recurrence rates, especially when dermal matrices have been used as interpositional bridging grafts.¹⁷ There is no consensus on whether there is any difference in effectiveness between placement of the matrix in an inlay or onlay fashion. An important consideration is the cost of the dermal matrices, which has been shown to be as high as US\$5100 per patient in patients undergoing repair of abdominal wall defects.¹⁸

In experimental models, porcine-derived matrices benefit from increased tensile strength compared with human matrices but have poorer neovascularization, which may affect long-term effectiveness. In clinical practice, human dermal matrices such as Alloderm (Life Cell Corp) are more commonly used than porcine (e.g. Permacol, Covidien, Boulder, CO, USA) or bovine-derived matrices. There is an absence of clinical trials comparing human with animal-derived products.

Complications common to all ADMs include hernia recurrence, infection, seroma and skin necrosis. Although relatively common, infection rarely leads to matrix extrusion and can often be managed with targeted antibiotics. Indeed, one of the purported benefits of dermal matrices over synthetic meshes is resistance to infection postulated to be a result of early capillary ingrowth and effective delivery of antibiotics and innate host defences. Even when implanted in a contaminated field, infection has been demonstrated to be as low as 16%.¹⁹ Seromas are common but rarely affect outcome. Strategies to reduce seroma formation include avoiding wide undermining of abdominal skin over fascia, preservation of suprafascial fat, use of quilting sutures and abdominal binders.²⁰

Components separation

Ramirez and colleagues described the technique of components separation to reconstruct midline defects, although the use of external oblique fascial relaxing incisions had previously been described for epigastric hernia repairs.^{21,22} The technique involves medial advancement of innervated musculofascial flaps involving a complex of rectus abdominis, internal oblique and transversus abdominis. Preoperative CT imaging is critical in determining the presence or absence of the rectus muscle complex, particularly in massive midline defects where the rectus muscles have been displaced very laterally.

The procedure is begun by elevating the skin flaps off the underlying abdominal musculature. This can be continued to the anterior axillary line as required. Subsequently, the linea semilunaris is identified (condensation of internal and external oblique fascia into rectus sheath). A vertical incision is made

through the external oblique fascia 2 cm lateral and parallel to the linea semilunaris. It should be just medial to the myofascial junction of the external oblique muscle itself. This is continued from the level of the costal margin superiorly to the arcuate line inferiorly. The plane between external oblique and internal oblique is developed, being careful to avoid damage to the internal oblique fascia or segmental intercostal neurovascular bundles supplying rectus. The dissection is continued lateral to the level of the midaxillary line. At this point, the mobility of the rectus abdominis–internal oblique–transversus musculofascial complex is assessed. If further advancement is required, the dissection can be continued to the posterior axillary line.

Each hemicomplex can deliver 4 cm of advancement in the upper abdomen, 8 cm in the mid-abdomen and about 3 cm in the lower abdomen (Figure 43.7). Release of the posterior rectus sheath from the undersurface of the muscle can increase medial translocation further by 2 cm at each point, making the total movement 6 cm, 10 cm and 5 cm, respectively. Therefore, components separation can reconstruct defects of 20 cm or more in the midline. The fascia is closed and the skin is advanced to the midline and closed in a layered fashion over suction drains.

Components separation has allowed the reconstruction of large midline and paramedian abdominal wall defects with well-vascularized innervated tissue and acceptable donor site morbidity compared with other autologous techniques. In addition, it frequently obviates the need for mesh and its associated complications such as infection, extrusion and enterocutaneous fistula development.

The hernia recurrence rates in published series ranges from 0% to 32%, suggesting that it can be a very effective technique.²⁴ Recurrence rates are reduced further by additional use of onlay synthetic meshes. In most cases, the strength of the abdominal wall is increased but does not return to premorbid levels. Although commonly used in adults, the components separation technique has also been applied successfully to closure of congenital abdominal wall defects in neonates, including gastroschisis and omphaloceles.²⁵

One of the potential pitfalls of the components separation technique is ischaemia of the medial skin edges and ensuing necrosis, infection or dehiscence. Compromise of the medial margin occurs due to the extensive undermining of the skin flaps required to allow sufficient exposure for division of the external oblique muscles. Modifications to the original procedure that reduce midline wound-healing complications include endoscopic-assisted components separation and techniques that preserve periumbilical perforators.^{26–28}

Soft tissue reconstruction in abdominal wall reconstruction

Rohrich and colleagues developed an algorithm for planning closure of abdominal wall defects.²⁹ They consider closure of the skin and musculofascial components independently and have a separate

Figure 43.7 Cross-sectional view illustrating components separation technique. E, external oblique muscle; I, internal oblique muscle; T, transversus abdominis muscle. Source: Dragu *et al.*, 2009.²³ Reproduced with permission of Springer.

scheme for partial and complete defects. Although this algorithm is helpful in providing some structure for framing decisions, in reality it is too complex to be a readily useful tool. Treatment needs to be individualized and the clinician should be aware of all options. In addition to closure of fascial defects by synthetic mesh, ADMs and components separation as discussed in the previous section, there is also a place for pedicled or free flaps as discussed below. There are a variety of means of achieving skin closure.

Direct closure

Due to the laxity of the abdominal wall skin envelope, direct closure is often feasible. If required, wide undermining in the prefascial plane can be performed to deliver additional advancement of the skin flap edges such as in an abdominoplasty or components separation.

Skin grafts

Split-thickness skin grafts are often used as a temporizing measure to close a wound that is not fit for immediate reconstruction. The graft can then be excised at the time of definitive closure.

Negative pressure wound therapy

NPWT has revolutionized the management of wounds over the past decade. In abdominal wall reconstruction, it has been used to accelerate healing by secondary intention and wound

preparation prior to reconstruction with grafts. It is frequently used as a bridge between initial wound care and final-stage, definitive wound closure.

In acute abdominal wall defects, NPWT is commonly used over a mesh repair to allow development of a sufficient bed of granulation tissue to accept a split-thickness skin graft. After several months when the scar has matured and the number and density of adhesions has rescinded, definitive abdominal wall reconstruction can be performed via components separation.³⁰ As discussed previously, NPWT also has a place in management of the open abdomen.

Flap reconstruction

Soft tissue flaps can be used to reconstruct both skin and fascial components of abdominal wall defects, delivering robust, well-vascularized tissue to aid primary wound healing and maintain abdominal wall integrity. Flaps are often used to repair fascial defects in contaminated wounds where synthetic mesh is best avoided. Another common indication for flaps is to provide soft tissue cover of mesh or ADMs in clean wounds following tumour extirpation. Flaps provide an alternative autologous reconstruction in situations where components separation is not feasible.

The *pedicled rectus abdominis* flap is the workhorse flap in abdominal wall reconstruction (Figure 43.8). It can be taken

Figure 43.8 Photograph showing vertical rectus abdominis muscle reconstruction of a full-thickness right upper quadrant abdominal wall defect following excision of a liposarcoma in a 59-year-old man.

with or without a skin paddle and a variety of orientations of the skin paddle are possible, providing flexibility in design. Based superiorly, the flap is perfused by the superior epigastric artery or inferiorly on the deep inferior epigastric system.

The *anterolateral thigh* (ALT) flap can be used to reconstruct large composite abdominal wall defects, providing both fascial and skin components. A very large area of fascia lata can be harvested from the thigh with the flap to reinforce or reconstruct large fascial defects. As a pedicled flap, it can easily reach above the umbilicus. Once elevated on the lateral circumflex femoral artery, the flap is passed deep to the rectus femoris and sartorius muscles to be delivered to the abdomen. The fascia lata is sutured to the fascial margins of the defect and the skin is closed in a layered fashion over suction drains. In upper abdominal wall defects and in cases where the flap does not reach the defect adequately, a pedicled ALT can be converted into a free ALT with similar outcomes.³¹ Where a free ALT is performed, the deep inferior epigastric vessels are first-choice recipient vessels due to their accessibility and size. If unavailable, the gastroepiploic vessels provide a reliable alternative.

The *tensor fascia latae* (TFL) flap can also be used to reconstruct composite defects of the lower abdominal wall but is inferior to the ALT flap, which has a larger, more reliable skin territory and longer vascular pedicle. Figure 43.9 demonstrates an example of

a TFL flap. In particular, tip necrosis is common in both free and pedicled TFL flaps, being reported to occur in up to 43% of flaps used in abdominal wall reconstruction.³²

The pedicled *rectus femoris* muscle has also been described for use in reconstruction of lower abdominal wall defects. In contrast to TFL flaps, it provides considerable muscle bulk, which is useful for dead-space filling. It has the same pedicle as the ALT flap (descending branch of the lateral circumflex artery) although the pedicle length is shorter than the ALT flap as the rectus branch typically comes off higher up than the ALT perforators.

Other flaps used in abdominal wall reconstruction include vastus lateralis, gracilis, internal oblique, external oblique and, in cases where large skin defects exist, free latissimus dorsi flaps.

Abdominal wall transplantation

Abdominal wall transplantation is an evolving technique used to facilitate abdominal wall closure in patients undergoing intestinal or multivisceral transplantation.³³ In this group of patients, abdominal closure can be very difficult due to loss of domain and swelling after organ transplantation. In addition, they have a high mortality and morbidity. The abdominal wall graft is a composite tissue allograft composed of skin, subcutaneous tissue and rectus myofascial complex. The flap is vascularized through anastomosis of donor and recipient inferior epigastric vessels or from an iliac vessel anastomosis in continuity with the femoral vessels. The muscle is not innervated and although muscle hypotrophy develops, significant hernia formation does not seem to be a problem.³⁴

Management of the postoperative bulge

Abdominal wall complications after primary abdominal surgery or flap harvest can manifest as either an abdominal wall hernia or myofascial laxity (bulge). It can be difficult to distinguish clinically between a hernia and a bulge. A bulge is a contour abnormality of the abdominal wall with underlying myofascial continuity that is the result of global weakness. In contrast, a hernia is associated with a discrete myofascial defect. Bowel entrapment and obstruction are therefore a less common sequelae of bulges compared with hernias.

Predisposing factors to development of bulges include muscle denervation (abdominal flap harvest), inadequate mesh tension, native myofascial laxity and increased intra-abdominal pressure. In a recent systematic review, the risk of bulging associated with DIEP flap harvest was one third of muscle-sparing transverse rectus abdominis myocutaneous (TRAM) flaps.³⁵ Most frequently, a bulge presents as a contour abnormality that changes with posture and activity and can be associated with a dull ache. In severe cases, it can significantly interfere with daily activities and cause progressive skin attenuation with

Figure 43.9 Elderly man with ventral hernia following previous laparostomy wound treated definitively by extended tensor fascia latae (TFL) flap composite reconstruction. (a) Skin graft on laparostomy wound. (b) TFL flap raised with fascial extension. (c, d) Flap inset. Source: Professor Wayne Morrison and Mr Ross Farhadieh. Reproduced with permission.

ulceration and infection. Diagnosis can be made by clinical examination and imaging, including contrast-enhanced CT scan and dynamic ultrasound assessment, which looks at the effect of posture and intra-abdominal pressure on abdominal wall integrity.

Indications for operative repair include massive bulges with loss of function due to truncal instability, progressive skin changes or significant aesthetic concerns. Pain relief is not a guaranteed outcome following repair. The principles of surgical correction include: (a) resect or plicate the area of myofascial laxity, (b) reapproximate intact dynamic fascial tissue under physiologic tension, and (c) reinforce the repair with adjunctive procedures such as mesh or components separation.³⁶ It is important to appreciate that bulges are associated with a global central or lateral fascial attenuation, often due to muscle denervation. Therefore, simple patching of the defect often results in recurrent bulges in adjacent

areas. This is best achieved by use of inlay mesh across the entire central or lateral bulge with fixation of mesh to stable points beyond the bordering oblique muscle complexes, ideally to innervated myofascia or bone. Postoperatively, patients can ambulate on day 1 but should avoid heavy physical activity and sports for six weeks.

CHAPTER 44

Genitourinary and perineal reconstruction

PERINEAL RECONSTRUCTION

Niri S. Niranjan

Department of Plastic & Reconstructive Surgery, St Andrews Centre, Broomfield Hospital, Chelmsford, UK

Introduction

The perineal region has two important organs – an excretory and a sexual. Malfunction or dysfunction of either of these can affect the whole body. The perineum has very rich blood supply, fed by both the femoral and the iliac arteries; branches from these vessels anastomose with each other around the urogenital and anal orifices and this enables reconstructing surgeons to use skin flaps based on the perforators from these vessels.

The soft tissue reconstruction is challenging in terms of achieving the best outcome with respect to maintaining the normal function and cosmetic appearance. Local flaps based on perforators are the best as they replace like tissues and should be considered for small to moderate defect. However, the management of advanced pelvic malignancy requires a multidisciplinary approach. The potential method of resection and reconstruction for total perineal defects should be discussed by a multidisciplinary team, which should consist of a colorectal surgeon, urologist, gynaecologist, oncologist, radiologist, plastic surgeon, specialist nurse practitioner, physiotherapist and psychologist. Factors that dictate the choice of method are the patient's general condition and habits (age, sex, diabetes, atherosclerosis, obesity, smoking and nutritional state) and the defect created (skin, pelvic viscera, pelvic muscles). Some of the patients will have already undergone surgery and radiotherapy. In these patients, the local option may have either already been used or is not possible because of radiotherapy. The patient should be fully informed of the surgical treatment, the outcome and possible major life adjustment postoperatively (e.g. colostomy and urinary conduit). An anaesthetist who is regularly involved in this type of procedure should assess the patient.

Anatomy of the blood supply of the perineum

In 1889 Carl Manchot¹ divided the cutaneous area of the perineum into anterior and posterior regions. He also described the blood supply of the perineum in great detail. Branches of femoral and internal iliac arteries form the rich vascular network of the perineum (Figure 44.1). The anterior region is supplied by the superficial external pudendal artery and deep external pudendal artery. The obturator artery, internal pudendal artery and branches of the inferior gluteal artery supply the posterior half of the perineum.

The internal pudendal artery gives out two terminal branches: the penile/clitoral branch and the perineal artery. The perineal artery supplies the labial/scrotal part of the perineum via its terminal branches, which anastomose with their contralateral counterpart. The perineal artery also gives off medial and the lateral branches. The medial branch supplies the perianal region and the lateral branch supplies an area of posterior surface of the upper thigh. All these branches anastomose with their counterpart from the opposite side and hence form a rich circle of vascular anastomoses around the orifice. This vascular network provides the basis of the perforator flaps.

Reconstruction of partial or moderate defect of the perineum

The ideal flap for any perineal defect should use reliable and robust like tissue, not be too bulky and should have protective sensation to maintain normal function and appearance. There should also be minimal donor site morbidity. For practical purposes the perineum can be divided into right, left and central area. A line drawn between the ischial tuberosities divides these areas into anterior and posterior halves (Figure 44.2). The central area contains the urogenital orifice in the anterior half and the anal orifice in the posterior half. In the majority of the cases the defect to be reconstructed is created in the central area, for example due to vulvar/vaginal or anal neoplasia. Other situations where flap reconstruction is

used are congenital malformations and severe debilitating infections (such as hidradenitis suppurativa). Traumatic defects requiring local flaps are uncommon. For defects in the upper quadrant, donor skin flaps could come from the groin and/or mons pubis area, whereas for the lower quadrant the donor site may be from the gluteal fold and/or gluteal area. The mid thigh can also provide a flap for these situations. For the central area of the perineum the donor could be selected from any of the above sites. The selection depends on the site and size of the defect.

Figure 44.1 Blood supply of the perineum. SIEA, superficial inferior epigastric artery; SEPA, superficial external pudendal artery; DEPA, deep external pudendal artery; OA, obturator artery; MCFA, medial circumflex femoral artery; PA, perineal artery; IPA, internal pudendal artery.

Figure 44.2 Schematic division of the perineum.

There are three ways of moving local perforator flaps, namely rotation (lotus petal flaps (Figure 44.3), V-Y advancement flaps (Figure 44.4) and transposition (pudendal, mons pubis flaps) (Figure 44.5).

Figure 44.3 Lotus flap schema based on local perforators.

Figure 44.4 V-Y advancement flap.

Figure 44.5 Transposition of pudendal and mons pubis flaps.

In 1973, Horton *et al.*² reported local random pattern flaps designed around the genital area. Other types of skin flaps used during the 1970s and 1980s were mostly myocutaneous flaps. Among these are the gracilis,³ tensor fascia lata^{4,5} and rectus-abdominus.⁶ These flaps were obviously bulky and accompanied by considerable donor site morbidity. The fasciocutaneous flap emerged in the early 1980s and in 1987, Wang *et al.*⁷ advocated medial thigh fasciocutaneous flaps, whereas Wee and Joseph in 1989⁸ described a pudendal thigh flap with an intact nerve supply for vaginal reconstruction. Woods *et al.* modified the same flap in 1992.⁹ The lotus petal flaps^{10–12} are perforator based and have become a standard method of reconstruction.

Operative technique

Surgery may be performed under either general or regional anaesthesia. The patient is placed in the Lloyd-Davies position. A urinary catheter is inserted. Prophylactic antibiotics should be given at induction and for 48 h post operatively. The defect is created during the resection for either cancer or infection or the debridement of traumatized tissue. Once the dimension of the defect is studied and assessed, the required flap is planned over the donor area. The flap is planned in a reverse manner by using a swab or a pattern of the defect turned towards the selected donor site in reverse.

The success of perforator flap reconstruction depends on the selection of the perforator vessel at or around the base of the selected flap. Before the operation, perforator vessels are mapped using a hand-held Doppler ultrasound probe at the base of the skin flap. An exploring incision is made along one edge of this flap down to the muscle. The flap is elevated with the deep fascia and the perforating vessel is reassessed. In rotation or transposition flaps, perforators should be selected

closer to the defect. However, for V-Y advancement flaps, perforators can be anywhere in and around the mid-axis of the V-Y flap.

Reconstruction of total defect of the perineum

Total perineal reconstruction, including skin and pelvic viscera, may be indicated for advanced cancer and post-irradiated cancer recurrence, total perineal skin loss in extensive debilitating infection or following full-thickness burn or trauma.

The 'clock-face' assessment of the defect is a very useful method of considering anatomically sound options available. There are numerous perforator-based or myocutaneous flaps available beyond the clock-face territory of the lotus petal flaps and extended lotus petal flaps, which serve this purpose.¹³ These flaps are away from disease and irradiated areas of the perineum and hence will provide well-vascularized tissue for primary healing. The aim is to achieve wound closure with primary healing. Sexual function has to be sacrificed and excretory function is diverted.

Regional flaps

Deep inferior epigastric artery-based flaps

The vertical rectus abdominis myocutaneous (VRAM) flap^{14–18} should be considered as first choice for patients undergoing abdomino-perineal resection. This is an ideal flap in total perineal resection (i.e. pelvic exenteration) (Figures 44.6, 44.7 and 44.8). The perforators of the deep inferior epigastric artery are marked over the abdomen using ultrasound Doppler and/or CT angiogram. The required skin following completion of resection, the perineal defect is reassessed in terms of the size of skin defect and the volume of pelvic cavity. The deep inferior epigastric vessels can be inspected through the abdominal wound and the required skin paddle is re-marked, working out the required length of the pedicle.

The midline incision is extended superiorly and the lateral incision of the skin paddle is incised down to the rectus sheath. The rectus sheath is incised just laterally to the lateral row of perforators and a strip of the fascia is kept intact all along the rectus muscle. The flap, consisting of muscle, a strip of fascia and an island of skin, is elevated. The deep inferior vessel is identified and carefully dissected right down to its origin. The lower attachment of the muscle is also divided, which helps in orienting the flap in the pelvic cavity and in delivering the skin paddle through the perineal wound.

The muscle is sutured to the pelvic floor. The skin paddle is usually larger than the defect, hence it is de-epithelialized, leaving the exact amount of skin required. The skin paddle is

inset, keeping two drains, and the abdominal wound is also closed in layers. Postoperatively the patient is mobilized as soon as possible.

Lateral circumflex femoral artery-based flaps

The anterolateral thigh (ALT) flap, first described by Song *et al.* in 1984¹⁹ as a septocutaneous flap, is now a workhorse in reconstructive surgery. The major advantages of this flap are that it provides a large amount of skin for harvest and that the pedicle is close enough to reach the perineum, but far enough to be away from diseased and irradiated areas of the perineum.

The blood supply of the ALT flap is dependent upon the perforators of the descending branch of the lateral circumflex femoral artery. In general, a large skin flap can be raised but a width of up to 8 cm can be closed directly and any wider skin flap requires a skin graft. The perforators are assessed for a visible pulsation and for venae comitantes. Where septocutaneous type, the vessels traverse the septum between rectus femoris and vastus lateralis muscles. If the perforators are of a muscular type, which usually

Figure 44.9 Superior and inferior gluteal artery perforator-based flaps. (a) Anatomy. (b) Skin paddle of superior gluteal artery (SGA) and inferior gluteal artery (IGA).

comes from the vastus lateralis, that part of the muscle may also be included to add bulk to the flap. The flap is passed under the rectus femoris muscle and through the subcutaneous tunnel to reach the perineum, making sure that there is no tension on the pedicle. The perineal wound is closed in layers with a drain and the donor area is either closed directly, or with a skin graft.^{20,21}

Postoperatively, the patient may be nursed in a slightly flexion and also abduction of the thighs to prevent any compression on the pedicle, although this is rarely necessary. The patient is mobilized after 48 h.

Gluteal artery-based flaps^{22–24}

The gluteus maximus muscle is a large muscle of the buttock area. It has two dominant blood supplies as a type III muscle flap. The superior and inferior gluteal arteries arise from the internal iliac artery and they emerge on either side of the pyriform muscles (Figure 44.9). The superior gluteal artery supplies the upper part of the gluteus maximus and the inferior gluteal artery supplies the lower half. The inferior gluteal artery is a direct continuation of the internal iliac artery emerging below the pyriform muscle, accompanying the sciatic nerve, inferior gluteal nerve, the internal pudendal vessel and posterior femoral cutaneous nerves. The cutaneous perforators of the inferior gluteal artery (about 8 ± 4) are concentrated in the middle third of the gluteal region, parallel to the gluteal crease.²³ The superior gluteal artery perforator or myocutaneous flaps would be suitable for the sacral part of the defect, whereas the inferior gluteal artery perforator or myocutaneous flaps would be suitable for a large part of the perineum and also in pelvic exenteration (Figures 44.10 and 44.11).

These flap are considered when VRAM or ALT flaps are not possible for reconstruction. When chosen for abdomino-perineal reconstruction, the surgery requires two different

positions of the patient. Initially, the resecting surgeon will carry out the abdominal part of the operation, including colostomy and urinary conduit and the abdominal wound is closed. The patient is then positioned in the prone, jack-knife position. Using ultrasound Doppler, the lateral groups of perforators of the inferior gluteal artery are selected in the ellipse of the skin so that the pedicle is long enough to reach without tension.²⁴ The skin flap is elevated from the lateral aspect and a small portion of the gluteus maximus muscle may be included, which not only adds to the bulk but also includes a number of perforators for the flap. Once the flap is islanded, the pedicle is dissected, ligating all other branches of the inferior gluteal artery. When the flap is transposed over the perineum, the deep layer is sutured with the pelvic floor and the skin is sutured in two layers of the perineum, with two drains.

Posterior thigh flap

The blood supply of this flap arises from the descending branch of the inferior gluteal artery. This flap contains the posterior cutaneous nerve of the thigh, which makes it a sensate flap. The course of the artery and the perforators can be mapped out by using ultrasound Doppler or by CT angiography. This helps in planning the required flap. A line is drawn from the ischial tuberosity to the lateral epicondyle of the femur. The skin paddle is centred at the midpoint of this line, with the width of the skin paddle being either the amount that can be closed directly or more if skin grafting is required. It is also possible to take two flaps or to use this in combination with other flaps. The flap is elevated by incising its lateral border and extending it towards the gluteal crease to expose the pedicle and following it up to its origin. Extra length can be obtained by dissecting the inferior gluteal artery. The flap may then be tunnelled under the skin to the perineal defect and inset.

Figure 44.10 Inferior gluteal artery flap, island flap V-Y advancement. (a) Post-perineal reconstruction wound showing intact gluteal fold flap. (b) Immediate post-op result. (c) Three months post-op result.

The postoperative regime is as described before. The donor scar of the inferior gluteal artery perforator flap will cause some discomfort for the patient during sitting for about 4–6 weeks post operatively.

Medial circumflex femoral artery-based flaps

Orticochea in 1972²⁵ and McCraw *et al.* in 1977²⁶ described the gracilis myocutaneous flap. The gracilis myocutaneous flap is a type II muscle flap, the blood supply of which is from the ascending branch of the medial circumflex femoral artery. The skin flap paddle orientation is usually in the line of the gracilis muscle, but in recent years, following the paper from Yousif *et al.* in 1992,²⁷ a transverse orientation of the cutaneous paddle has been shown to be more reliable. This is now called a transverse myocutaneous gracilis (TMG) or transverse upper gracilis (TUG) flap.^{28,29} The muscular artery for the gracilis enters the muscle about 8–10 cm from the pubic tubercle. The

gracilis muscle can be used as a myocutaneous flap, or a muscle flap in combination with other skin flaps (Figure 44.12).

The gracilis myocutaneous flap is indicated for abdomino-perineal resection with surgery carried out in the Lloyd-Davies position. A skin paddle is drawn about 1–2 cm below and parallel to the groin crease and the inferior line is drawn depending on the amount of skin available for direct closure. This gives an ellipse measuring 18–20 cm in the anterior posterior direction.

The flap is elevated from anterior to posterior in the subfascial plane until the intramuscular septum between adductor longus and gracilis is encountered. The great saphenous vein is protected and preserved (i.e. not included in the flap). The adductor longus muscle can be identified easily and the fascia over the adductor longus muscle is included with the flap. The gracilis muscle is below adductor longus and the septum between the two can be easily separated by finger dissection,

Figure 44.11 Superior gluteal artery flap islanded transposition flap. (a) Reverse flap design around the perforator. (b) Islanded flap. Figure 44.12 Bilateral transverse myocutaneous gracilis (TMG) design.

exposing the distal part of gracilis. The pedicle of gracilis, ascending branch of the medial circumflex femoris artery and the vein can easily be seen under the fascia.

Postoperatively, the patient is kept in a supine position with the legs slightly abducted, with a pillow under the knees to keep them flexed. After 24–48 h, the drains are removed and the patient is mobilized.

The gracilis muscle may also be considered for functional transposition for perineal reconstruction by preserving the nerve to the muscle.

Discussion

Perineal reconstruction is complex and involves a multidisciplinary approach. The ablative surgery often leaves the patients with significant and sometimes difficult lifestyle changes. Adherence to basic reconstructive surgery principles with provisions of a water-tight and reliable reconstruction offer the patients the best chance of meaningful recovery and quality of life. The lotus petal flap and the V-Y perforator fasciocutaneous flaps have become workhorses in perineal reconstruction. The perineum is basically divided into anterior and posterior halves by a line joining the ischial tuberosities. When one half of the perineum requires reconstruction, any one of the petals of lotus petal flap would be sufficient. When both halves or the whole of the perineum require reconstruction, an extended lotus petal is selected according to the required size and volume. In general, one needs three structures to reconstruct when the whole of the perineum is resected: pelvic floor, deadspace and skin cover. The first can be reconstructed either by acellular dermal matrix or de-epithelialized skin flaps. The second needs bulky but vascularized muscle or a de-epithelialized myocutaneous or fasciocutaneous flap and the last by a skin flap.

GENITAL RECONSTRUCTION

Paige Fox, Paul Mittermiller and Gordon K. Lee

Department of Plastic and Reconstruction Surgery, Department of Surgery, Stanford University School of Medicine, Stanford University, Stanford, CA, USA

Introduction

Congenital anomalies of the genitalia result from a variety of genetic and prenatal causes. Abnormal genitalia are seen in patients with 46,XX chromosomes, 46,XY chromosomes and mixed sex chromosomes. The expressions of these chromosomal abnormalities are the results of complex biological interplay. The manifestations range broadly and can affect multiple areas of human anatomy and physiology. In males, testosterone promotes development of the epididymis, vas deferens and seminal vesicle; and Müllerian-inhibiting substance (MIS) prevents the maturation of the uterus,

cervix and upper vagina. In females, the absence of MIS allows maturation of the uterus, cervix and upper vagina. At approximately the 9th week of gestation, normal males have produced enough testosterone to allow synthesis of DHT (dihydrotestosterone). DHT then induces fusion of the genital folds and promotes growth of the genital tubercle.³⁰

A defect in any of the genes or environmental milieu that affect this developmental process can result in abnormal genitalia. Certain developmental problems, such as bladder exstrophy, can simply disrupt normally developing anatomy. Other developmental problems, specifically those disrupting gender-specific development, result in anatomy that lies on a spectrum between normal female and male external genitalia. The Prader Scale, originally described by Andrea Prader in 1954, is often used to describe this anatomy. It is a 5-level scale where 1 represents normal female external genitalia with clitoromegaly and 5 represents normal male external genitalia.³¹

The type of reconstruction required for each patient varies depending on the cause of ambiguous genitalia and the resulting appearance. The most common causes of anomalous genitalia in those patients undergoing feminization procedures are congenital adrenal hyperplasia and mixed gonadal dysgenesis.^{32,33} Gender assignment in those with anomalous genitalia is crucial, although the timing of surgery is a controversial issue. Some have suggested that the birth of ambiguous genitalia is a neonatal emergency and requires immediate intervention. Others have advocated delaying surgery until the patient can give informed consent. Most physicians, however, suggest performing surgery prior to the age of 3. Performing surgery during this earlier time increases compliance with dilations and decreases parental concern about their child's gender.³⁴ The goals in vaginal reconstruction of ambiguous genitalia include preserving fertility, adequate sexual function and eliminating the risk of malignancy in the intra-abdominal gonads.³⁴

Vaginal reconstruction

Acquired vaginal defects are commonly due to oncologic resections, although other causes include trauma and infection. Rectal adenocarcinoma is frequently cited as the most common indication for vaginal resections, accounting for approximately half of all reconstructions. Other causes include anal squamous cell cancer, cervical carcinoma, bladder or urethral transitional cell, bladder or urethral squamous cell cancer, vaginal or vulvar squamous cell cancer, endometrial adenocarcinoma and trauma.^{35,36} According to Crosby *et al.*,³⁶ the most common surgical procedures resulting in vaginal defects are abdomino-perineal resections and pelvic exenterations.

In 2002, Cordeiro and colleagues published a classification system to define full-thickness vaginal defects.³⁵ Type I defects include those involving the anterior, lateral or posterior walls of the vagina. Type IA defects involve the anterior or lateral vaginal wall, whereas type IB defects involve the posterior wall. Type II

refers to circumferential vaginal defects. Type IIA defects encompass up to two thirds of the upper portion of the vagina, whereas type IIB defects are the result of circumferential total vaginectomies. The most common vaginal defect is a Cordeiro type IB or full-thickness posterior wall defect.^{35,36}

Vaginal reconstruction has positive effects on the psyche and has been shown to improve wound healing. Placing healthy, well-vascularized tissue in a previously radiated area prevents enteroperineal fistulas and limits deadspace, thereby reducing pelvic fluid collections.³⁷

Non-surgical options

In cases of vaginal agenesis, where a dimple of vaginal mucosa is present, often non-surgical techniques are preferred to surgical creation of a neovagina.³⁸ The Frank procedure involves the use of serial vaginal dilators. Using the dilator, pressure is placed on the vaginal dimple for 30 min to 2 h per day. Over time the width and length of the dilator are increased to allow for a neovagina that is appropriately sized for sexual activity. Some discomfort is expected during dilations, but after dilations are complete, only intermittent dilation is required if sexual activity is frequent enough to maintain patency.³⁹ Edmonds *et al.*⁴⁰ document a 94.9% success rate with dilation treatment in patients with Mayer–Rokitansky–Küster–Hauser syndrome. Ingram⁴¹ described a modification of the Frank procedure in which the serial dilators are attached to a bicycle seat upon which the patient sits. The modified positioning allows for improved patient comfort during serial dilations.

Surgical options

The reconstructive surgeon must consider multiple factors when planning the surgical creation of a neovagina. The location and size of the defect is the most important factor. However, it is also valuable to consider the patient's position on the operating room table. The oncologic surgeon may have completed the procedure with the patient in the prone or supine position. This may influence the options that are available without repositioning the patient. The type of incision, particularly whether a laparotomy incision was performed, and whether the initial incision remains open or has been closed can alter the operative plan. The desired neovagina length and width should be based on the patient's postoperative goals for sexual activity. The need for a connection between the neovagina and the uterus, when present, must be considered in congenital reconstruction.

Small defects of the vagina are amenable to *primary closure* if they do not significantly alter the length or width of the vagina. For larger defects, which are superficial or partial thickness, a *skin graft* can be considered. A vaginal conformer is often used to help promote take of the skin graft, which provides compression and immobilization of the graft to the underlying wound bed. In the paediatric gynaecology literature, the preferred method for surgical creation of a neovagina in patients with vaginal agenesis is the Abbé–McIndoe procedure.³⁸ First documented in 1938, this involves creating a space between with rectum and bladder

and inserting a skin graft-lined mould to create the neovagina.⁴² This procedure requires the use of a mould or vaginal conformer for 6–12 months post operatively and dilations to maintain a vagina that can be used for sexual activity. However, case series document success with this technique.⁴³ Fussey *et al.*⁴⁴ have described the use of continuous negative pressure therapy to aid in skin graft take during vaginoplasty.

The *pedicled rectus abdominis myocutaneous flap* is the work-horse of vaginal reconstruction. Cordeiro described the use of the rectus flap for both partial posterior vaginal defects and circumferential upper two thirds defects.³⁵ The myocutaneous flap can be designed and harvested with a vertical or transverse skin paddle. The senior author prefers the VRAM flap as it is aligned with the midline incision that is most often used for a laparotomy incision and, therefore, provides the greatest length of flap and greatest reach for the vaginal and perineal defect. The flap is based upon the deep inferior epigastric artery and can be passed directly into the pelvis/vaginal defect. Authors have recently described the harvest of the flap as a perforator flap for vaginal reconstructions, noting decreased donor site morbidity.⁴⁵ However, incorporation of the rectus muscle provides additional bulk and blood supply, which can be helpful in eliminating pelvic deadspace and facilitating healing.

The *pedicled gracilis myocutaneous flap*, based on the medial femoral circumflex vessels, is another versatile option for vaginal and perineal reconstruction. The flap can be harvested with a transverse or longitudinal skin paddle. Cordeiro favoured the longitudinal skin paddle for total circumferential vaginal defects, whereas the transverse skin paddle can be used for labial reconstruction (Figure 44.13). It is important to note past reports of necrosis of the gracilis skin paddle when designed distally on the muscle down the thigh. Surgeons should note that the gracilis muscle tapers distally and becomes more tendinous, and that the blood supply of an overlying skin paddle at this level becomes less reliable. Hence, a skin paddle that incorporates the proximal major skin perforator, which enters at approximately 8–10 cm below the pubic ramus, is important for maintaining maximal perfusion.

The *puddendal thigh flap* was first published by Wee and Joseph in 1989,⁸ and is often referred to as the 'Singapore flap'. The flap is an innervated fasciocutaneous flap based off perforators from the internal pudendal artery, which travel from posterior to anterior. The skin flaps are designed over the proximal medial thigh and harvested deep to the fascia of the adductor muscles. Proponents of this flap cite the benefit of an inconspicuous donor site and more reliable blood supply than the gracilis myocutaneous flap. This technique has been used in the reconstruction of both congenital and acquired defects.⁴⁶ This flap is of limited bulk and should be considered for defects that do not require a large amount of deadspace obliteration.

Intestinal conduits, including the colon and jejunum, have also been utilized for vaginal reconstruction. This type of reconstruction is more widely documented for congenital defects. Erman Akar *et al.*⁴⁷ described their experience with vaginal reconstruction

(a)

(b)

Figure 44.13 Transverse upper gracilis (TUG) flap for total vaginal reconstruction. (a) Defect after oncologic resection and flap design. (b) Final flap inset with donor site closed.

for congenital defects (33 of 34 patients) using a free vascularized jejunal flap. At a mean follow-up of 50 months, the authors noted satisfactory vaginal depth and diameter. However, six patients noted jejunal hypersecretion post reconstruction and ten patients required two lengths of jejunum opened along its antimesenteric border in order to increase luminal diameter. In contrast, the benefit of the colon in vaginal reconstruction is its larger diameter in comparison to the jejunum. Lima *et al.*⁴⁸ reviewed their 34-year experience treating 46 cases of vaginal agenesis with sigmoid colon interposition. Although they noted no cases of excessive mucus production, eight patients had stenosis, six of who required operative intervention. Of note, 34% of the group was sexually active at a mean follow-up of 12 years. Anecdotally, some patients may report a foul odour with the use of intestinal conduits as a result of mucus secretions.

Omental flaps, which have been used to treat rectovaginal and vesicovaginal fistulas as well as to close off the pelvic inlet after

pelvic exenteration, can be modified for vaginal reconstruction. Authors have documented the use of a cylindricized omental flap based off the left gastroepiploic artery with a skin graft for neovaginal creation.⁴⁹ The minimal donor site morbidity and ease of flap harvest are among the benefits of this flap. However, like other skin graft-based reconstructions, stenting is necessary for up to six months post operatively to maintain adequate vaginal depth and to prevent strictures and stenoses.

The *ALT flap* has emerged as another option for vaginal and perineal reconstruction.^{50,51} Based on the descending branch of the lateral femoral circumflex artery, the ALT flap is a versatile flap for reconstruction. The flap can be harvested as a fasciocutaneous, an adipofascial or a musculocutaneous flap. This versatility is beneficial for reconstruction in the perineum where deadspace obliteration may be required or thinner pliable tissue may be ideal. The flap is tunnelled beneath the rectus femoris and sartorius to improve pedicle length.

Complications

The most common complication after vaginal reconstruction is delayed wound healing or dehiscence. Other more devastating complications include: flap necrosis, fistula formation and pelvic abscesses. Strictures may develop which require dilations or revision surgery. Donor site infections may also be seen, as vaginal reconstruction is not a clean procedure. It is advised to use a separate clean set of instruments for flap harvest outside of the abdominal cavity if practical. After vaginal reconstruction with a rectus abdominis myocutaneous flap or an intestinal conduit, neovagina prolapse can occur which becomes bothersome to the patient. Huffman *et al.*⁵² have published a case series of correction of rectus abdominis myocutaneous flap prolapse utilizing sacral suspension.

Penile reconstruction

Acquired penile defects may be secondary to trauma, infection or oncologic resections. Penile trauma is rather uncommon since the penis has a relatively protected position between the thighs and pubic bone, but can occur, particularly in military injuries where the trunk is often protected but the lower extremities and pelvis are not and vulnerable to explosive devices. Penile skin loss occurs from necrotizing infections, burns, constrictive bands, degloving injuries as well as dog and human bites. Avulsions are most often caused by power tool injuries or motor vehicle accidents. They have also occurred from self-inflicted causes such as insertion of the penis into vacuum cleaners or other suction devices. Penetrating penile trauma is usually secondary to stab or gunshot wounds.⁵³

The most common cause of penile carcinoma requiring major resection is squamous cell cancer. Approximately 1500 new cases are diagnosed each year in the United States, accounting for less than 1% of all malignancies in men.⁵⁴ The tumour is age-related, with a peak incidence in the fifth and sixth decades.⁵³ In addition to squamous cell carcinoma, almost all tumours that involve the skin, subcutaneous tissue and smooth muscle have been found in the penis.⁵⁵ Resection can include circumcision for foreskin lesions, Mohs micrographic surgical resections, glansctomy, wide local excision, partial penectomy and total penectomy.⁵⁶

Surgical options

Preoperatively, the surgeon should discuss with the patient his sexual history as well as his goals for reconstruction. The need for multiple procedures in order to fully restore sexual function should be discussed in detail with the patient. If the defect is self-inflicted, a psychiatric evaluation is necessary prior to reconstruction. Akin to vaginal reconstruction, the reconstructive surgeon must consider the size and location of the defect.

Subtotal reconstruction

Subtotal injuries to the penis may involve the shaft and/or glans. For injuries involving the skin only, such as those due to avulsion or infection, a skin graft is the best option

for reconstruction. A full-thickness skin graft is preferred for shaft resurfacing due to decreased contracture during the healing process. Injuries to the glans only can be reconstructed using a split-thickness skin graft or a urethral flap. A urethral flap involves dissection of the penile urethra from the corpora cavernosa. The distal end of the urethra is then spatulated and folded ventral to create a pseudoglans.⁵⁷

Total reconstruction

Total penile reconstruction may be based on the tube-within-a-tube concept to create the shaft and glans as well as the penile urethra. Gillies was among the first to describe a technique for total penile reconstruction.⁵⁸ Because of the unique anatomy of the erectile tissue of the penis, urologists recommend maintaining penile length whenever possible and then utilizing secondary procedures, such as excision of the suprapubic fat pad or division of the suspensory ligament, to increase penis length. However, if the trauma, tumour or infection is so severe that total penile reconstruction is required, local/regional flaps as well as free tissue transfer techniques are available.

Local and regional flaps available for phallus reconstruction include the pedicled rectus abdominis, groin and tensor fascia lata flaps. Recently, the ALT flap has been described for total penile reconstruction.^{59,60} The available width and length of skin and soft tissue which can be harvested and tailored as well as the favourable donor site make the ALT flap the favoured option for many reconstructive surgeons⁶¹ (Figure 44.14) A neurotomy between the lateral femoral cutaneous nerve harvested with the ALT flap and the dorsal pudendal nerve gives sensation to the neophallus. Insertion of a prosthetic stiffener can allow the patient to have an erect reconstruction.

Free tissue transfer techniques have allowed the use of the radial forearm free flap (RFFF), based on the radial artery, and the free fibula, based on the peroneal vessels, for penile reconstruction. The use of bone within the flap avoids a second stage surgery for implantation of penile prosthesis, which is required in soft tissue only reconstructions if erectile function is desired.⁶² However, this creates a permanently erect penile reconstruction, which can potentially be problematic. With regard to the RFFF, the conspicuous donor site involving the majority of the skin on the forearm can leave an unsightly scar.

As advances in transplant immunology continue and the immunosuppression needed to accept transplanted composite tissue decreases, penile transplants may be considered in the future. Transplantation would allow replacement of the unique erectile tissue of the penis and eliminate donor site morbidity. However, the current risks of immunosuppression remain too great for this to be a viable option in the near future. Psychological considerations and consequences associated with penile transplantation must also be factored.

Gender reassignment surgery

Gender reassignment surgery can be performed in patients with gender identity disorder to help alleviate gender dysphoria. Gender identity disorder is defined as the disturbance from a strong and persistent cross-gender identification and it cannot be concurrent with a physical intersex condition.⁶³ A variety of treatments exist, ranging from medical and hormonal therapy to gender reassignment surgery. Similar to gender assignment surgery for ambiguous genitalia, gender reassignment surgery

aims to create an outcome that optimizes appearance, urinary function and sexual function.

The timing of gender reassignment surgery is important for developing a lasting benefit. Studies of prepubertal children who were referred to clinics for gender dysphoria have suggested that fewer than 30% of those patients had persistence of this dysphoria into adulthood.⁶⁴ The percentage of lasting gender dysphoria increases with increasing age of initial presentation.

Upon embarking on gender reassignment, a number of steps should be taken prior to surgical reassignment. These include

social changes and reversible hormonal treatments.⁶⁴ The World Professional Association for Transgender Health recommends only carrying out genital surgery when the patient has reached a legal age to give informed consent and after the patient has lived for at least 12 continuous months in the gender role that is congruent with his or her gender identity.⁶⁴ A multidisciplinary approach with psychiatrists, endocrinologists, speech and language therapists, breast surgeons, plastic surgeons, gynaecologists or urologists is often employed.⁶⁵

Conclusion

Successful genital reconstruction requires open communication between the surgeon, the patient, and other medical personnel. The reconstructive surgeon must have a comprehensive picture of the patient's postoperative goals. In cases of tumour resection, the oncologic and reconstructive surgeons should develop a team approach. For congenital reconstructions or gender dysphoria cases, a psychologist or psychiatrist should be involved to help the patient navigate the complex and diverse psychosocial issues involved in gender assignment and reassignment. The reconstructive surgeon has a variety of options available to achieve functional and satisfying results in vaginal and penile reconstruction.

HYPOSPADIAS

Kathryn Evans and Imran Mushtaq

Department of Urology, Great Ormond Street Hospital for Children, Great Ormond Street, London, UK

Introduction

Hypospadias is the commonest congenital abnormality of the penis. It is characterized by the association of three anatomical abnormalities that are present in a variable manner:

- a proximally located urethral meatus on the ventral aspect of the penis;
- a ventral curvature of the shaft of the penis (chordee); and
- a dorsally placed hooded prepuce that is deficient and incomplete ventrally.

Hypospadias results from a deficiency of the tissues forming the ventral aspect of the penis beyond the division of the corpus spongiosum, most likely due to incomplete virilization of the genital tubercle. As a consequence, there is a ventral triangular defect with the apex located at the division of the corpus spongiosum, the sides of the triangle being formed by the two pillars of the atretic spongiosum and the base by the glans. The typical hypospadiac penis has the glans open ventrally, with an absent segment of urethra of variable length. In place of the normal tubular urethra is the urethral plate which extends from the ectopic meatus up onto the glans. The urethral plate is often hypoplastic or dysplastic, and may be partially responsible for the chordee. For this reason the fibrotic tissue that forms a part of the urethral plate is referred to as the 'chordee tissue'. The

corpus spongiosum, which would normally encircle the urethra, is either absent or displaced laterally in the region of the urethral plate. More proximal to the ectopic urethral meatus, the structures forming the ventral aspect of the penis are mostly normal.

The diagnosis of hypospadias is usually made at birth but occasionally when the child is brought for circumcision. In both instances, the parents should be advised not to have the child circumcised, as the foreskin may be required for surgical reconstruction.

Classification

Hypospadias is most commonly classified anatomically according to the position of the urethral meatus (Figure 44.15), with 70% of cases being located at the glanular, coronal and sub-coronal level. The remaining 30% are described as midshaft, penoscrotal, midscrotal and perineal. Mouriquand *et al.*⁶⁶ have proposed that a more accurate means of classification would be according to the level of division of the corpus spongiosum, as the urethra can be hypoplastic and adherent to the ventral skin distal to the division of the spongiosum.

Incidence and aetiology

Hypospadias occurs in around 1 in every 250 male births, with a degree of geographical variation. In Western countries the incidence of hypospadias has been noted to increase over the

Figure 44.15 Classification of hypospadias according to the position of the urethral meatus.

past 15 years.⁶⁷ Some of the differences in prevalence reported between countries and over time are artefacts of study methodology. However, there appears to be a genuine increase in the incidence of related abnormalities such as cryptorchidism and testicular cancer, as well as a fall in male fertility. The precise cause is unknown but likely to be multifactorial. The main aetiological factor is believed to be exposure to endocrine-disrupting chemicals. These are exogenous substances that interfere with endocrine pathways. Examples would include dietary phyto-oestrogens, pesticides (e.g. dichlorodiphenyltrichloroethane (DDT)) and other toxins that are known to disrupt reproduction. There is also genetic component as well, as the incidence is higher if there is a positive family history (1 in 100 to 1 in 80 male births). For example, brothers of affected individuals have a 6–17% chance of also being affected. In a series of 205 hypospadias patients compared to 205 controls, the risk of having another child with hypospadias was increased 17-fold. In a Swedish series of 2500 patients, 7% reported one additional family member with hypospadias.⁶⁸

Associated anomalies

Although hypospadias is mostly an isolated anomaly, 10–15% of patients have additional congenital malformations, primarily affecting the urogenital system. Some of these will have a pattern of malformations suggestive of recognizable chromosomal abnormalities, as summarized in Table 44.1. Boys with hypospadias and an undescended testis should be investigated for the possibility of an underlying disorder of sex development. Karyotyping should therefore be performed in children who have hypospadias in association with other anomalies.

Surgical principles

The main goals of surgery are to straighten the penis, to reconstruct the urethral defect, to create a slit-like meatus in a near terminal position on the glans and finally to reconstruct the penile shaft skin, either with or without circumcision. A successful surgical reconstruction should allow the individual to micturate standing up with a single straight urinary stream and to allow for sexual intercourse with straight erections. At the same time, the cosmetic result must be acceptable to the parents

and the individual. This is a formidable challenge, which is perhaps why more than 300 different operations have been described for hypospadias repair.

Correction of chordee

The first step in hypospadias surgery is the correction of chordee. This begins with fully degloving the penis all the way down to the base of the penis, and sometimes beyond the penoscrotal junction. In the majority of cases (87%) this manoeuvre alone will straighten the penis as the chordee commonly results from an abnormal attachment of the ventral skin to the penile shaft. If the chordee persists after degloving then some surgeons would advocate mobilizing the urethral plate off the ventral surface of the corpora cavernosa. This can jeopardize the blood supply to the urethral plate and is thus not a popular technique.

Most surgeons in Europe would perform a dorsal plication in the corpora cavernosa to correct the residual chordee. The two most common techniques for this are the Nesbit procedure and the Baskin modification. The Nesbit procedure was initially described in 1965 and modified in 1994. It is performed by plicating the tunica albuginea by suturing two parallel incisions with a 6-0 monofilament suture. The Baskin modification⁶⁹ is performed in the midline to avoid injury to the neurovascular bundles. The correction of the chordee can be confirmed by means of manual pressure on the bulbospongiosus, without the need for a formal artificial erection test. The potential disadvantage of a dorsal plication is that it may cause shortening of the penis. For this reason some surgeons, particularly those in North America, would favour ventral lengthening. There are essentially two ways to achieve ventral lengthening. The first involves multiple superficial transverse incisions along the corpora cavernosa and the second involves a single incision through the tunica albuginea at the point of maximal curvature and the placement a graft into the resulting defect, using dermis,⁷⁰ tunica vaginalis⁷¹ or small intestinal mucosa.⁷²

Reconstruction of the urethra

When the urethral defect is relatively short and the urethral plate is wide, the urethra can be reconstructed by simple tubularization of the lateral edges (Thiersch–Duplay technique). If the urethral plate is narrow then a midline longitudinal incision may provide further width to allow tubularization (Snodgrass technique). The other option would be to suture a pedicled rectangular flap of penile or preputial skin to the lateral edges (Onlay island flap procedure).

With a lengthier urethral defect, there are essentially two options. The first would be to perform the surgery in a staged manner, with the first stage involving placing a free or pedicled graft (inner prepuce, penile skin, postauricular skin or buccal mucosa) on the ventral aspect of the corpora and glans. Once the graft is mature (after six months) this can be used to fashion the urethra by tubularization in the second stage. This two-stage technique has gained significant popularity worldwide. The alternative would be to substitute the urethra with a tubularized

Table 44.1 Syndromic gene mutations associated with hypospadias

Gene	Disorder
<i>SF1</i>	No adrenal glands
<i>WT 1</i>	Wilms' tumour
	Denys–Drash syndrome (Wilms' tumour and renal failure)
	Frasier syndrome
<i>SOX9</i>	
<i>HOXA13</i>	Hand–foot–genital syndrome

flap of pedicized inner prepuce (Duckett procedure) or buccal mucosa. The Duckett procedure, once very popular in the 1980s, has lost favour due to high reoperation rates.

Reconstruction of the penile shaft skin

Once reconstruction of the urethra has been completed, it is customary to cover the urethroplasty with a 'waterproofing' layer which is harvested from the adjacent dartos tissue or a dorsal pedicle of dartos tissue which is brought ventrally to cover the urethra. Finally the penile skin is reconstructed with or without a circumcision.

Surgical techniques

The main challenge of hypospadias surgery is whether the desired outcome can be achieved in a single operation or will require a staged procedure. In some cases this cannot be determined until during the actual surgery.

Most surgeons focus on two or three preferred techniques and presently the Snodgrass technique or tubularized incised plate (TIP) repair is the favoured technique for distal hypospadias. For the more proximal repairs, most surgeons use a two-stage repair ('Bracka technique'). The remainder of this chapter will focus on these two most common techniques for hypospadias repair.

The surgery is ideally performed between 6 and 18 months age. If a two-stage procedure is anticipated, then the aim should be to complete both stages by the age of 2 years. This is based on emotional, cognitive and psychosexual factors as well as improved tissue healing in the younger patient. Some surgeons prefer to do the surgery around the age of 5 years due to anaesthetic limitations. Another advantage of performing surgery at an older age is that the tissues may be more robust, making the repair somewhat easier.

There is considerable debate regarding preoperative penile hormonal stimulation when the penile size is very small. It can be administered systemically as beta-human chorionic gonadotrophin (beta-HCG) or testosterone or topically in the form of dihydrotestosterone gel. There is emerging evidence, however, that their use can lead to delays in healing.⁷³

Tubularised incised plate (Snodgrass) repair

Warren Snodgrass described the technique in 1994.⁷⁴ It is versatile, easily performed, has fewer complications and results in a cosmetically acceptable slit-like meatus. Relative contraindications include proximal hypospadias, a distal hypospadias with significant chordee or a poor glans groove, which would be too narrow for tubularization.

Operative technique

Degloving the penis and chordee correction

A polypropylene traction suture is placed in the glans just beyond the anticipated dorsal lip of the neomeatus. The urethra and overlying skin are assessed with a urethral sound or the tip

of the forceps. The distal portion of the urethra may be quite thin and adherent to the skin. Usually, a circumscising skin incision is made 1–2 mm proximal to the meatus and the shaft skin is degloved to the penoscrotal junction. If the urethra is excessively thin, a U-shaped incision is made extending to more healthy tissues. At this stage the penis is assessed for any chordee and this can be corrected (as described above) (Figure 44.16).

Urethroplasty

The urethral plate is separated from the glans wings by parallel longitudinal incisions. The glans wings are mobilized laterally, taking care to avoid damage to the margins of the urethral plate. In most cases the urethral plate is not sufficiently wide at this point to tubularize into a functional urethra. Therefore a relaxing incision is made in the midline from within the meatus to the end of the urethral plate. This incision should extend through the epithelium to near the underlying corpora cavernosa. An 8Fr stent is passed into the bladder. The urethral plate is then tubularized over this stent using a fine monofilament suture. The neomeatus should be generously sized. Adjacent dartos layer is then used to cover this suture line; alternatively a dartos pedicle is developed from the dorsal shaft skin and transposed to the ventral surface. Following this the glans wings are mobilized and then closed in two layers using a fine monofilament suture.

Skin closure and dressing

The skin is then reconfigured, ensuring that there is enough skin to cover the deficiency of skin on the ventral surface. The excess dorsal skin is excised to complete the circumcision. The stent is secured in place using the traction suture and an expanding foam dressing (Cavicare®) is applied and this is then covered with Elastoplast®. This remains *in situ* for 7 days with a one week course of antibiotics and anticholinergics to prevent bladder spasms.

Outcomes

With careful patient selection, the results of the TIP repair are very favourable and reproducible. Snodgrass reported a multi-centre experience using the TIP urethroplasty.⁷⁵ The study included 148 boys operated on by six paediatric urologists. All patients had a vertically orientated and normally placed meatus. The cosmetic appearance was considered superior to that obtained by standard flap techniques, with a 7% complication rate. Five boys developed a fistula, two of these closed spontaneously, three boys developed meatal stenosis and three had a partial glans dehiscence.

Two-stage repair

The two-stage technique described by Bracka⁷⁶ is indicated when the meatus is located at the midshaft or more proximally, in the presence of severe chordee and in those with an inadequate urethral plate. This technique is also excellent for failed hypospadias repairs.⁷⁷ The main aim of the first stage is to lay the foundation for the construction of a straight, aesthetic and

Figure 44.16 (a) Placement of the glans stitch. (b) Degloving of the penis. (c) Assessment of chordee once fully degloved. (d) Glans wings are formed. (e) The urethroplasty is performed. (f) Dartos waterproofing layer is secured over the completed urethroplasty. (g) The glans wings are closed in 1 or 2 layers. (h) The excess dorsal skin is excised. (i) The excess skin is reconfigured to complete circumcision. (j) Cavicare and Elastoplast dressing are applied.

normally functioning penis in the second stage. The first stage comprises correction of the chordee, circumcision and grafting the ventrum of the penile shaft and glans.

The ideal material for the graft should be non-hair bearing, robust and supple. It should be able to be harvested without leaving a cosmetic defect. The inner preputial skin is most commonly used for the graft, as it is readily available. In its absence posterior auricular skin is a good alternative as it is relatively thin, pliable and essentially non-hair bearing. It also leaves an inconspicuous scar. Some surgeons would prefer to use buccal mucosa, as it is abundant and particularly useful when balanitis xerotica obliterans is a complication of previous repairs with skin grafts. Buccal mucosa can be harvested from the inner cheek or a combination of inner cheek and inner lip. The parotid duct located near the upper second molar should be identified and carefully preserved.

First stage operative technique

Degloving and chordee correction

The penis is fully degloved down to the penoscrotal junction following a circumscribing incision. Dorsally the dissection continues superficial to Buck's fascia and on the ventral aspect the urethral plate, Buck's fascia and the corpus spongiosum are mobilized from the corpus cavernosa and excised. The meatus moves to a more proximal position and this should be opened ventrally to ensure it is of adequate size. The glans is incised in the midline, deep enough to clearly visualize the corpora cavernosa. The dorsal limit of this incision will correspond to the dorsal margin of the future external urethral meatus. At this stage if there is still residual chordee then one of the techniques described previously can be utilized (Figure 44.17).

(g)

(h)

Figure 44.17 (a) Midshaft hypospadias suitable for a two-stage procedure. (b) Penis is fully degloved and any chordee is corrected. (c) The glans is split in the midline. (d) The penis is split in the midline to allow placement of the graft. (e) The graft is harvested from the dorsal prepuce. (f) The graft is prepared on a silicone block. (g) The graft is secured in place. (h) The vaseline gauze dressing is secured in place.

Harvesting the graft

The size of the graft needs to be adequate to fully cover the ventral defect without tension. The graft is usually harvested from the inner and/or outer aspect of the prepuce, or alternatively the posterior auricular skin or buccal mucosa. On occasions composite grafts may be required if the defect is large. The graft is tacked down to a silicone board to facilitate removal of the surplus subcutaneous fat and alveolar tissue. This process should result in a translucent membrane.

Securing and immobilizing the graft

The graft is placed onto the defect, trimmed to size and secured with fine monofilament sutures. Fenestrations may be made in the graft to allow any haematoma to escape. A few midline quilting sutures are recommended to secure the graft in place.

A roll of Vaseline gauze dressing is secured onto the graft with sutures. This will minimize shearing forces on the graft and is supplemented with a foam dressing (Cavicare) and Elastoplast. The dressing is left *in situ* with a dripping stent for 7 days.

Post op care

The dressing should be removed under general anaesthetic, at which stage the graft can be inspected. The parents should be instructed to apply an antibiotic ointment (chloramphenicol) three times daily to the graft for a period of two weeks. After a further four weeks the graft should be moisturized daily with a simple emollient cream.

Second stage operative technique

The second stage is usually performed after a minimum period of six months. The graft should be smooth, well vascularized and the glans cleft sharply delineated. A U-shaped incision on the grafted skin is marked from the ventral limit of the neourethral meatus with the lower limits skirting closely around the margin of the proximal urethral meatus (Figure 44.18). The marked ventral strip is incised and mobilized to allow tubularization of the neourethra over an 8Fr stent. A layer of adventitia should be used to cover the urethroplasty. The glans wings are mobilized and closed in one or two layers, although this may not be possible in all cases. The skin is approximated and the stent is secured using the glans traction suture. A Cavicare foam dressing is applied and secured with Elastoplast. The dressing and stent are then removed after 7 days in the outpatient setting.

Outcomes

A study on the outcome of the two-stage repair in 62 boys was published from the authors' institution.⁷⁸ Indications for a two-stage repair included proximal meatus (midshaft, penoscrotal or perineal), poor glans groove and lichen sclerosis with a median age at surgery of 27.6 months. Inner preputial skin was the graft of choice and was successful in all the patients. One patient developed a haematoma. Overall cosmetic results were

subjectively excellent. Complications included partial glans dehiscence (3 patients), residual mild curvature (3) and meatal stenosis (3).

Complications

Complications include bleeding, infection, meatal stenosis, urethrocutaneous fistula and urethral stricture.

Bleeding

The most common early complication is bleeding but it is rarely significant. Bipolar diathermy is used during the surgery for precise pinpoint cauterization. Excessive cauterization should be avoided to avoid tissue ischaemia. The risk of bleeding is minimized by using the supportive foam dressing and applying the compressive Elastoplast. Early haematoma formation can lead to infection, fistula formation and breakdown of the repair. It is rare for a patient to return to theatre for bleeding, and if required the haematoma should be evacuated, the bleeding controlled and the dressing reapplied.

Infection

Skin infections following hypospadias repair are uncommon as the patients are maintained on a 7-day course of oral antibiotics. If following dressing removal an infection is evident, the antibiotic treatment should be broadened and continued for a further 7–10 days.

Meatal stenosis

Ensuring a wide distal anastomosis while preserving good blood supply can minimize the incidence of meatal stenosis. It may result from ischaemia of the glans wings or an overzealous attempt to terminalize the urethral meatus in the setting of an inadequate glans. In such cases it may be pertinent to leave the meatus in a coronal location. The child may present with straining to void, a fine urinary stream, spraying or urinary tract infections due to incomplete emptying of the bladder. When meatal stenosis is suspected, the child should be evaluated with an assessment of the urinary flow rate and a careful external inspection. If confirmed, the patient will require a meatal calibration and meatoplasty. Meatal stenosis can occur many years following the hypospadias repair and in these delayed cases, balanitis xerotica obliterans should be suspected.

Urethrocutaneous fistula

Fistulas are the most common significant complication following hypospadias repair. A fistula may be seen at the time of dressing removal and some of these may heal spontaneously. The patient may present with a history of passing urine with two streams or dripping from the ventral surface of the penis. Usually a dimple can be seen on the ventral surface proximal to the neomeatus. It is always important to exclude a distal obstruction at the time of fistula repair.

Figure 44.18 (a) The location of the incision is marked. (b) The incision is made with a scalpel and/or monopolar diathermy. (c) Urethroplasty is performed in one or two layers. (d) Waterproofing layer is secured over the urethroplasty. (e) Skin closure.

The reported fistula rate for a single stage repair is 10–15%. This may be lower than the actual incidence as small fistulas may not become apparent until years after the procedure. Success rates for fistula repair are in the region of 90%.⁷⁹

Urethral stricture

Urethral strictures are less common with modern techniques. They may respond to urethral dilatation but more often require a two-stage redo urethroplasty.

CHAPTER 45

Pressure sores

Adam C. Gascoigne¹ and Stephen Flood²

¹Department of Anatomy and Neuroscience, University of Melbourne, Australia

²Department of Plastic and Reconstructive Surgery, Austin Health, Heidelberg, Australia

Introduction

Pressure sores – also known as pressure injuries, pressure ulcers, decubitus ulcers and bedsores – are a common problem among certain patient populations. A pressure sore comprises a 'localised injury to the skin and/or underlying tissue usually over a bony prominence, as a result of pressure, or pressure in combination with shear and/or friction'.¹ The development of a pressure sore has implications for patients and healthcare providers, increasing length of admission and requiring increased utilization of healthcare resources. Australian studies have shown that developing a pressure sore increases length of hospital stay by a median 4.31 days, resulting in AU\$285 million in additional healthcare costs.^{2,3} With an ageing population and more widespread predisposing comorbidities, the overall prevalence of pressure sores and their associated costs is likely to increase. In this setting there is great need for the development of specialist multidisciplinary teams for the care of patients with pressure sores, including reconstructive surgeons for the management of advanced, complex, or refractory pressure sores.

Epidemiology

Pressure sore incidence and prevalence are determined by the characteristics of the population studied. The normal response to an injurious stimulus, such as the prolonged application of pressure, is withdrawal from the noxious source. However, in some individuals this does not occur, either because the pain stimulus is not present, as in sensory impairment, or because of an inability to reposition the body in order to redistribute pressure. Such patients include the elderly, the acutely unwell, patients who are immobilized as a result of spinal cord injury or following surgery, and patients with sensory impairment due to diabetes or chronic neurological conditions. Other risk factors include a past history of pressure sores, obesity, smoking, and peripheral vascular disease, among others (see Box 45.1).

The prevalence of pressure sores in the general population is low. A study of the population of a county in Denmark found a prevalence of 0.04%,⁵ and an American study of elderly patients seen in general practice found a prevalence of 0.31–0.7%.⁶ However, the epidemiology of pressure sores among hospitalized patients is of greater interest, partly because hospitalization is a significant risk factor for pressure sore development, and partly because it is increasingly used as an indicator of health-care quality and safety. A number of studies have examined the epidemiology of pressure sores among hospital inpatients, resulting in prevalence ranging from 10.2 to 19.7%, and incidence from 0 to 7.3%.^{7–12} Such wide variation partly results from differences in study design. However, there are two further major difficulties that prohibit study comparison.

The first is the variable nature of the population studied. As noted above, it has long been recognized that pressure sores are more common among certain patient populations, such as the elderly, among patients with spinal cord injuries, and among patients with sensory impairment.⁵ As such, the prevalence of pressure sores in a given hospital or institution is significantly influenced by the characteristics of the patient population serviced by that facility than any difference in quality of care or pressure sore prevention strategies. As an example, a centre that specializes in the care of patients with spinal cord injuries is likely to have a much higher incidence of pressure sores than other institutions which may be identical in every other regard. The second difficulty is how the study defines a pressure sore. Though most studies now use the National Pressure Ulcer Advisory Panel/European Pressure Ulcer Advisory Panel (NPUAP/EPUAP) classification system, they may differ on whether or not the milder forms are included, such as a grade 1 pressure injury which comprises only non-blanching erythema (see below, under Assessment).

The EPUAP collected detailed data in 2001 and 2002 and found an overall prevalence of pressure sores in five European hospitals of 18.1%.¹³ However, the majority of these consisted of only a grade 1 pressure injury, with a minority (2.5% of the

Box 45.1 Risk factors for development of pressure sores⁴

- Past history of pressure sores
- Immobility (spinal cord injury, post-surgery/injury, critical illness)
- Neuropathy (spinal cord injury, diabetic neuropathy, other neurological causes)
- Abnormal posture (musculoskeletal abnormalities, spastic contractures)
- Anaemia
- Poor nutrition
- Diabetes
- Peripheral vascular disease
- Obesity
- Poor skin quality (age, endocrine disorders)
- Smoking

total) suffering the most severe, a grade 4 pressure injury. For these reasons it is important to carefully review the methodology when reviewing studies of the epidemiology of pressure sores, and they should be interpreted warily if used as indicators of healthcare quality and safety.

Pathophysiology

Pathologically, pressure sores are areas of localized tissue necrosis resulting from external forces.¹⁴ As the name suggests, external pressure is the key causative element in their pathogenesis. In experimental studies of the effect of pressure on limb vascular volume using human volunteers in the 1940s, Landis established a threshold pressure of 35 mmHg, noting that external pressures above this figure resulted in reduced vascular volumes, likely reflecting capillary occlusion.¹⁵ This process, if repeated or sustained, ultimately results in ischaemic necrosis of skin, subcutaneous tissue and deeper tissues. Further studies by Kosiak demonstrated irreversible changes in muscle of rats subjected to 70 mmHg of constant pressure for a period of 2 h or more. Such changes were also seen in rats exposed to pressure which was applied and removed at 5 min intervals, but only at much higher pressures (155 mmHg). Importantly, it was also established that denervated muscle required the same magnitude and duration of pressure in order to demonstrate signs of injury and that normal and denervated muscle had the same susceptibility to pressure injury. This was contrary to prior thinking that supposed that the absence of neurotrophic factors secreted by functional nerves was causative in pressure sore pathogenesis.¹⁶

More recent studies in an animal model have demonstrated pressure sore formation and progression resulting from repeated and sustained application of pressure, the extent of injury varying according to these two factors.¹⁷ In combination with external pressure, shear stress and the presence of moisture may contribute to the extent of injury.¹⁸ Shear stress is a mechanical force acting parallel to the plane of compressive pressure. In the

Figure 45.1 Pressure sore pathogenesis.

presence of a significant degree of shear stress, the magnitude of external pressure required to cause a pressure injury is significantly reduced.¹⁹ This is hypothesized to occur due to the deforming effect of shear stress on tissues deep to the skin resulting in direct injury through sustained deformation of cells and worsening of ischaemia by microcirculatory injury.^{20,21} Recent research has also identified reperfusion injury as an important factor in the pathogenesis of pressure sores, with greater tissue necrosis and reduction in functional capillary density following repeated compression and release of tissues by comparison with compression alone.²² The interaction of these biomechanical factors in the pathogenesis of a pressure sore is complex, and research into their relative contributions is ongoing. However, it is clear that the key pathological insult in the formation of a pressure sore is repeated compression of tissues by external pressure over a prolonged period, which may be exacerbated by contributory factors including shear forces, moisture, and reperfusion injury (Figure 45.1).

Pressure sores have been described as occurring in many locations, though the vast majority occur over bony prominences in the lower limb. The aforementioned epidemiological study by the EPUAP found the following to be the commonest sites of pressure injury of any severity, in descending order (percentages stated according to data collected in the United Kingdom): sacrum (37.5%), heel (26.2%), ischium (13.7%), elbow (10.3%), ankle (6.4%) and hip (5.8%).¹³ The reason for pressure injuries occurring most frequently over bony prominences may seem intuitively obvious; nevertheless the physiological explanation follows. Sangeorzan *et al.* compared the effects of applied external pressure to skin overlying the subcutaneous surface of the tibia with that over tibialis anterior. The researchers established that much greater external pressure was required to reduce capillary perfusion in skin overlying muscle than in skin directly overlying bone.²³ Crucial to this is the realization that the subcutaneous (interstitial) tissue pressure is of greater physiological significance than the external

pressure. The interstitial pressure resulting from a given external pressure is determined by the nature of those tissues and whether they overlie bone. Over bony prominences where there is a thinner layer of soft tissue between skin and bone, a relatively minor external pressure may result in significant, ischaemia-inducing interstitial pressure.

Prevention

Effective pressure sore prevention requires ongoing assessment of patients for risk factors, together with appropriate interventions to minimize risk to vulnerable patients. Pressure sore risk factors are common in the hospitalized population (see Epidemiology, above).

Assessment of risk

Pressure sore risk assessment should be performed for all patients on admission and repeated daily in order to identify at-risk patients and track response to interventions. A number of structured risk assessment tools have been developed to identify patients at risk of developing a pressure sore. The Norton scale was developed in 1962, from which were developed the Waterlow and Braden scales in 1985 and 1987, respectively. The latter two are in widespread use today and have been demonstrated to have a high sensitivity in predicting patients likely to develop a pressure sore.^{24,25} There is, however, no good evidence to suggest that the use of these tools results in a decreased incidence of pressure sores.²⁶ Regardless of whether or not a scale is used, assessment of patients for pressure sore risk allows identification of patients likely to benefit from prevention strategies.

Prevention strategies

Interventions for the prevention of pressure sores follow two main strategies. First, the extrinsic causes of pressure sores (see Pathophysiology, above) should be minimized. The effect of external pressure may be ameliorated using pressure redistribution techniques, such as manual repositioning and the use of appropriate lifting devices for patient transfers. There is no evidence to recommend any particular manual positioning regimen over any other.²⁷ Use of pressure-relieving support surfaces such as gel-filled overlays during surgery and air mattresses or cushions on the ward are also beneficial, though again there is nothing to suggest the superiority of any particular surface type, except over basic mattresses.²⁸ Medical-grade sheepskins are also of benefit in reducing pressure sore risk, which may be particularly relevant in the nursing home environment.²⁹ However, if achievable, early mobilization is the best strategy for external pressure reduction. Daily skin care and prompt cleaning and changing following episodes of incontinence reduces the effect of moisture and may allow the identification of early-stage pressure injuries.

Second, modifiable risk factors should be managed. The management of any medical comorbidities should be reviewed and the patient's nutritional state assessed and managed if

Box 45.2 Institute for Healthcare Improvement recommendations for pressure sore prevention

- Conduct a pressure sore admission assessment for all patients
- Reassess risk for all patients daily
- Inspect skin daily
- Manage moisture
- Optimize nutrition and hydration
- Minimize pressure

necessary. Patients should be discouraged from smoking, and obese patients should be counselled regarding the benefits of weight reduction. These strategies are summarized in the Institute for Healthcare Improvement (IHI) recommendations for pressure sore prevention (Box 45.2).

Assessment

The aims of assessment of the patient with a pressure sore are: to establish the severity of the pressure sore; to evaluate treatment options and their appropriateness and acceptability for the individual patient; and to assess risk of complications and recurrence of pressure sores.

General assessment

If the patient has a past history of pressure sores, a complete history of their prior management should be taken. An evaluation of the patient's general health status should be made, including reviewing their complete medical history, to identify comorbidities such as diabetes mellitus, peripheral vascular disease and sensory impairment, which may increase their risk of complications such as recurrence or the development of further pressure sores. In particular, diabetic control should be assessed through testing of HbA1c levels, and referral to a specialist endocrinologist considered if control is poor. Furthermore, a complete functional assessment should be completed in order to determine the patient's cognitive state and capacity for ambulation. A full nutritional assessment should be performed, including testing of serum albumin. Where there are concerns regarding the patient's mood or mental state, formal psychological assessment is recommended. The patient's social situation and support network, including the availability and appropriateness of caregivers should be examined, and the goals of care should be discussed with the patient and their family, especially in cases where overall prognosis is poor. In palliative patients, or if the patient's medical or nutritional status indicate that a poor outcome following surgery would be likely, conservative management of the pressure sore is indicated.

Wound assessment

Features of the pressure sore should be ascertained by taking a history from the patient regarding symptoms, including pain, associated features to indicate infection such as fever

Box 45.3 Pressure sore features

- Size of pressure sore
- Location of pressure sore
- Stage of pressure sore
- Presence of eschar or exudate
- Signs of local infection and collections
- Evidence of osteomyelitis

Table 45.1 Classification (International NPUAP-EPUAP Pressure Ulcer Classification System)³¹

Stage	Features
Stage I	Non-blanchable redness of intact skin. Area may also be painful, firm, soft, warmer, or cooler by comparison to adjacent tissue
Stage II	Partial-thickness skin loss involving epidermis and/or dermis presenting as a shallow open ulcer with a pink wound bed without slough/eschar. May also present as open/ruptured fluid-filled blister
Stage III	Full-thickness skin loss with subcutaneous fat visible but without exposure of deeper structures such as bone, tendon, or muscle
Stage IV	Full-thickness tissue loss with extensive tissue necrosis and exposure and/or involvement of deeper structures such as bone, tendon, or muscle. Slough or eschar may be present
Suspected deep tissue injury	Area of discoloured intact skin or blood-filled blister. Skin integrity maintained with suspected damage to deeper tissues
Unstageable	Full-thickness tissue loss in which actual depth of ulcer is obscured by slough and/or eschar in the wound bed

and localized swelling. Relevant characteristics to note are summarized in Box 45.3. The familiar four-stage grading system for pressure sores was devised by Shea in 1975.³⁰ This system was revised by the NPUAP in 2007 to include two new categories: suspected deep tissue injury and unstageable (see Table 45.1). The addition represents the recognition that pressure sores may develop from bottom to top rather than progressing through the classic four stages, resulting in rapid development of an advanced pressure sore. Comprehensive assessment and staging of the pressure sore is important in order to avoid underestimating severity and to determine what treatment may be required. This may necessitate debridement to ascertain depth of tissue loss. It is important to note that in the special situation of a pressure sore on the heel, the eschar layer is an important part of the wound-healing process and it is recommended that it not be removed.^{32,33} If osteomyelitis is suspected, appropriate imaging with scintigraphy or MRI is indicated.

Management

Multidisciplinary team

Management of the patient with a pressure sore should involve a multidisciplinary team to allow collaboration between reconstructive surgeons, rehabilitation medicine physicians, specialist wound care nurses, and members of allied health disciplines including occupational therapists, physiotherapists, dieticians and social workers if required.

Wound care

Cleansing the wound with an antiseptic solution and dressing with a non-adherent dressing (such as hydrocolloids, hydrogels, hydrofibres, foams, films, alginates and soft silicones) provide an optimum wound healing environment. There is little evidence to recommend a particular type of dressing or antiseptic over any other, though some trials have found a benefit for hydrocolloid dressings over saline gauze.^{34,35} Negative pressure wound therapy (NPWT) is frequently used in management of chronic sores including pressure sores. It has advantages in reducing frequency of dressing changes and may have a positive effect on wound healing.⁴ Constant assessment for signs of infection allows early diagnosis and treatment. Tissue obtained during debridement and any swabs taken of fluid exudate should be sent for microbiological examination to allow tailoring of antimicrobial agents to the pathogenic organism and its sensitivities.

Pain management

Patients with pressure sores frequently have numerous sources of pain. The pressure sore itself may directly cause pain, there may be chronic pain issues related to musculoskeletal abnormalities or neuropathy, and healthcare interventions may also cause pain. Wound debridement is a particular cause of breakthrough pain that may require additional short-acting analgesia. Strategies to reduce pain include regular repositioning, regular and sufficient analgesia, coordination of interventions such as dressing changes, debridement, and wound examination with analgesia administration, prescription of additional analgesia as required, use of non-adherent dressings (not gauze), and adjuvant analgesia for neuropathic pain.

Nutrition

It is important to ensure the patient with a pressure sore is adequately nourished and to give nutritional supplementation for wound healing. Enteral feeding by nasogastric tube may be necessary in patients unable to tolerate oral feeding. Mixed nutritional supplementation with protein, arginine, zinc and vitamin C has been demonstrated to be effective in some clinical trials.³⁶ Suggested daily intakes for patients with pressure sores are: energy: 30–35 kcal/kg, protein: 1.2–1.5 g/kg³⁷ as part of a high-protein supplement containing arginine, zinc and vitamin C.

Box 45.4 Initial surgical management

- Drainage of all collections
- Adequate debridement of necrotic, infected, and scarred tissue
- Excision of pseudobursa
- Removal of infected bone
- Haemostasis, drainage

Adjunctive treatments

Many experimental treatments have been trialled in the treatment of pressure sores. These include therapies such as electrical stimulation, pulsed electromagnetic field treatment, ultraviolet light C, ultrasound and hyperbaric oxygen. Currently there is little evidence to recommend their routine use in the management of pressure sores.³¹

Initial surgical management

Prior to attempting reconstruction, there are several surgical measures which may be employed to assist pressure sore healing (Box 45.4). Debridement of necrotic and infected tissue is an essential part of the care of any wound. Devitalized tissue provides a focus for infection, prevents healing by stimulating a persistent inflammatory response, and prevents wound contraction.³³ Pressure sores are commonly associated with collections of fluid surrounded by a wall of scar tissue, which are called pseudobursae. These and any other serous or infected collections should be excised or drained. Any osteomyelitic bone should be resected, though bone excision should be minimized if possible, as removal of bone results in alteration of pressure distribution patterns and the potential for development of new pressure sores in previously uninvolved areas. The wound may then either be closed if possible to do so without tension, with drain tubes left *in situ*, left open to heal by secondary intention or in preparation for a reconstructive procedure.

Reconstruction**Preoperative management**

Prior to embarking on surgical reconstruction of a defect resulting from a pressure sore, all of the above strategies should be instituted to minimize the need for surgery and to improve the chance of success of any reconstructive procedure. The physiological stress resulting from a prolonged operation such as is generally required for the reconstruction of a pressure sore would have a dire effect on any patient who is acutely unwell. As such the management of any medical conditions should be optimized and any nutritional deficiencies remedied preoperatively. Furthermore, careful patient selection is vital in order to ensure that surgical reconstruction is the appropriate course for the individual patient. Factors that may increase the risk of failure of a surgical reconstruction or recurrence of a pressure

Box 45.5 Indications and contraindications for reconstructive management of pressure sores**Indications**

- Stage 3/4 pressure sore
- Unlikely to/has not responded to more conservative management

Contraindications

- Poor overall prognosis
- Poor compliance
- Acutely unwell
- Malnourished/cachectic

sore postoperatively include any of the risk factors listed above (see Box 45.1) and poor compliance with previous treatment.

Patients in whom these risk factors are present should only be considered for reconstructive surgery if there is a clear plan in place to ameliorate or reduce the effect of the risk factor, as a poor outcome is otherwise highly likely. In addition, patients with a poor overall prognosis are generally unsuitable for reconstructive surgery for pressure sores (Box 45.5). The preoperative period is also a good time in which to educate patients and caregivers regarding the operation and strategies for prevention of further pressure sores.

Reconstructive ladder

The reconstructive ladder is a concept every plastic surgeon should be familiar with. It arranges options for surgical reconstruction in order of increasing complexity, from basic healing by secondary intention to the technically and physically demanding free vascularized tissue transfer. It is important to note that this does not necessarily mean that the simplest reconstructive option is the most appropriate for the individual patient. There are often situations where a more advanced procedure will have benefits over a simpler procedure. This is particularly true in the management of the patient with a pressure sore, in whom reconstructive options that do not provide tissue bulk, such as healing by secondary intention, primary closure and skin grafting, are likely to result in recurrence. For this reason myocutaneous or fasciocutaneous flaps are usually the treatment of choice, as they provide vascularized tissue bulk to fill dead space and allow wider distribution of pressure over bony prominences. Local or regional flaps are most commonly used, though free flaps may be a viable alternative where all other options have been exhausted. In general, procedures should be planned so as to preserve other options, as pressure sore recurrence is common and another flap may be required in future.

Reconstructive options by pressure sore site**Sacral**

The area overlying the sacrum and coccyx is very commonly affected by pressure sores, usually occurring in bedridden patients who remain in the supine position for prolonged

periods. Local myocutaneous flaps based on the gluteus maximus muscle, or fasciocutaneous flaps based on the overlying fascia, are versatile and effective methods for reconstructing these defects.^{38,39} Techniques include V-Y advancement flaps, rotation flaps and split flaps. Note that myocutaneous flaps based on the gluteus maximus muscle are not generally recommended for ambulatory patients due to the resultant functional deficit. Other techniques include the superior gluteal artery perforator flap and the transverse back flap. In particular, the perforator-sparing rotation technique allows re-rotation in patients likely to experience sore recurrence.⁴⁰

Ischial

Pressure sores overlying the ischial tuberosities are common in wheelchair-bound patients, such as patients with spinal cord injuries. Similarly techniques to those used for sacral pressure sores may be effective in the reconstruction of defects caused by ischial pressure sores, such as myocutaneous flaps based on the gluteus maximus muscle, or fasciocutaneous flaps based on inferior gluteal perforators. The posterior thigh flap (Figure 45.2) is another useful option, its advantages including a reliable blood supply, good long-term outcomes, no functional deficit, and the preservation of other options for repeat flap repair in cases of

(a)

(b)

(c)

recurrence.^{41,42} It is a fasciocutaneous flap composed of posterior thigh skin and subcutaneous tissue, based on perforators from either the first and second perforating arteries of the profunda femoris or the inferior gluteal artery.⁴³ Other options include flaps based on the hamstring muscles, such as the V-Y advancement biceps femoris myocutaneous flap, or the gracilis flap.

Trochanteric

Patients spending a prolonged period in the lateral recumbent position are at risk of developing pressure sores overlying the greater trochanter of the femur. Common options for reconstruction of these defects are flaps based on the tensor fascia lata (TFL) muscle.⁴⁴ This flap is based on a branch of the lateral circumflex femoral artery and may be composed of muscle and skin or muscle alone.⁴⁵ It may also be used for reconstruction of ischial pressure sores, and is particularly useful in situations where both trochanteric and ischial sores are present. Other options include the anterolateral thigh flap, which may provide

additional tissue bulk where the size of the TFL may be insufficient. Another option is the groin flap, based on the superficial circumflex iliac artery, which may be useful if the TFL has already been used as a local or free flap for reconstruction of pressure sores elsewhere.

Heel and lateral malleolus

Pressure sores on the posterior aspect of the heel and overlying the lateral malleolus are common in neuropathic or insensate patients. They pose a challenge to the reconstructive surgeon due to the scarcity of local tissue for coverage. Options for reconstruction of a pressure sore on the heel or elsewhere in the foot include the lateral calcaneal and medial plantar artery flaps.^{46,47} The lateral supramalleolar flap (Figure 45.3), based on a distal perforator of the peroneal artery,⁴⁸ is a rotation and/or propeller flap which provides coverage of a lateral malleolar defect, while the donor region can be safely covered with a split-thickness skin graft.⁴⁹ For recurrent or refractory pressure sores,

(a)

(b)

(c)

Figure 45.3 Lateral supramalleolar perforator flap reconstruction of a lateral malleolar pressure sore. (a) Preoperative markings. (b) Flap raised on peroneal artery perforator. (c) Flap sutured into defect, donor site closed with split-thickness skin graft.

the distally based superficial sural artery flap is a versatile option that may be rotated to cover either of the malleoli or the heel.⁵⁰

Last resort

If the above strategies fail, or if they have been used in prior reconstructions, then the situation is a difficult one. The management of a patient suffering from recurrent pressure sores is complex, and requires the involvement of all members of the multidisciplinary team to evaluate the causes of recurrence. If all potential causes of recurrence have been addressed, then further reconstruction may be considered. Further procedures should be tailored to the patient, and may require some creativity. Free flaps from distant sites, or tubed pedicle flaps from the contralateral side are options, and choice of one over another is reserved for the surgeon's clinical judgement.

Postoperative care

Excellent postoperative care and follow-up following surgical reconstruction of a pressure sore is essential if complications and a poor outcome are to be avoided. Potential complications to be vigilant for include: sepsis, wound dehiscence (superficial and deep), haematoma, seroma, partial or total flap loss, and pressure sore recurrence.^{51,52} Good operative technique with low-tension skin closure and use of drains reduce the risks of haematoma, seroma and wound dehiscence. Rates of partial or total flap loss may be reduced by attentive nursing care, and by having a low threshold for returning to theatre to revise flaps that appear to be failing. Recurrence or the development of a new pressure sore is unfortunately very common. Following reconstruction of a pressure sore, it is crucial to continue prevention strategies for pressure sores. As stated above, in patients with recurrent or refractory pressure sores, the causes for recurrence should be addressed. Pressure sores provide a focus of necrotic tissue which acts as a nidus for bacterial growth, increasing the risk of postoperative wound infection. For this reason broad-spectrum antibiotics are frequently continued for extended periods. Other potential complications following pressure sore reconstruction are corollaries of immobility. Loss of muscle and bone mass result from prolonged bed rest, and immobilization of joints may result in the development of contractures. It is also important to be aware of the risk of deep venous thrombosis and pulmonary embolism, and staff should be especially vigilant for the signs of these conditions in the postoperative period.

A general protocol followed by the senior author is for surgical sutures and drains to be left *in situ* for 2–3 weeks to minimize the risk of complications such as seroma, haematoma and wound dehiscence, all of which may compromise flap viability. Appropriate broad-spectrum antibiotics, administered orally or intravenously, should be continued for up to six weeks, with a low threshold for referral to specialist infectious diseases physicians if there is uncertainty regarding choice of agent, especially if there is suspicion of osteomyelitis or if multiresistant

organisms are present. In the absence of major bleeding, prophylactic doses of anticoagulation should be administered from the first postoperative day for prophylaxis of deep venous thrombosis and embolic events.

The strategies outlined in the prevention and general management sections above should be continued to prevent recurrence or the development of a new pressure sore, including repositioning and use of pressure-relieving support surfaces. Minimizing shear and pressure on the operative site is especially important in the postoperative period. Protection of the flap pedicle should be a priority, and intensive monitoring of flap viability using clinical examination including bedside Doppler ultrasound by resident medical staff and specialist nurses is essential.

Once the immediate postoperative period is successfully navigated, the patient is likely to require a period of rehabilitation with graduated increase in pressure on the operative site. During this period any required devices, such as wheelchairs, should be evaluated and customized for the patient.

Conclusion

Pressure sores are a common problem in the inpatient population, particularly among patients with sensory impairment or reduced mobility. The development of a pressure sore has implications for patient length of stay and increased use of healthcare resources. Through a sound knowledge of the pathophysiology of pressure sores, and using the prevention strategies outlined in this chapter, occurrence of pressure sores and their attendant costs may be reduced. The patient with a pressure sore is best managed with a multidisciplinary team approach, incorporating physicians and allied health practitioners. Their general medical condition and nutrition should be optimized and any management of modifiable risk factors reviewed. Following initial surgical debridement and treatment of any infection, further reconstructive procedures may be considered if indicated. Careful patient selection is necessary prior to embarking on any advanced reconstructive procedure to avoid a poor outcome. Ideally, a local fascio- or myocutaneous flap should be chosen to provide well-vascularized tissue bulk. Following the procedure, attentive postoperative care will reduce the risk of complications and pressure sore recurrence.

²Department of Orthopaedics, St Mary's Major Trauma Centre, Imperial College Healthcare NHS Trust, London, UK

Introduction

Open tibial fractures are severe limb-threatening injuries associated with considerable morbidity. They largely affect young men of working age and often occur as a result of motor vehicle accidents. Typically, high-energy transfer results in fragmentation and periosteal stripping at the fracture site. Recovery from these injuries is prolonged and the average time to fracture union is between 41 and 43 weeks.^{1–3} The rate of fracture non-union or delayed union following high-energy trauma is estimated to be 10–31%.^{4,5} Moreover, as the soft tissue envelope is breached, all open fractures are contaminated by microbes and susceptible to infection. Indeed, 8–13% of Gustilo IIIB fractures are complicated by deep infection, which may result in delayed amputation.⁶ A multicentre study conducted by the Lower Extremity Assessment Project group found that 8.6% of salvaged limbs were complicated by osteomyelitis and 31% developed non-union.⁵ Furthermore, between 20% and 50% of patients with open lower limb fractures were permanently disabled⁷ and almost 40% had not returned to work by 3.4 years.² One retrospective study found that despite a successful limb salvage rate of 93% in patients with open tibial fractures, only 28% returned to long-term employment, and no patient returned to work after 2 years of unemployment.⁸ Hence, these injuries place a significant health, social and economic burden on the individual and wider society.

Classification of open fractures

Injury characteristics, including the level of energy, fracture configuration, soft tissue disruption and wound contamination determine the final clinical outcome.⁹ Various classification systems of open fractures have been described. The most widely used is the Gustilo and Anderson classification,¹⁰ which is relatively simple but has poor interobserver reliability¹¹ and is best applied after wound debridement (excision) (Table 46.1). Other more comprehensive systems such as the AO classification

are more difficult to apply and tend to be used for research purposes. Extremity injury scoring systems such as the Mangled Extremity Severity Score (MESS)¹² were developed to identify patients who would benefit from primary amputation. The score is specific, but lacks sensitivity.¹³ The decision to amputate remains challenging and is best taken on detailed assessment of each patient in a multidisciplinary setting.

The combined orthoplastic approach

Trauma care pathways adopting a multidisciplinary and integrated orthoplastic approach have been shown to improve outcomes.^{14–18} Critical aspects include meticulous surgical planning and execution, microbiological management and rehabilitation tailored to the individual. Coordinated treatment carried out in a timely manner can reduce the mean union time for tibial diaphyseal fractures to 26 weeks.¹⁹

The development of major trauma centres with associated trauma networks in the USA and UK has facilitated the primary transfer of patients with these complex injuries to specialist centres. Hospitals that lack a team with requisite expertise should arrange for immediate referral to the nearest specialist centre.

Early assessment and initial management

The initial assessment and management of the vital systems follows Advanced Trauma and Life Support (ATLS) principles before attention is focused on the injured lower limb. Direct manual pressure or a tourniquet is used to control limb haemorrhage. A thorough vascular assessment is crucial to identify a devascularized limb or compartment syndrome. Absent pulses may be restored by realignment of the limb. Examination and documentation of the neurological status is essential. Although the instability of the fracture and pain often preclude assessment of movement and power, it is important to assess sensation, including in the territory of the deep peroneal nerve (web space

Table 46.1 Gustilo and Anderson classification of open fractures¹⁰

Type	Description
I	Low energy fracture with clean wound less than 1 cm
II	Wound more than 1 cm but without extensive soft tissue damage or major bone comminution
III	Open fracture with extensive soft tissue damage and high-energy fracture pattern
IIIA	Type III with adequate periosteal cover at fracture site and flap cover not required
IIIB	Type III with periosteal stripping at fracture site, flap cover required
IIIC	Type III with arterial injury requiring repair, irrespective of soft tissue injury

between the first and second digits). The wound is then examined, photographed and covered with sterile gauze moistened in saline and a semipermeable film to prevent dessication. No attempt should be made to lavage the wound as this simply ‘washes in’ the debris. The dressing should then be left undisturbed until the patient is examined in the operating room. Antibiotics are administered intravenously and tetanus prophylaxis should be given if necessary.

The neurovascular status must be reassessed after attempts at fracture reduction and splintage. Plain radiographs, showing orthogonal views of the fractured bones and including the joints above and below the fracture, should be obtained.

Antibiotic prophylaxis

Early antibiotic prophylaxis reduces infection in open fractures and should ideally be given within 3 h.²⁰ Although open fractures are contaminated during injury, the majority of deep infections are due to nosocomial organisms. Most patients are exposed to hospital organisms prior to definitive soft tissue coverage.²¹ The commonly cultured organisms from infected fractures are staphylococci (including methicillin-resistant strains), coliforms and pseudomonads.^{22,23} These findings led to the development of a two-phase antibiotic prophylaxis protocol,⁶ the first to cover bacteria encountered at the time of injury and the second for prophylaxis against hospital-acquired organisms.

Gustilo grade I open fractures should not receive antibiotics beyond 24–48 h. For more severe injuries, prophylaxis should be continued until definitive soft tissue closure or for a maximum of 72 h, depending on the timing of debridement. There is no evidence for prophylactic antibiotic use beyond definitive soft tissue closure.

Antibiotics should be tailored to the local microbiological profiles (Box 46.1). Coverage against gram-negative bacteria and *Clostridium* spp. in addition to gram-positive bacteria remains controversial and depends on the nature of the injury.²⁴ Agricultural injuries are often contaminated by staphylococci, enterococci and aerobic gram-negative bacilli,²⁵ whereas multi-drug-resistant acinetobacter has been found in military injuries.²⁶

Box 46.1 Antibiotic guidelines^a

- 1 Co-amoxiclav 1.2 g 8-hourly IV or a cephalosporin (e.g. cefuroxime) as soon as after the injury as possible and continued until debridement.
 - 2 Co-amoxiclav/cephalosporin and gentamicin 1.5 mg/kg at the time of debridement and co-amoxiclav/cephalosporin continued until definitive soft tissue closure, or for a maximum of 72 h, whichever is sooner.
 - 3 Gentamicin 1.5 mg/kg/h and either vancomycin 1 g or teicoplanin 800 mg on induction of anaesthesia.

^aPatients with penicillin allergy should receive clindamycin.

Wound debridement

Meticulous debridement of the traumatic wound is essential to prevent infection after open lower limb fractures but immediate surgical exploration is not indicated unless there is agricultural or aquatic contamination of the wound, compartment syndrome, a devascularized limb or a multiply injured patient. In the absence of these conditions, debridement should be performed as a combined orthoplastic procedure by experienced surgeons on the next scheduled operating list during normal working hours and 18 h of injury. There is a lack of evidence to support the oft-quoted ‘six hour debridement rule’.¹

The limb is initially washed with a soapy solution and a tourniquet applied but not inflated. The skin is prepared with an alcoholic chlorhexidine solution, avoiding contact with the open wound and pooling under the tourniquet.

We recommend wound extensions along accurately mapped fasciotomy lines used for compartment decompression (Figure 46.1). These extensions allow inspection of perforators for local fasciocutaneous flaps and provide access to the posterior tibial vessels. First, the subcutaneous borders of the tibia are marked. The posteromedial incision is marked 1.5 cm medial to the medial subcutaneous border of the tibia. The anterior incision is marked 2 cm lateral to the lateral subcutaneous border of the tibia. Care must be taken as a simple error can lead to inadvertent division of a perforator or an incision that is too posterior. Either would preclude the use of local fasciocutaneous flaps. To avoid undermining, the subcutaneous tissue and deep fascia are divided in the precise line of the cutaneous incision.

Once the zone of injury has been exposed by wound extensions, debridement of devitalized tissues can be undertaken while preserving local perforator vessels and neurovascular bundles. Soft tissue debridement under tourniquet control allows identification of neurovascular bundles, which may be displaced and permits accurate examination of tissues by avoiding blood-staining. The tissues are assessed systematically from superficial to deep (skin, fat, muscle, bone) and from the periphery to the centre of the wound. Non-viable skin, fat, muscle and bone are excised. Bone fragments that are not viable

Figure 46.1 Recommended incisions for fasciotomy and wound extensions. **(a)** The incisions lie either side of the tibial border. Care must be taken to avoid dividing the perforators positioned approximately 5, 10 and 15 cm from the medial malleolus. **(b)** Cross-section of the leg showing the incisions used to decompress all four compartments of the leg. Source: Nanchahal & Nayagam, 2009.¹ Reproduced with permission of BAPRAS.

and fail the 'tug' test are removed. Careful attention is paid to the medullary cavity and the soft tissues posterior to the tibia, which often harbour devitalized bone fragments.

Microbiological tissue sampling after debridement in patients with a delayed presentation or after transfer from another centre is recommended. Deep bone and muscle specimens are most relevant (3–5 samples collected with sterile instruments), ideally after antibiotics have been discontinued for 24 h. Tissue sampling in patients presenting following the primary injury has little merit as positive cultures do not predict subsequent deep infection.⁶ As mentioned above, most deep-tissue infections post fracture are due to nosocomial organisms.^{22,23}

The wound is then lavaged with saline, but high pressure must be avoided as this drives devitalized tissue and bacteria deeper into the tissues²⁷ and predisposes to non-union.²⁸ After debridement the injury is classified and the combined ortho-plastic team plans definitive reconstruction.

Degloving

Degloving injuries are caused by shearing forces, which separate the skin and subcutaneous tissues from the underlying deep fascia. Four patterns of injury are recognized:²⁹

- localized abrasion/avulsion with limited adjacent degloving;
- non-circumferential single plane degloving;
- circumferential single plane degloving; and
- multiplanar degloving.

The full extent of degloving can be difficult to assess and subcutaneous fat necrosis is often more extensive than skin necrosis. Fixed staining of the skin or subcutaneous vein thrombosis³⁰ are indicative of necrosis. The most reliable sign of adequate debridement is bleeding from the cut skin edge. Skin that has not been directly traumatized but has lost its blood supply can be used as a source of split-thickness skin graft. Circumferentially degloved skin never survives. Multiplanar degloving is particularly challenging and requires meticulous systematic excision of all non-viable muscle, with a second look usually required 24–48 h later.

Temporary wound dressings

If single-stage skeletal and soft tissue reconstruction is not undertaken, a dressing is applied until definitive surgery is performed. Negative pressure wound therapy (NPWT) has revolutionized the management of heavily exuding wounds. It provides a sealed wound environment limiting bacterial ingress and wound desiccation and simplifying nursing care. A randomized trial of NPWT in open fractures showed an overall deep infection rate of 5% for NPWT compared to 28% for gauze alone.³¹ Simple gauze dressings fail to control the wound exudate and allow rapid microbial colonization. Soaking the gauze in anti-septic solutions, such as povidone iodine, does not offer any benefit as the latter is rapidly inactivated by serum.³²

Although antibiotic cement bead pouches have been shown to reduce deep infection rates compared to systemic antibiotics alone,^{33–36} the use of antibiotic pouches, even for segmental bone defects, has been superseded by NPWT. A combination of antibiotic cement with NPWT can be used without adversely affecting local antibiotic levels. An experimental study of antibiotic beads with or without NPWT found comparable levels of antibiotics in the periosteal tissues and the drain fluid in both groups.³⁷ The choice of wound filler and interface material is based on the wound characteristics. Gauze is useful for complex three-dimensional cavities, whereas relatively simple wounds can be managed using foam. An interface dressing reduces ingrowth of granulation tissue into the filler and facilitates dressing change. Repeated dressing changes should be avoided to reduce the risk of further bacterial contamination.

Surgeons must be aware of the limitations of NPWT in open fracture care. NPWT does not maintain a sterile environment. A retrospective comparison of NPWT with gauze found the total bacterial load was comparable between the groups. NPWT was associated with a decrease in pseudomonads accompanied by an increase in *Staphylococcus aureus*.³⁸ Experimental studies have also found a decrease in *Pseudomonas* with NPWT but no change in the *Staphylococcus aureus*.³⁹

The importance of NPWT as a temporary dressing is emphasized by the findings of deep infection rates of 0.3–12% in Gustilo IIIB fractures if NPWT was applied for less than 7 days compared to 31–57% with NPWT beyond 7 days.^{40,41} Another study reported deep infection rates of 4% with NPWT for 3 days or less compared to 21% if applied for longer than 7 days.⁴²

We do not advocate extended NPWT in order to reduce the need for flaps by encouraging the development of granulation tissue, which can be skin grafted.^{40,43–45} Careful analysis of papers supporting extended NPWT reveals high infection and non-union rates together with increased amputation rates.

Principles of skeletal fixation

Prompt reduction and stabilization of open fractures reduces further soft tissue injury by minimizing motion at the fracture site and by relieving pressure on the soft tissues from fracture fragments. Restoration of limb alignment also improves blood and lymph flow at the injured area. Fixation aids deadspace management by restoring soft tissue tension and provides a stable platform for subsequent soft tissue reconstruction. Effective fracture stability also decreases pain, enables patient mobilization and facilitates subsequent investigations (e.g. angiography).

The method of fixation remains controversial. Systematic reviews of open fracture fixation have been undermined by the inclusion of historical data relating to obsolete, unstable fixation systems which have biased the conclusions.⁴⁶ The choice of skeletal stabilization is largely determined by the injury characteristics, with internal fixation used for less severe injuries and external fixation for more complex fractures.

Planning fixation

Plastic surgeons must be intimately involved in the fixation planning process because of the potential impact of the fixation on both soft tissue reconstruction and the final outcome. Poor external fixation design may impede access, leading to early fixation revision. Early internal fixation in the presence of complex soft tissue defects, requiring staged reconstruction, may result in exposed metal work. This is a risk for biofilm formation and later deep infection.⁴⁷

Temporary external fixation

Temporary or bridging external fixation (BEF) is a powerful and flexible method for the initial stabilization of severe limb injuries and should be considered in the following situations: extensive soft tissue injury, significant bone loss, wound contamination, metaphyseal fractures and for rapid stabilization of severe injuries in a physiologically unstable patient. If there is doubt regarding tissue viability at the end of the initial debridement, a BEF frame should be applied until conditions become favourable for definitive fixation.

Careful half pin insertion and optimum frame design are the keys to successful BEF. The number and configuration of the half pins and the width and the number of connecting longitudinal bars determine frame stability.

We recommend marking all definitive reconstruction incisions and access zones on the limb before pin placement. Half pins are ideally located outside the zone of injury and within safe corridors whenever possible.⁴⁸ Pin insertion involves pre-drilling with water-cooled drills and tissue-friendly techniques. Modern external fixation pin clamps are flexible and half pins do not need to be precisely aligned to reduce the fracture. A minimum of two anterior half pins per limb segment with maximum pin spread is recommended. A simple four-pin

unilateral fixator along the anterior border of the tibia will resist anterior and posterior forces. An additional 2–4 pins placed at an angle to the anterior pins and connected by short rods will significantly increase stability (delta configuration) but may hamper access for soft tissue reconstruction. Fracture reduction is achieved by manipulation before tightening the clamps and bone-on-bone contact should be obtained whenever possible to increase the stability of the final construct.

Joint spanning is indicated in proximal and distal tibial fractures. A simple anterior BEF utilizing two half pins in the distal femur and two half pins in the shaft of the tibia can be used to maintain stability across the knee joint and the proximal tibial fractures. A triangular-type construct can be used for stabilizing distal tibial fractures (Figure 46.2a). Smaller half pins can be placed into the metatarsal or tarsal bones and connected to the tibial half pins by appropriately positioned bars and clamps. The addition of an elevation frame to a distal tibial external fixator ensures limb elevation and limits shear forces and direct pressure on fragile soft tissues⁴⁹ (Figure 46.2b).

Careful insertion techniques and adequate frame stability will limit pin site infection and loosening, which are potential problems with all external fixation. A recent Cochrane review did not reach any definitive recommendations regarding pin site care.⁵⁰ Pins placed through a muscular compartment such as the anterior compartment are at risk of pin site infection, because of the adjacent mobile soft tissues. We recommend rolling gauze soaked in alcoholic chlorhexidine around the pin between the bar and the skin to produce gentle axial compression on the local soft tissue.

Conversion of BEF to internal fixation can be considered provided it is within 72 h of the index procedure, the pin sites are clean and definitive soft tissue cover will be accomplished immediately after fixation. Studies have shown that the longer

(b)

Figure 46.3 A 38-year-old female patient with an isolated open mid-shaft tibial fracture, suitable for single-stage reconstruction ('fix and flap'). (a) Small, well-circumscribed medial soft tissue defect with minimal degloving. (b) The initial plain radiograph shows a non-comminuted tibial shaft fracture suitable for intramedullary nail stabilization. (c) The wound was debrided and a distally based fasciocutaneous flap marked on limb before a nail was inserted via a suprapatellar approach while the patient remained supine (d). The distally based fasciocutaneous flap was raised based on the perforator located 15 cm from the tip of the medial malleolus (e) and inset. The donor site was covered with a meshed split-thickness skin graft (f). The plain radiograph at three months confirms fracture union (g).

the external fixator is in place, the greater the risk of infection after intramedullary nailing (IMN) because of contamination of the medullary canal by external fixator pins.⁵¹ Overdrilling and lavage of all pin sites immediately before internal fixation may minimize subsequent infection. The presence of frankly infected pin sites precludes internal fixation.

Internal fixation

Definitive internal fixation and soft tissue cover may be considered at the index procedure ('fix and flap') only if the injury characteristics are favourable (Figure 46.3). Meticulous aseptic techniques similar to those used during joint replacement are paramount in order to minimize infection risk. Surgeons should

(e)

(f)

Figure 46.3 (Continued)

de-gown and re-prepare the injured limb after completing debridement and the internal fixation instrumentation and implants are only opened immediately prior to their use.

Metaphyseal fractures with intra-articular extensions may be stabilized with plates utilizing biological fixation methods, which avoid further soft tissue damage by stripping. Alternatively, circular external fixation (CEF) can be considered for metaphyseal and periarticular open fractures.

IMN is ideally suited for open shaft fractures with minimal contamination and predictable soft tissue defects.⁵² We

(g)

advocate the recently described supratibial approach for IMN of open tibial shaft fractures, which offers a number of advantages⁵³ (Figure 46.3). The patient can remain in the supine position throughout the surgical procedures and repositioning is minimized. The injured limb is securely held in a reduced and aligned position by an assistant throughout the nailing procedure allowing local flaps to be mobilized prior to fracture stabilization and held with holding sutures. The flap can then be inset at the end of the IMN procedure.

Definitive external fixation

Definitive external fixation principally involves either a monotube unilateral fixator or CEF and both are used in open fractures with satisfactory outcomes.^{19,54} The main advantages of definitive external fixation are the ability to modulate the fracture site and a reduced risk of fracture infection.

Unlike the smaller unilateral fixators used for BEF, *monotube unilateral fixators* (Orthofix®-type) have a large-diameter connecting body, which increases the rigidity of the fixator.⁵⁵

These devices attach to bone by clusters of half pins at each end of the monotube body, which limits the flexibility of pin placement but avoids the problems of soft tissue transfixation caused by wires. Monotube fixators are suitable for mid-shaft fractures and can also be used in cases with bone loss.

Circular external fixators are extremely versatile and can be used to stabilize both mid-shaft and metaphyseal fractures (Figures 46.4, 46.5 and 46.6). The frame design can be customized to the specific injury characteristics and easily modified to

Figure 46.4 Acute shortening of distal tibial fracture in an 84-year-old female. allow soft tissue access. CEF systems comprise varying sized rings or half rings connected by longitudinal rods to form a cylinder and fixed to the skeleton by half pins (in the shaft) and tensioned smooth wires (in the metaphysis). Wires with

spherical swellings ('olives') can be used to increase the construct stability or for fixation of periarticular fragments. CEF can be used to correct limb deformity or fracture reduction in an outpatient setting. Stable CEF allows full joint and patient

mobilization with early active weight bearing. The rings also offer protection for skin grafts during maturation.

Recent modifications of CEF include the hexapod fixator such as the Taylor Spatial Frame™ (Smith and Nephew Richards, Memphis, TN, USA), which has the advantages of ease of application and very accurate, computer-driven fracture reduction. The hexapod frames have simplified many of the demanding techniques associated with standard Ilizarov circular frames and they can be easily mounted on the half pins of the initial BEF at the time of the definitive fixation. In order to minimize the number of operations, we recommend application of an incomplete but stable CEF frame at the time of the initial debridement, which allows access for soft tissue reconstruction. The definitive CEF is then completed at the end of the soft tissue coverage.

Bone loss

The management of bone loss depends on the size and site of the defect. Partial posterior defects may spontaneously heal because of the local vascularized muscle bed. Anteriorly based partial defects or complete defects under 2.5 cm will require open

grafting at six weeks. Exchange nailing is a useful technique for healing of small defects around a nail, which involves removing the original nail, reaming the canal and inserting a larger nail. Alternatively, the fracture site can be manipulated by an external fixator to encourage healing (compression–distraction).

The management of larger bone defects remains controversial. Non-vascularized options include the Masquelet technique. The original bone defect is plugged with a bone cement spacer, which facilitates the formation of an induction membrane. The cement plug is removed at around six weeks and bone graft is packed into the membrane.

Disadvantages of bone grafting large defects include a lack of available autograft, pain from the donor sites and inconsistent bone formation. We favour a combined orthoplastic approach to bone grafting beneath a flap. The patient is placed in the lateral position to facilitate a simultaneous approach to the posterior iliac spine to harvest bone graft while the flap is being raised.

Vascularized options for large defects include free fibular flaps. However, free fibular flaps are technically demanding and associated with problems including mismatch with the tibial fracture ends, prolonged partial weight bearing and late fracture

of the fibular flap. The use of a free fibular flap in the presence of a large soft tissue defect poses additional challenges.

We prefer the Ilizarov method for the management of major bone defects.¹⁹ A low-energy fracture (corticotomy) is created in the metaphyseal bone adjacent to the fracture gap and the fracture surfaces are slowly distracted after a latency period of around a week. Reliable bone can be produced by this method (distraction osteogenesis). Bone transport describes the method whereby the moving segment is brought down to close the gap created by the original defect until the bone ends meet or dock. Additional surgery may be required to bring about union at the docking site. Alternatively, the gap at the original bone defect can be closed either acutely or gradually by shortening and limb length is gradually restored by distraction at the corticotomy site.

Acute shortening of 2–3 cm is particularly useful for open fractures with transverse soft tissue defects in elderly patients and may preclude the need for additional complex plastic surgery and hasten healing times (Figure 46.4). A shoe raise easily compensates for the resultant shortening.

The Ilizarov method is not without complications, and pin site problems and impaired rehabilitation due to pain are common. Bone formation may be delayed resulting in prolonged frame times. Later problems include analgesic addiction and fracture or deformity of the regenerate bone.

Soft tissue reconstruction

Timing

Early definitive soft tissue coverage of open fractures is associated with reduced free flap failure and deep infection rates.⁵⁶ Delays due to patient preparation, including investigations such as angiography need to be balanced against technical demands as the perivascular soft tissues become increasingly oedematous, friable and fibrotic with time. Current guidelines advocate definitive coverage ideally within 72 h^{1,42} and no later than 7 days after the injury.^{40,41}

Type of soft tissue coverage

The surgeon must consider the size and location of the defect, availability of flaps and donor site morbidity when planning soft tissue coverage. In addition, there is increasing evidence to support the potential biological role that soft tissue flaps may play in the fracture repair process.

Local flaps

In general, local flaps are best suited for small defects with a limited zone of injury. The flap chosen should lie outside the zone of injury to prevent complications such as partial or complete necrosis.

Local muscle flaps

There are limited local muscles available for coverage. The medial or lateral heads of the gastrocnemius provide versatile coverage around the knee but do not reach as far proximally as

the proximal pole of the patella (Figure 46.5). The dominant proximal blood supply with a relatively clear separation between the two heads allows for easy dissection and means that the flap is extremely robust and reliable. It is most easily harvested through a posterior paramedian incision, taking care not to inadvertently divide the sural nerve. The muscle can be mobilized proximally as far as its origin but we would recommend not detaching the origin to avoid undue tension on the pedicle. The flap is then usually tunnelled to cover anterior defects and it is important to ensure that the tunnel is sufficiently capacious to allow for postoperative muscle swelling. Harvesting a small cuff of the Achilles tendon insertion facilitates inset of the flap by avoiding cut out of sutures through the muscle fibres. Coverage of the muscle with split-thickness skin graft completes the procedure. Harvest of a single head of the gastrocnemius is associated with very little functional loss and the contour of the reconstructed site improves as the muscle atrophies through disuse.

A tibialis anterior muscle turnover flap can cover long narrow defects over the tibial crest. The anatomical arrangement of the muscle is unusual in that the blood supply splits around a central tendon, which permits unfolding of the muscle like opening a book. This flap has limited application as it only covers defects up to about a centimeter wide.

The soleus muscle flap has been advocated for coverage of middle third tibial defects. Unlike the gastrocnemius, the soleus muscle has proximal and distal pedicles as well as multiple nutrient vessels entering the muscle along its length. Mobilization of the muscle by necessity involves division of the proximal or distal primary pedicle as well as some of the secondary vessels. Together with the fact that the muscle lies close to the posterior aspect of the tibia and hence is injured when the bone fractures are driven backwards, it is in the authors' view a precarious flap prone to partial or complete loss. Furthermore, the rich venous plexus within the muscle makes it an important pump for venous return.

Local fasciocutaneous flaps

An appreciation of the lower limb angiosomes⁵⁷ combined with accurate mapping of perforating vessels⁵⁸ has enabled the reliable use of local fasciocutaneous flaps. On the medial aspect of the tibia just distal to the knee are multiple perforators, including those traversing the muscle and via intermuscular septae. Proximally based flaps extending as far distally as the perforator usually situated 15 cm from the tip of the medial malleolus can be reliably raised on these perforating vessels. The reliability of the flap is enhanced by inclusion of the saphenous vein and the accompanying artery, which runs approximately 1 cm anterior to the vein. The anterior border of the flap runs 1.5 cm posterior and medial to the medial subcutaneous border of the tibia, coinciding with the medial fasciotomy incision. The posterior margin can extend to the posterior midline, taking care to avoid inadvertent injury to the sural nerve. The deep fascia is included within the flap, thereby protecting the delicate vascular plexus

that lies just superficial to the fascia. It is essential to preserve the filmy vascularized tissue overlying the proximal part of the tendoachilles to ensure an adequately vascularized bed for the split skin graft used to reconstruct the flap donor site.

Distally based fasciocutaneous flaps are based on relatively constant septocutaneous perforators that arise from the posterior tibial artery and venae comitans 5, 10 and 15 cm from the tip of the medial malleolus (see Figure 46.3e). The anterior border of the flap is based on the medial fasciotomy incision, 1.5 cm behind the medial subcutaneous border of the tibia. The integrity of the perforator must be confirmed before raising the flap and the flap is planned in reverse, ensuring that the flap territory lies outside the zone of injury. By definition, extensive degloving precludes the use of these local flaps due to avulsion of the perforators. The 10 or 15 cm perforator is usually dominant and inspection of each allows planning to ensure flap survival. The 5 cm perforator is almost never adequate as the basis of a flap. It is important to either exclude the long saphenous vein from the anterior border of the flap or, if this is not possible, to ligate the vein at the base of the flap to prevent venous congestion of the flap as the venae comitans of the perforator struggle to cope with the venous drainage from the medial side of the foot. Again the deep fascia is included in the flap to protect the delicate pre-fascial vascular plexus. Islanding of the flaps allows turning through a greater angle and a neater inset. However, in a series of 61 patients with open fractures treated with islanded distally based flaps, there was a 20% complication rate in patients with Gustilo IIIB injuries and an overall flap failure rate of 7.6%.⁵⁹ It is our preference not to island the distally based flaps and to allow the 'dog-ear' to settle spontaneously over a few months.

Although fasciocutaneous flaps provide coverage of 'like with like' and harvest does not result in any functional deficit,⁶⁰ the donor defect can be aesthetically unsatisfactory.⁶¹ In our practice, local fasciocutaneous flaps are most commonly used in male patients with small, localized defects who undergo simultaneous definitive skeletal fixation and flap reconstruction.

The sural artery flap, based on the sural artery and venae comitans that run with the sural nerve has recently gained popularity. However, we do not recommend this flap in patients with open tibial fractures. The supplying perforator arises from the peroneal artery, which is often injured when the fibula fractures. Although the flap has been shown to be useful for chronic disorders, a review of 70 flaps⁶² found that up to 36% developed necrosis, particularly in the presence of comorbidities such as diabetes, venous insufficiency and peripheral arterial disease. This is the subgroup that is erroneously considered by some surgeons to be unsuitable for free flaps. Careful optimization of the patient and techniques⁶³ can result in free flap success rates in open fracture equal to those for elective reconstructive surgery.

Free flaps

Free tissue transfer has revolutionized the management of open fractures. Almost any defect can now be reconstructed with a variety of tissues, including fasciocutaneous, muscle,

bone and chimeric flaps. Donor site morbidity as well as defect size and configuration influence flap selection. For example, the rectus abdominus muscle has now fallen out of favour because of the subsequent anterior abdominal wall weakness. In addition, the biological contribution of the constituent tissues should also be taken into consideration during flap selection.

Muscle flaps easily fill complex defects and in our practice the latissimus dorsi is used for covering large areas, whereas the gracilis, with minimal donor site morbidity, is ideally suited to small defects. Although the muscle flap is bulky initially due to oedema, this can be controlled with a pressure garment once the overlying skin graft is stable and any external fixator has been removed. The denervated muscle soon atrophies and does not require thinning. The disadvantage of muscle flaps is that the overlying skin graft may be susceptible to minor trauma and the flap can be difficult to raise and re-inset if bone grafting is required for non-unions.

The anterolateral thigh flap is the commonest fasciocutaneous free flap for open tibial coverage (Figure 46.6).^{64,65} The pedicle is long (8–16 cm × 2 mm) and use of the contralateral thigh allows a two-team approach and the recipient vessels of the injured limb can be dissected under tourniquet control. Very large flaps can be harvested by including multiple perforators and a segment of vastus lateralis can be included in chimeric flaps (Figure 46.6d). Although the bulkiness of the flap is a disadvantage in obese individuals, this can be subsequently addressed by liposuction.⁶⁶ We prefer secondary liposuction as edge necrosis may result from primary thinning of large flaps.

When choosing the recipient vessels for anastomoses, it is important to select an area outside the zone of injury. Our preference is to site the anastomoses proximal to the defect. Recipient vessels, in particular the venae comitans, can be injured at the level of the fracture and intimal injuries may not be apparent on inspection of the external wall. The posterior tibial vessels are less likely to have been injured during the initial trauma and are more reliable.⁶⁷ The anterior tibial vessels run deep just proximal to the ankle joint and the venae comitans can be of small calibre. The posterior tibial vessels are easily identified distally as they lie just deep to the fascia covering the flexor hallucis longus. Proximally the vessels lie deep to soleus. The artery is always anastomosed end-to-side to preserve distal vascular supply. A single vessel leg is not a contraindication to it being used as a recipient. We also favour use of the venae comitans as the recipient veins as they are more reliable than the superficial veins.⁶⁸ There is often a size mismatch but this is not a problem when using end-to-side anastomoses. Proximally in the leg, frequent branching, multiple valves and deeply situated vessels add to the challenges of the venous anastomoses. There is no evidence to suggest that utilizing only one donor vein increases the flow across the anastomosis and we also do not believe there is any merit in using a combination of a deep and superficial vein as recipients.

Although deep vein thrombosis can result in late loss of the flap, the risk is best mitigated by the use of low molecular weight heparin and encouraging early ankle motion to activate the calf pump.

Choice of muscle versus fasciocutaneous flaps

There is no clinical evidence to support the use of one form of soft tissue cover over another for open tibial shaft fractures. Published evidence consists almost entirely of descriptive, retrospective, observational case series (level IV evidence) with major discrepancies in outcome measures, which precludes a meaningful meta-analysis of these data. However, there is increasing experimental evidence which clearly shows that muscle coverage of shaft fractures leads to superior fracture healing compared to fasciocutaneous tissue.^{69–71} Muscle in direct apposition with diaphyseal fractures may aid healing by supplying important mesenchymal stem cells, which can undergo osteogenic differentiation into bone-forming osteoblasts.

In order to combine the benefits of a fasciocutaneous flap with the healing potential of vascularized muscle, we advocate the use of a free anterolateral thigh flap that includes a segment of vastus lateralis⁷² (Figure 46.6d). The plasticity of muscle also helps to obliterate the dead space, thereby reducing potential complications associated with haematoma formation.⁷³

From the available data and our own experience, we suggest that fasciocutaneous flaps may be superior to muscle for coverage of rapidly uniting metaphyseal fractures, particularly around the ankle, thereby avoiding skin grafts, which might be susceptible to minor trauma.

Compartment syndrome

Compartment syndrome develops when the pressure in the unyielding osseofascial compartments rises to reduce capillary flow to the point where nerve and muscle viability is impaired. Patients with open fractures can develop compartment syndrome. The first clinical sign is impaired function of the nerves traversing the compartment, leading to paraesthesia, followed by severe pain out of proportion to the injury and aggravated by passive muscle stretch.⁷⁴ Impaired pulses and reduced cutaneous capillary refill are late features, by which stage permanent nerve and muscle damage have already occurred. Pain can be obscured in patients with regional nerve blocks and particular vigilance is required in patients with impaired consciousness and in children. Measurement of compartment pressure using dedicated devices may be helpful, particularly serial measurements. A difference of 30 mmHg or less between the diastolic blood pressure and the compartment pressure may be used as a threshold for surgical decompression, but this results in unnecessary surgery in a number of patients. Increased specificity may be achieved by combining pressure with clinical findings but at the expense of much reduced sensitivity.⁷⁵ Discretion is the better part of valour and ultimately the diagnosis of

compartment is a clinical judgement and any suspected case should have urgent fasciotomies irrespective of measured compartment pressures.

Surgical decompression of the compartments is a surgical emergency as irreversible muscle necrosis may occur within 3–4 h. Decompression is best performed using the two incision technique (see Figure 46.1).¹ The cutaneous incisions are identical to those for wound extension: 1.5 cm medial to the medial subcutaneous border of the tibia and 2 cm lateral to the lateral subcutaneous border. The fascia is divided in line with the skin incision, avoiding any undermining. The deep posterior compartment is decompressed proximally by removing the origin of soleus from the tibia and distally by dividing the deep fascia over the flexor hallucis longus, taking care not to inadvertently injure the posterior tibial neurovascular bundle. The lateral incision decompresses the anterior tibial compartment. The dissection proceeds laterally in the subfascial plane until the vertical septum separating the anterior and peroneal compartments is encountered and divided. Care should be taken not to expose the peroneal tendons or injure the superficial peroneal nerve. Decompression must be accompanied by debridement of necrotic muscle. If extensive necrosis is encountered, a second look 24–48 h later is indicated. NPWT is then applied to the wounds.

The management of late diagnosis of compartment syndrome is controversial. Decompression may necessitate the excision of all non-viable muscle to avoid infection and subsequent free flap reconstruction may be necessary. Alternatively, closed treatment may be utilized ensuring adequate patient hydration, renal perfusion and functional joint splintage. The affected muscle will fibrose and the patient may have a reasonable outcome, depending on the function of the nerves traversing the affected compartment.

Vascular injuries

Vascular injuries are uncommon but potentially devastating. Prompt recognition is vital and requires a high index of suspicion. A compromised circulation results in irreversible muscle and nerve injury within 3–4 h.⁷⁶ Not all devascularized limbs should be reconstructed. Delayed reperfusion of ischaemic tissue results in systemic reperfusion syndrome, including renal failure and death. Furthermore, protracted attempts at limb salvage can adversely affect the patient.⁷⁷ Amputation should be considered and discussed preoperatively whenever possible. An algorithm for managing lower limb fractures with ischaemic vascular injuries has been formulated based on a meta-analysis of published series.⁷⁶

The pattern of injury is usually predicted by the fracture configuration. Common fracture patterns leading to an avascular limb include displaced femoral fractures, often with an associated butterfly fragment, fracture dislocations of the knee, proximal third tibial fractures and fracture dislocations of the

ankle.¹ Fracture reduction in the emergency department may improve blood flow, particularly in the case of ankle dislocations. Presence of capillary return in the toes can be misleading as blood pooling can give the same appearance. Palpation or Doppler ultrasound of the dorsalis pedis and posterior tibial arteries is preferable. Departmental preoperative angiography is contraindicated as it will delay revascularization.⁷⁶

If angiography is required, it can be performed in the operating theatre by locating the femoral artery via a groin incision, and directly injecting contrast medium while applying pressure proximally. If the patient is undergoing a CT scan for multitrauma, a CT angiogram of the injured limb may be performed at the same time. The suspected site of vascular injury should be explored and vascular shunts (e.g. Javid or Pruitt) inserted to restore the arterial supply. For injuries at the level of the popliteal vessels or more proximally, the vein is also shunted. The anaesthetist must be informed prior to reperfusion because the return to the systemic circulation of the metabolic products from the ischaemic limb may compromise systemic parameters such as blood pressure. Restoration of distal flow by shunting enables an assessment of tissue viability. If the limb is deemed salvageable, a bridging external fixator is then used to stabilize the skeleton. Finally, approximately 2 h after insertion of the shunts, definitive vascular repair can be performed. Our preference is for forearm cephalic or basilic vein grafts, which lie outside the zone of injury, are easily harvested and tend to adapt their calibre to accommodate the flow.

It is important to assess the patient for compartment syndrome by frequent serial pressure measurements in all four compartments. Unnecessary fasciotomies should be avoided to reduce bleeding as the patient often has a coagulopathy. If free flap reconstruction is indicated, the vein grafts can be used as recipient vessels if necessary.

Amputation

The surgeon's desire for reconstruction coupled with the patient's wish for limb salvage has to be balanced by the excellent functional outcomes of successful transtibial amputation. Published outcomes of salvage or amputation for severely injured limbs are similar^{78–80} but successful transtibial amputees enjoy shorter inpatient stays, fewer surgeries and a faster return to unaided ambulation. Early decision making is key and multiple unsuccessful attempts at limb salvage leading to delayed amputation must be avoided.

Absolute indications for immediate amputation include incomplete traumatic amputation, a devascularized limb with a warm ischaemia time in excess of 4–6 h, a severely crushed foot and severe open limb trauma in an unstable polytraumatized patient. Common scenarios where amputation may be preferred to reconstruction include loss of two or more muscle compartments in the leg, especially the posterior compartment and extensive bone loss involving one third or more of the tibia.

Combined open tibial and severe foot trauma may be best served by an early amputation. Suspected tibial nerve injuries must be explored and transected or avulsed neural injuries should be considered in the context of associated tissue trauma. It is not sufficient to rely on clinical assessment of absent or impaired plantar sensation.⁸¹

Despite recent advances, the decision to amputate remains difficult and scoring systems have not proven useful.⁸² We advocate a staged multidisciplinary approach to decision making in difficult cases. The zone of injury is assessed and photographed at the initial debridement. The patient and relatives are counselled and introduced to amputees and limb salvage patients before an informed decision is reached within 4–5 days. Delay beyond 5 days is associated with a rapid increase in deep infection rates.⁸³

Amputation surgery

The aim of surgery is the creation of an ideal residual limb with a cylindrical shape, a functioning myodesis, no end neuroma and sensate skin throughout. A functioning knee joint must be preserved whenever possible. Transtibial amputation results in 10–30%^{84–86} increase in ambulation energy expenditure with a prosthesis compared to 40–70%⁸⁵ for transfemoral amputation.

Through-knee amputations are occasionally preferred to transfemoral because of significantly improved limb fitting characteristics and faster mobilization.⁸⁷ However, the patient must be advised that the knee joint will be at a different level to the contralateral limb. We advocate early involvement of the limb fitting team who can provide valuable advice, particularly in complex bilateral limb trauma cases.

Amputation surgery in the presence of a wide zone of injury is challenging (Figure 46.7). Skin flaps can be difficult to plan at the outset so we use a fillet technique whereby all the soft tissues are initially preserved by making an incision along the pretibial border. The residual tibia should be approximately 15 cm long and ideally not less than 10 cm. The fibula is cut shorter, preserving the proximal tibiofemoral joint. The cut vessels are ligated but the perforators to the skin envelope are maintained as far as possible. Nerves should be cut short after infiltration of the epineurium with bupivacaine and allowed to retract into the muscles. Regional anaesthesia may reduce the incidence of phantom pain. Available calf muscles are used to achieve an end myodesis via drill holes through a well-rounded bone end. An adductor myodesis is essential to prevent a transfemoral limb drifting into valgus. The available skin is then fashioned to achieve tension-free closure using as much normal skin as possible and avoiding end-bearing wounds and skin grafts. Occasionally, special techniques such as the fillet of foot flap may be necessary.⁸⁸

Infection

A severe open tibial fracture has all the ingredients for infection: a contaminated wound and devitalized tissue, ideal for bacterial proliferation; subsequent exposure to hospital pathogens which

(e)

Figure 46.7 Transtibial amputation. A 62-year-old man fell from a roof sustaining a grade IIIB open tibial fracture that was unsalvageable. (a) Initial radiographs show a displaced fracture of the distal tibial shaft with a significant intra-articular component. There were also segmental comminuted fractures of the fibula. (b) There was periosteal stripping of the exposed bone ends and approximately 4 cm bone loss following debridement. (c) The posterior tibial nerve, held in the forceps, was partially divided and severely contused. (d) Postamputation appearance highlighting a cylindrical-shaped residual limb with normal skin where possible and tension-free wound closure avoiding end-bearing wounds. (e) Progress at three months showing successful limb fitting and unaided walking.

Figure 46.8 Infection of grade II midshaft tibial fracture. **(a)** Discharging wounds at eight weeks following injury. Note the separate lateral incision that had been used for the initial debridement without excision of the original open wounds. **(b)** Left AP X-ray immediately after nail fixation showing clips on the separate lateral surgical incision. At six weeks (right) bone resorption can be seen at the fracture site suggestive of deep infection (arrow). **(c)** Excision of the original injury wounds exposed the bone ends, which were devoid of periosteum. **(d)** The intramedullary nail was extracted, the canal reamed and lavaged and bone resected back to bleeding bone. Vancomycin-containing bone cement was inserted into the resection gap and a BEF applied for stability. **(e)** Negative pressure wound therapy (NPWT) was used as temporary dressing. All tissue specimens cultured sensitive *Staphylococcus*. **(f)** A proximally based fasciocutaneous flap was raised and the bone defect closed by acute shortening. A circular external fixator was applied for definitive fixation prior to proximal corticotomy. **(g)** Radiograph showing early bone formation in the distraction gap and compression at bone resection site. **(h)** Final radiograph showing healing of the regenerate bone and union at the fracture site.

Figure 46.8 (Continued)

adhere to dead bone and metalwork and produce 'slime' or bio-film. Stagnant blood filling dead spaces can provide further enrichment in a microenvironment with limited penetration by host immune cells and antibiotics.

Prevention of infection in high-risk cases can only be achieved by a strict adherence to evidenced-based protocols and meticulous surgical techniques. Cases at high risk for infection include farmyard and agricultural injuries, delayed presentation or debridement, extensive zone of injury, vascular injuries and bone loss. A more aggressive debridement will be required and we advocate multiple tissue sampling after debridement in all potentially contaminated and high-risk cases. Definitive fixation and soft tissue cover are only performed when cultures are negative. Deep infection associated with an implant is a potentially devastating complication and the orthopaedic surgeon must be confident that the conditions are suitable before considering internal fixation. The plastic surgeon must also ensure the flap is not simply covering dead tissue which is unable to bring about a healing response and fracture union, but rather serves as a nidus of deep infection.

The incidence of infection after open tibial fracture has reduced with the advent of modern techniques but around 1 in 10 patients will develop deep infection^{4,5} and treatment depends largely on the time since contamination.⁸⁹

Acute Infection

Acute or early infection usually means within four weeks of injury. Careful clinical monitoring combined with a high index of suspicion enables early detection. Complications such as erythema, wound drainage and subflap collections must be expected and managed urgently to prevent established deep infection. Regular C-reactive protein (CRP) monitoring is the most valuable investigation and rising CRP levels invariably herald infection. Imaging modalities such as ultrasound and MRI are not very useful in the acute setting and may delay treatment. Prompt surgical exploration is mandatory to prevent deep infection, ideally after stopping antibiotic therapy for at least 24 h to enable representative microbiological sampling.

Fracture stability and tissue viability are carefully assessed at surgery and any collection is evacuated. Multiple deep surgical samples including bone are obtained before high-dose, broad-spectrum bactericidal antibiotics are given pending culture results. The common infective organisms are *Staphylococcus aureus*, *Enterococcus*, *Enterobacter* and *Pseudomonas*.⁶

The orthopaedic team must be prepared to undertake an aggressive debridement if devitalized tissue is encountered and contaminated internal fixation should be removed and replaced by stable CEF. We do not advocate retaining internal fixation in the presence of infection, even with sensitive organisms.

Published studies do not support this approach, particularly in cases of open fractures and IMN.^{90,91}

Flap tip necrosis will require debridement and flap advancement if possible (Figure 46.8). Alternatively, flap revision may be indicated particularly if the fracture site is exposed. Acute infection after grade I and II open trauma managed initially by wound closure, usually have a soft tissue defect after debridement and may require flap cover. Staged treatment should be considered with antibiotic-loaded cement spacers providing local antibiotic delivery and deadspace management until the bed is ready for cover.

An aggressive orthoplastic approach to acute infection is supported by our series of open tibial fractures initially managed in non-specialist centres and characterized by inadequate initial debridement, suboptimal fixation and contamination or frank infection at presentation.¹⁹ Despite late definitive treatment, the final outcomes in these patients were excellent and similar to patients receiving early treatment.

Chronic infection

Chronic infection implies the patient has lost the 'race for the surface' and deep infection of bone and hardware is established. Wound healing and fracture repair are severely impaired and definitive treatment usually requires demanding, complex surgical intervention. We recommend a multidisciplinary approach to select the most appropriate treatment modality involving orthopaedic and plastic surgeons, musculoskeletal radiologists, medical microbiologists and rehabilitation specialists.

The general health of the host is established:

- Type A: normal immune status;
- Type B: some degree of immunocompromise (e.g. smoking);
- Type C: significant immunocompromise (e.g. diabetes).⁸⁹

The functional limitation caused by the infection is considered and a thorough orthoplastic assessment of the involved limb is undertaken. Proximal and distal joint function is examined as well as limb alignment, local soft tissue status and limb vascularity. Imaging modalities are used selectively: CT scans define bone architecture and extent of necrosis, MRI and nuclear scanning help delineate the zone of injury and angiography will highlight local vascular abnormalities. Finally, accurate microbiological information obtained by multiple deep sampling allows the microbiologist to decide the most appropriate antimicrobial therapy.

Complex limb reconstruction in the presence of chronic sepsis can only be justified if salvage offers distinct advantages over a well-performed transtibial amputation. Chronic infection associated with a non-union may not cause major morbidity and definitive treatment may be worse than the disease. Low-risk treatment options such as intermittent antibiotic suppression or limb shortening with external fixation may be preferred for high-risk patients with low functional demands. Transtibial amputation should be considered, particularly if there is chronic ankle stiffness or significant muscle wasting which will preclude a good outcome from salvage.

If reconstruction is selected, an aggressive 'tumour excision' debridement of necrotic and ischaemic tissue is essential. The extent of surgical clearance is predictive of recurrent infection and a clearance margin of 5 mm is recommended.⁹² We use the presence of punctate bone bleeding (the 'paprika sign') to indicate viable bone margins. Staged treatment is preferred until post-debridement samples are culture negative and definitive cover can be performed. Cement spacers combined with NPW will eliminate deadspace between surgical procedures and antibiotic-loaded cement aid bacterial clearance.

We advocate skeletal stabilization by CEF, which provides long-term stability and addresses bone deficiencies while respecting the blood supply of remaining fragments. The use of CEF also limits the risk of cross-contamination associated with secondary internal fixation. Bone defects are managed principally by bone transport. Shortening of smaller defects may be also used to eliminate deadspace, improve limb stability and facilitate early fracture healing.

Soft tissue cover is selected according to the site and size of the defect. Microsurgical reconstruction can be challenging due to extensive perivascular fibrosis associated with chronic inflammation and anastomosis outside of the injury zone is recommended whenever possible. The Ilizarov method alone has been advocated for the treatment of both bone and soft tissue defects without the use of flap coverage.⁹³ However, the final soft tissue envelope is poorly vascularized and does not compare to the quality of vascularized soft tissue cover provided by modern plastic reconstructive techniques.^{94,95}

Conclusion

An integrated orthoplastic approach in a major trauma centre is the cornerstone of limb reconstruction after severe open trauma. Experienced orthopaedic and plastic surgical teams working closely with rehabilitation and infectious disease specialists provide the best chance for the successful restoration of limb function.

CHAPTER 47

Lymphoedema

Kelvin Ramsey¹ and Peter Mortimer²

¹Department of Plastic & Reconstructive Surgery, The Royal Marsden NHS Foundation Trust, London, UK

²Department of Dermatological Medicine, St George's Healthcare NHS Trust, London, UK

Lymphoedema is a chronic debilitating disease resulting from an abnormal collection of protein-rich fluid within the subcutaneous tissues of the body. It may be due to aberrant development or malfunction of lymphatic channels (primary lymphoedema) or from permanent damage to a normal lymphatic system (secondary lymphoedema). This disruption to lymph drainage routes prevents the normal flow of interstitial fluid into and along lymphatic vessels with ultimate drainage back into the veins of the neck at the thoracic duct. The consequence is swelling within the affected drainage basin. This swelling, or lymphoedema, causes significant skin and subcutaneous tissue changes, as well as repeated infections which can be severe. The change in volume of the limb also results in an extremely unsightly and disfigured limb.

Embryology and anatomy of the lymphatic system

The Italian anatomist Gaspare Aselli published the first anatomical description of lymphatics as 'milky veins' in the mesentery of a dog in 1627. In 1651, Jean Pecquet in Dieppe discovered the thoracic duct and its entry into the left subclavian vein. At the same time, Olaus Rudbeck in Uppsala discovered that lymphatic vessels form a distinct vascular network throughout the body. His observations, together with those of Thomas Bartholin (who introduced the term *lymphaticus*) led to the first full description of the human lymphatic system, in which the role of lymphatic vessels in transporting fluid filtered from the blood was suggested.¹ In 1746 William Hunter demonstrated that lymphatic vessels are the absorbing vessels throughout the body. His comprehensive work laid the foundations for the modern knowledge of the anatomy, physiology and pathology of the lymphatic system. Subsequently Marie Sappey, a professor of anatomy from Paris, published his extensive work detailing the anatomy of the cutaneous lymphatic system,² using his procedure of injecting mercury into cadaveric skin.

By the end of the nineteenth century the anatomy of most of the lymphatic system had been described but its origins remained in dispute. Two theories were proposed regarding the embryological origin of the lymphatic endothelium. The first suggested that lymphatic endothelium derived from epithelial buds arising from venous channels in the early stages of embryologic life (centrifugal theory). The second suggested that lymphatic endothelium differentiates *in situ* from primitive mesenchyme, and secondarily acquires connection with the vascular system (centripetal theory).¹

Studies of mammalian embryos have shown that there are eight lymph sacs; three paired and two unpaired.³ The paired ones are the jugular, subclavian and posterior lymph sacs, and the unpaired are the cisterna chyli and the retroperitoneal lymph sac. Lymph sacs are venous derivatives that sprout into all parts of the body, except for the central nervous system and the bone marrow. According to this centrifugal theory, the peripheral lymphatic system originates from the primary lymph sacs and spreads by endothelial sprouting into the surrounding tissues and organs, where local capillaries are formed. Lymph sacs later will give rise to primary lymph nodes.

The alternative model proposed that lymphatic vessels developed independently from mesenchymal precursor cells and that connections with veins were only established later on during development. According to this model, lymphatic vessels originate by fusion of mesenchymal spaces into a primitive lymphatic network, which spreads centripetally (centripetal theory) and then establishes a connection to the venous system.¹ Both of these theories are now thought to play a role in lymphatic embryology: The main parts of the lymph sacs are derived from adjacent venous vessels, whereas the superficial, dermal lymphatics are derived from local lymphangioblasts. The two compartments fuse to form the lymphatic system.

Lymphatic vessels generally follow blood vessels within the tissues but the vascularity of a particular area is not always proportional to its lymphatic drainage. There are also areas that do not have lymphatic vessels, such as bone marrow and the central

nervous system as well as areas that have neither blood nor lymphatic vessels such as cartilage, the cornea of the eye and the epidermis of the skin. In order to provide the high cellular oxygen requirements, lymphatics have a rich network of blood vessels performing a nutritive function.

There are five main type of lymphatic conduit: initial lymphatics, collecting vessels, lymph nodes, trunks and ducts. Within the skin, there are two plexuses of lymphatics – superficial and deep. The superficial lymphatics are valveless and the vessels of the deep lymphatic plexus have valves.

Having left the interstitium, lymph enters the initial lymphatics, which include the smallest lymphatic capillary and the larger precollector vessel.⁴ The precollectors drain into collecting vessels, which pass through lymph nodes. From these collecting vessels the lymph drains into larger trunks, which then drain into ducts (apart from intestinal, hepatic and lumbar lymphatics which drain directly into the cisterna chyli). The ducts finally return the lymph back into the bloodstream.

Physiology

Oedema represents an increase in interstitial fluid volume sufficient to manifest with swelling. Whatever the cause of the oedema, it is due to an imbalance between capillary filtration and lymph drainage.⁵ Most examples of limb oedema are caused by capillary filtration overwhelming lymph drainage capacity. Lymphoedema generally occurs when swelling is due to a failure of lymph drainage in circumstances in which capillary filtration is not increased.⁶ There are a number of mechanisms for chronic oedema that may equate to lymphoedema:

- If there is simple lymphatic failure with no increase in capillary filtration (normal lymph load) then this is lymphoedema.
- If there is lymphatic failure with increased capillary filtration (high lymph load overwhelming lymph drainage capacity) then this results in filtration oedema with lymphatic failure.
- If there is lymphatic failure resulting from sustained increased capillary filtration exhausting lymph drainage capacity then lymphoedema is the result.⁷

The physiology of lymph drainage

The lymphatic system is crucially important for maintaining fluid balance in tissues. It is a one-way drainage route that removes from the interstitium unwanted material and excess fluid. Approximately half of the total circulating protein escapes from the blood vessels each day and the key function of the lymphatic system is to return to the blood vascular compartment protein, colloids, and particulate matter too large to re-enter the bloodstream directly.⁸ This maintains the plasma volume and prevents an increase in tissue pressure. The distances between cells and capillaries also need to be kept to a minimum to maintain cell nutrition and so any excess fluid within the interstitium must be constantly cleared.

The protein composition of lymph is similar to that of interstitial fluid and slightly less concentrated than that of blood plasma. The exception to this is intestinal lymph or chyle, which is a milky emulsion as a result of its high fat content. The lymphatic system is also involved in the body's response to infection: antigen-presenting cells are directed to the lymph nodes by lymphatic vessels and are essential for the development of cellular immunity. Impairment of these lymphatic functions results in a number of diseases that are characterized by oedema, impaired immunity, and fibrosis.⁹

The ends of lymphatic capillaries are open to the interstitium in order that fluid and molecules can pass into the vessels. In addition, the outer surfaces of the lymphatic endothelial cells are tethered to the surrounding tissues by anchoring filaments. If the interstitial volume increases, this stretches the surrounding connective tissue, thereby pulling on the anchoring filaments. This has the effect of widening the lymphatic lumen (allowing an increase in fluid transport), and also opening intercellular channels, which facilitates the passage of fluid and molecules into the lymphatic. Thus an increase in interstitial pressure results in an increase in lymphatic flow, but only up to a maximum level (approx. +2 mmHg). Once the pressure exceeds this level, there is no further increase in flow, and oedema results.⁹

The collecting lymphatics are the main limb lymphatic vessels that provide the afferent flow to the lymph nodes. The smooth muscle in their walls in conjunction with their valves is responsible for the intrinsic propulsion of lymph centripetally and this is the essential motor for lymph flow.¹⁰ However, flow can be only as good as the supply of lymph to these collectors and hence the physiology is often compared with Starling's law of the heart.

The supply of lymph from the initial lymphatics depends on a different mechanism. Flow of interstitial fluid and macromolecules into and consequently along initial lymphatics is caused by intermittent changes in hydrostatic and oncotic pressures locally and is termed convective flow.¹¹ Deformation or movement of the tissues by surface pressure or underlying muscle contractions and by other contractile structures, such as arterioles, causes compression of the initial lymphatics which forces lymph along initial lymphatics. Valves ensure that flow is unidirectional.

Differential diagnoses

Non-inflammatory oedema may occur whenever there is a disturbance to Starling pressures and an increase in microvascular fluid filtration. Circumstances where this occurs include an increase in intravascular hydrostatic pressure (e.g. heart failure) or a fall in plasma colloid osmotic pressure (e.g. protein losing state). Contrary to popular belief, kidney failure does not cause oedema except in nephrotic syndrome or endstage renal disease when salt and water retention occurs. There are numerous clinical settings where oedema is caused by increased fluid filtration overwhelming lymph drainage and they must be

distinguished from oedema caused by sole failure of lymphatic drainage as seen in true lymphoedema.

Increased hydrostatic pressure can result from either impaired venous return or from arteriolar dilatation. The commonest cause of impaired venous return is congestive cardiac failure, but pericarditis, liver cirrhosis and venous obstruction should also be considered. Arteriolar dilatation may result from heat, neurohumoral abnormalities or from calcium channel antagonists used to treat hypertension.

Reduced plasma oncotic pressure results from the proteinuria seen in nephrotic syndrome, impaired protein synthesis due to liver cirrhosis, gastrointestinal conditions that lose protein and malnutrition.

Advanced renal disease results in sodium retention and causes systemic oedema.¹²

Lymphatic malformations may exist in isolation, with no communication with a normally draining lymphatic system. In such cases swelling arises from lymph fluid distending malformed lymphatic vessels. If malformations communicate and interfere with lymph drainage then lymphoedema occurs. One such example is Klippel–Trenaunay syndrome (capillary malformations of an extremity overlying a venous or lymphatic malformation, associated with limb hypertrophy and bony enlargement), which has been shown to have an associated primary abnormality of the lymphatics in up to 55% of cases.¹³

Aetiology

Lymphoedema arises when there is an intrinsic fault within the lymph conducting system (primary lymphoedema) or when damage occurs from factors originating outside the lymphatic system (secondary lymphoedema).

Primary lymphoedema

Primary lymphoedema is caused by an intrinsic abnormality of the lymphatic drainage channels. This may be due to:

- *aplasia* – absence of subcutaneous lymph trunks;
- *hypoplasia* – commonest type in which there are an insufficient number of lymphatic collectors; demonstrated by lymphographic studies;¹⁴ or
- *hyperplasia* – enlarged lymphatics that are increased in number and may be tortuous.

The diagnosis of primary lymphoedema is made once other causes have been excluded. The frequency at birth of those who will develop primary lymphoedema is estimated to be about 1 in 6000, with a sex ratio of about one male to three females.

Inheritance has been thought to be one of the causes since 1892, when William Milroy from Omaha described a family with the condition passing through six generations.¹⁵ If swelling is present from birth (i.e. congenital) as well as being familial then it is most likely to be Milroy's disease. In such patients the form of inheritance is now known to be autosomal dominant caused by mutations in the *VEGFR3* gene.¹⁶ The

mechanism for Milroy lymphoedema is a failure of the initial lymphatics, despite their presence in the skin and subcutaneous tissues.¹⁷ Overall, nine discrete gene mutations have been linked with primary lymphoedema, among them *VEGFR3* (Milroy's disease), *FOXC2* (lymphoedema distichiasis syndrome) and *SOX18* (hypotrichosis lymphoedema telangiectasia syndrome).¹⁸

However, for the majority of cases of primary lymphoedema, swelling does not develop until puberty, in which cases it remains unclear as to whether the lymphatic vessels are abnormal at birth. In cases of hypoplasia, lymphoedema develops either at puberty (lymphoedema praecox or Meige's disease) or later in adult life (lymphoedema tarda), yet the genetic fault is present from birth. It is possible that the defect may be programmed from birth (as suggested by the familial nature of such cases of primary lymphoedema) and that a degenerative process develops to cause subsequent lymph drainage failure. The demonstration of severe atrophy of the smooth muscle layer in proximal limb lymphatics with relative sparing of distal vessels suggests that a degenerative process may begin proximally and spread distally.¹⁹ This could help explain the variable time for onset of all lymphoedema.

Another subset of primary lymphoedema is where lymphatics are excessive in size and number (hyperplasia). Lymphatic collectors that are expanded and enlarged are also termed megalymphatics. Lymphatic valvular insufficiency and reflux is, perhaps unsurprisingly, often seen in these cases.²⁰ Such cases may also be associated with the low flow vascular malformations known as lymphatic malformations.

Secondary lymphoedema

If a pathological cause for the lymphoedema can be determined then it is termed secondary lymphoedema and this is much commoner than primary. In the developed world the majority of secondary lymphoedema results from cancer and its therapy, but in developing countries various forms of infection can also result in reduced drainage. The causes can be summarized as:

- *Malignancy* – infiltration of lymphatics and nodes by cancer.
- *Damage* to nodes and or channels by surgery/radiotherapy/accidental trauma/silica absorption through skin (podoconiosis). The resultant lymph drainage impairment may arise from downstream obstruction, valvular incompetence and backflow (hence dermal backflow) or obliteration of peripheral lymphatics.²⁰
- *Infection* – chronic inflammation secondary to infection with filariasis caused by *Wuchereria bancrofti* is a classic infective cause worldwide. Not only can the worms cause mechanical obstruction but also the products of the filarial parasites depress lymphatic contractility.²¹ However, with respect to global causes of infective lymphoedema, tuberculous lymphadenitis and chronic sepsis are commoner. Recurrent bouts of cellulitis/lymphangitis result in obliteration of lymphatic vessels and deterioration of the lymphoedema.

Breast cancer-related lymphoedema

Chronic oedema following mastectomy for breast cancer was first described by Halstead in 1921.²² Modern trends in therapy for breast cancer, including the Z11 study²³ have resulted in more conservative surgery and fewer axillary clearances, but breast cancer-related lymphoedema (BCRL) remains a common problem. Reports of incidence vary, but one large cohort displayed a cumulative incidence of 28%.²⁴

Similarly, a 10-year follow-up of 256 patients treated with breast irradiation following sentinel node biopsy or axillary clearance showed chronic lymphoedema occurring in 34% of patients.²⁵ The same group have also proven the widely accepted fact that lymphoedema is significantly more likely to occur subsequent to axillary clearance than after sentinel node biopsy alone.²⁶ A recent meta-analysis still puts the incidence of arm lymphoedema at more than one in five women.²⁷ This takes no account of increasing levels of breast lymphoedema as a result of breast-conserving surgery, a problem that never existed with mastectomy.

Cases of lymphoedema continue to emerge up until 5 years after breast cancer surgery, if not longer.²⁸ Clearly in these cases relapsed carcinoma must be excluded in the first instance. After an initial rapid expansion period, arm volumes tend to stabilize and remain in a relatively steady state.⁶

The pathophysiology of BCRL would seem to be the result of damage to the axillary lymphatic system caused by surgery and/or radiotherapy, which thus impair lymph drainage from the arm. Lymphangiography performed subsequent to treatment but before swelling shows dilatation of the main collecting lymphatics in the arm²⁹ and contrast medium appears to be delayed in the axilla. Normally, lymph from the superficial system drains into the deep lymphatic system across fascial connections. As oedema develops, the deep lymphatic system is no longer visualized and there is much dermal collateralization with retrograde flow from deep vessels back to the superficial skin lymphatics.³⁰ This reversal of flow or 'dermal backflow' indicates valvular incompetence.

If lymph drainage is reduced (as is the case in lymphoedema) then capillary filtration and consequently protein concentration (and interstitial osmotic pressure) would be expected to rise. However, the analysis of interstitial fluid extracted from both swollen and non-swollen arms demonstrated that protein concentrations were *lower* in the swollen arm, to the extent that protein concentration correlated negatively with the severity of arm swelling.³¹ It was thought that this might be due to a vascular contribution such as increased capillary filtration.

Venous obstruction has been suggested to have a causative role – altered venous anatomy has suggested obstruction³² and duplex ultrasound imaging has shown that only 30% of patients with chronic arm swelling after breast cancer are normal. However, in contradiction of these facts, measurement of venous pressures in postmastectomy lymphoedema arms did not show an increase.³³

Another possible vascular cause would be failure to maintain precapillary resistance, allowing blood flow and capillary

pressure to rise and therefore increasing the filtration rate. Spectral Doppler studies of mean axillo-subclavian blood flow have demonstrated a 68% increase in lymphoedematous limbs.³⁴ Venous occlusion plethysmography has also shown that total arm blood flow is increased in the majority of such patients.³⁵

This finding of increased blood flow to the whole arm suggests either vasodilatation of existing resistance vessels or formation of new ones (angiogenesis). Studies investigating the possibility of vessel dilatation have shown that vasoconstrictor control and sympathetic vasodilator control were normal in BCRL, but local vasodilator control was impaired.³⁶ Sustained vasodilatation as a cause of the rise in capillary pressure was not seen. Regarding new vessel formation, a study has found evidence of an increase in total capillary numbers in BCRL.³⁷ Such capillary angiogenesis could be increasing the surface area for an exchange and so increase the filtration load.

All oedemas result from an imbalance between capillary filtration and lymph drainage and thus the state of the microcirculation must be considered as well as of the lymphatic drainage. Lymph flow was raised in both the subcutis and muscle of both arms in postsurgical breast patients who later developed BCRL, compared with those who did not. Changes in the contralateral arm suggest that systemic factors contribute to BCRL.³⁸ There is therefore strong evidence to believe that haemodynamic factors contribute to the oedema.

Clinical history, features and assessment

Lymphoedema can be difficult to differentiate from other types of oedema. However there are a number of clinical pointers that would suggest a diagnosis of true lymphoedema:

- Oedema that only slightly resolves with overnight elevation is likely to be a lymphoedema as elevation does not improve lymph flow (indeed the opposite because it reduces microvascular fluid filtration).
- Diuretics do not improve lymphoedema because diuretics reduce body salt and water with no stimulation of lymph drainage.
- More than one attack of cellulitis suggests lymphatic insufficiency.
- Exercise improves lymph drainage.
- Lymphoedema pits in its early stages like any other oedema.
- Lymphoedema causes skin thickening and hyperkeratosis, so-called elephantiasis.

Lymphoedema generally presents with limb swelling and this may be associated with symptoms of heaviness or aching of the affected limb. Pitting (pressure from a finger or thumb leaving an indentation after removal) is often seen in the early stages due to the fact that the increase in limb size is mostly due to its fluid component. As the disease progresses, fibrosis and fat deposition occur, with the result that the limb may no longer pit.

Historical teaching suggested that pitting oedema differentiated lymphoedema from other causes of swollen limbs. However oedema of many causes (including lymphoedema) may initially

show pitting but similarly oedema of any nature may not pit once it becomes chronic. All oedema represents a form of lymphatic failure. This is because, contrary to traditional teaching, the evidence indicates that all interstitial fluid is reabsorbed by the lymphatic in the steady state with no venous reabsorption. Hence any peripheral oedema is either solely due to lymph drainage failure in the face of a normal microvascular fluid filtration (normal lymph load) or lymph drainage capacity is overwhelmed by increased fluid filtration (increased lymph load). Therefore all oedema is either absolute or relative lymph drainage failure.^{5,7}

The swollen limb is disfiguring and commonly causes functional impairment, a feeling of heaviness and aching, psychosocial maladjustment and psychological morbidity.³⁹ Features of lymphoedema seen in the lower limb include loss of ankle contour, square profile of toes and lichenified filiform fronds. A positive Stemmer's sign,⁴⁰ which is the inability to pinch a fold of skin (due to increased skin thickness) at the base of the second toe, is pathognomonic of lymphoedema.

Recurrent acute inflammatory episodes ('cellulitis' or 'erysipelas') can affect up to one-third of patients. Such attacks increase swelling and compound the problem by causing further damage to lymph drainage routes. It has been suggested that this propensity for infection is due to increased fluid and protein content of the skin and subcutaneous tissues.⁴¹ A much more likely explanation is the effect disturbed immune cell trafficking has on local tissue immunity. Cellulitis exacerbates swelling, may require hospitalization for intravenous antibiotics and can destroy residual lymphatics. If multiple repeated episodes of cellulitis occur, the limb may reach massive proportions and may become pachydermatous (elephantiasis).

The psychological harm that results from lymphoedema is a significant problem that should not be underestimated. A study of a cohort of women presenting for therapy for their lymphoedema has shown that these patients have high levels of psychological distress and of functional and social dysfunction. There is no linear relationship between severity of lymphoedema and levels of distress. Women with pain of any intensity were the most distressed, and had the most significant difficulties in psychological and physical functioning.⁴² Unfortunately this psychological distress can result in an avoidant coping style and low perceived social support, which may interfere with any treatment. Efforts must therefore be made to strengthen the patient's coping skills, ideally through a multidisciplinary approach.⁴³

A thorough clinical examination is crucial, in particular of the vascular system, which can be assessed with suitable imaging such as a duplex scan or venogram. Assessment tools that can be used to clinically evaluate patients with extremity lymphoedema include circumference measurement, water displacement volumetry and perometry as well as bioimpedance spectroscopy. The latter two may be less prone to human error. Imaging techniques are also useful and are discussed elsewhere in this chapter.

The water displacement method (water plethysmography) is an accurate way of calculating limb volume and is the only reliable method available for the measurement of oedematous hands and feet. There are issues with hygiene and access to such equipment that limit its use.

Perometry uses infrared light beams to measure the outline of the limb; from which localized areas of differential oedema can be quantified, as well as an overall volume assessment. This is arguably the gold standard. Bioimpedance spectroscopy measures tissue resistance to an electrical current in order to determine extracellular fluid volume. Although not yet established in routine practice, it may prove useful in demonstrating early lymphoedema and in monitoring response to treatment.⁴⁴

There is no effective method for measuring the head and neck, breast, trunk or genitalia, although 3D photography or imaging may have a role for these areas.

Lifestyle questionnaires such as the Disabilities of the Arm, Shoulder and Hand (DASH score) have been used for the assessment of lymphoedema patients. They concentrate on evaluating the capability of the patient to carry out everyday tasks and can be used to assess the efficacy of different intervention according to these parameters.

Investigations/imaging

The search for the ideal method of imaging the lymphatic system has been a source of extensive research with some invaluable recent advances. Nineteenth-century anatomists used materials such as mercury, wax and gelatine to perform lymphography on cadavers. *In vivo* studies have used interstitial injections of contrast agents, which are then taken up by the lymphatic circulation. Radioactive proteins or colloids are imaged by a gamma camera (lymphoscintigraphy). Vital dyes such as patent blue, injected intra- or subdermally, can be seen with the naked eye and used to identify lymphatics *in vivo*. Traditionally, radiocontrast agents were injected directly into subcutaneous lymphatic collectors and imaged by X-ray (lymphangiography). The latter lost popularity because it is an invasive technique and can damage the lymphatic vessels and worsen lymphoedema.

In recent years the introduction of fluorescent tracers, water-soluble contrast agents and isotopes, in parallel with the advent of physiological surgical procedures, has reinvigorated the role of imaging in lymphoedema. Surgery planned to divert lymphatic fluid may only be successful if the surgeon can identify the position of the tiny lymphatic channels (on average 0.3–0.8 mm diameter) and establish whether they are patent and functional. Near-infrared spectroscopy, lymphoscintigraphy and MR lymphangiography have had particular success in the assessment of candidates for physiological procedures.

Lymphoscintigraphy is perhaps the most well-recognized modality used for the evaluation of lymphatic function in lymphoedema. Although it provides quantitative assessment of

lymphatic function and flow abnormalities, it is time consuming, expensive and unsuitable for perioperative use.

Near-infrared spectroscopy allows real-time visualization of lymphatic vessels with minimal invasiveness. It accurately shows the flow of lymphatic fluid without the need for radioactive isotopes. It uses the principle of fluorescence lymphography, which detects near-infrared light emitted by a fluorophore (commonly indocyanine green) that has been injected into the affected limb. The fluorophore binds with albumin, which is then selectively taken up by, and transported through, the lymphatic circulation. This not only demonstrates the position and path of lymphatic vessels within a limb, but also provides a dynamic functional assessment (Figure 47.1) that is comparable to lymphoscintigraphy.⁴⁵

Fluorescence lymphography using indocyanine green dye in this manner has previously been used for various clinical situations such as liver function evaluation, assessment of burn depth, sentinel lymph node detection, cardiac assessment, perforator identification and evaluation of flap viability.^{46–48} The only factor excluding patients from this technique is a history of allergic reactions to iodine. A recent anatomical and physiological study used near-infrared fluorescence to image lymphatics in normal volunteers and lymphoedema patients. It elegantly displayed active propulsion, architecture and extravascular leaks.⁴⁹ This imaging technique can also be used to show postoperative flow in the diverted lymphatic channels to prove patency.⁵⁰

Magnetic resonance (MR) lymphangiography, a technique in which lymphangiograms are obtained by injecting standard MR contrast agents such as gadopentate in the subdermal plane followed by a series of image acquisitions, has been used to image lymphatics with some success.⁵¹ Imaging is generally performed with a 3 or 4 tesla scanner using a 3D spoiled gradient-echo sequence. Although this provides reasonable imaging of the lymphatics, it is both more invasive and expensive than near-infrared fluorescence. There have also been challenges in the

ability of these scans to differentiate between the venous and lymphatic circulation.

Lymphatic function can also be assessed in terms of tissue clearance rate, which describes the rate of removal of an injected radiolabelled substance from the tissues. This provides a quantitative measure of function in an easily reproducible manner.⁵² Lymphatic function can also be assessed by measurements of solute concentration ratios between plasma and lymph, as well by direct measurements of lymphatic capillary pressures.⁵³

Classification

The fact that there are multiple systems for classification of lymphoedema perhaps suggests that no single method is ideal. Generally, staging of lymphoedema can be differentiated into systems that assess clinical factors, immunohistochemical appearances and disability.

The increase in use of near-infrared spectroscopy by indocyanine green lymphography has resulted in accurate delineation of lymphatic anatomy. This imaging modality has been used to create a new classification system of lymphography findings in secondary lymphoedema of the lower limb reflecting both pathophysiology and severity of lymphoedema.⁵⁴ The findings are largely classified into 'linear' or 'dermal backflow' patterns and each of these are subclassified into three groups. This system certainly has merit for planning of microsurgical lymphatic bypass procedures but it remains to be seen whether the scientific community as a whole adopts it.

One of the most commonly cited classification systems for severity of lymphoedema is that of Campisi (Table 47.1).

The International Society of Lymphology (ISL) produces a consensus document on behalf of the international community. In its most recent publication⁵⁶ it summarizes the ISL classification of lymphoedema as follows:

- *Stage 0 (or Ia)*: A subclinical condition where swelling is not yet evident despite impaired lymph transport.
- *Stage I*: Early accumulation of fluid relatively high in protein content which subsides with limb elevation and may display pitting.

Table 47.1 Campisi extremity lymphoedema staging system

Stage 1A	No oedema despite the presence of lymphatic dysfunction
Stage 1B	Mild oedema that spontaneously regresses with elevation
Stage 2	Persistent oedema that regresses only partially with elevation
Stage 3	Persistent, progressive oedema; recurrent acute erysipeloid lymphangitis
Stage 4	Fibrotic lymphoedema with column limb
Stage 5	Elephantiasis with severe limb deformation, including sclero-indurative pachydermitis and widespread lymphostasis warts

Source: Campisi and Boccardo, 2004.⁵⁵

Figure 47.1 Indocyanine green lymphography showing propulsion of a bolus of dye along a linear lymphatic in the antecubital fossa. Source: Campisi & Boccardo, 2004.⁵⁵ Reproduced with permission of Springer.

- *Stage II*: Limb elevation alone rarely reduces swelling. In early stages pitting is manifest but as it progresses the limb may or may not pit as a result of excess fat and fibrosis.
- *Stage III*: encompasses lymphostatic elephantiasis where pitting may be absent and trophic skin changes such as acanthosis, further fatty deposition and fibrosis, and hyperkeratoses have developed.

Although this is an internationally accepted staging system, it only refers to the physical condition of the lymphoedematous limb and not pathophysiology. Another consensus document has been recently published by the International Union of Phlebology, but the classification is confined to primary lymphoedema although it does consider aetiology including causal mutations.⁵⁷ Another recently published classification system uses an algorithm based on phenotype and genotype to decipher clinical presentations of primary lymphoedema.⁵⁸

As understanding of the pathological, physiological, genetic and clinical features of lymphoedema improves, this will certainly lead to further evolution in our staging systems.

Management, complications and outcomes

Non-operative

The main challenges in the management of lymphoedema are:

- reversal of increased interstitial volume;
- amelioration of some of the secondary skin and subcutaneous tissue changes;
- prevention of infection.

Conservative measures are the mainstay of treatment designed to manage the condition and to minimize complications rather than to provide a cure.⁵⁹

Initial management of lymphoedema includes education and support, skin care, stimulation of lymph drainage and management of any concomitant conditions. The effect of exercise and movement on lymph flow is enhanced by compression. Intensive treatment using manual lymph drainage, multilayer lymphoedema bandaging and exercises is designed to reduce limb volume, restore limb shape and improve the condition of the skin. Once completed, maintenance treatment is in the form of exercises and compression. Compression can be implemented by prescription hosiery or Velcro wraps (e.g. Farrow wraps). Elevation is to be recommended when relaxing but never undertaken in preference to exercise.

Compression hosiery is designed to (a) reduce capillary pressure and consequently microvascular fluid filtration and (b) increase tissue interstitial pressure and so enhance fluid absorption into, and transport along, initial lymphatics. Clearly the presence of comorbidities, in particular vascular disease and heart failure, as well as the ability of the patient to tolerate them, must be considered with any compression techniques.

The use of *multilayer compression bandaging* has been shown to reduce volumes more effectively than compression garments. A mean overall reduction rate of lower limb lymphoedema of up

to 31% can be achieved after bandaging, followed by compression stockings compared with 15% using compression stockings alone.⁶⁰ However, stockings are more convenient and allow easier continuation of routine activities.

Manual lymphatic drainage (MLD) is designed to direct lymph drainage to normal lymph drainage basins. This manual technique concentrates on central lymphatics to 'clear the way ahead' for lymph draining from limbs. For example in BCRL, lymph fluid around the shoulder and on the trunk is directed through collateral routes to the contralateral upper quadrant lymph drainage basin before the ipsilateral arm oedema is drained by bandaging. The evidence in support of MLD is limited although one prospective trial supports the combination of MLD with compression bandaging for mild lymphoedema.⁶¹

Decongestive lymphatic therapy/complex decongestive therapy comprises MLD, multilayer compression bandaging, therapeutic exercise and skin care.⁴⁴ Földi defined two treatment phases of this (initial intensive intervention followed by multiple maintenance treatments), which have since been modified. A systematic review of these techniques combined together indicated that they reduce arm volumes more effectively than compression hosiery alone.⁶² However, multiple subsequent randomized trials have failed to show that it confers a significant benefit beyond that of compression alone, and therefore is difficult to justify as first-line therapy for early lymphoedema.⁶³

Intermittent pneumatic compression devices sequentially inflate and deflate along the length of the limb in order to push lymph and interstitial fluid proximally towards the trunk. Their benefit is not well proven.

Pharmacological treatment plays little role in the management of lymphoedema. Benzopyrones and diuretics have been used but there is little evidence to support their use.

Surgical management of lymphoedema

Many surgical procedures have been described, broadly divided into 'excisional' or 'physiological' techniques. Physiological operations are designed to improve the lymphatic function of the limb, whereas the other techniques involve debulking or removing skin and/or subcutaneous tissue.

In addition to these, simpler surgical procedures may be used to manage the cutaneous vesicles of lymphangiectasia such as diathermy, hyfrecation or laser therapy.

Excisional procedures

These surgical procedures have involved excision of some or all involved tissue, but can be severely mutilating operations. Homans' operation (1936)⁶⁴ involved raising flaps of skin and removing a longitudinal segment of involved skin and subcutaneous tissue. This was popularized by Miller in 1973 and was one of the most accepted surgical treatment for lymphoedema. Scars were extensive and wound complications common.⁶⁵ Kondolean procedure (1912) involves resection of the lymphoedematous tissues as well as creating a fascial window as a means of establishing communication with deeper lymphatics.

Thompson's procedure (1962) involved advancement of de-epithelialized dermal flaps into muscles in the hope of drawing lymphatics into the deep circulation.⁶⁶ The most severe of these procedures was the Charles procedure (1912),⁶⁷ which involved the circumferential excision of all involved skin and subcutaneous tissue before covering the areas with split-thickness skin grafts. Proponents who quoted symptomatic improvement justified the cosmetically shocking results, but these procedures are now rarely performed.

Liposuction

As lymphoedema becomes chronic, the volume differential between limbs may be increasingly due to fatty deposition rather than fluid accumulation,⁶⁸ although the rate of this transition from fluid to fatty excess appears to vary greatly.

In order to treat fat deposition within a lymphoedematous limb liposuction techniques have been utilized. An assessment of the affected limb is essential to determine the fat to fluid ratio within the swollen limb. If fluid dominates then decongestive lymphatic therapy (DLT) or microsurgical bypass techniques should be considered. If the excess volume is due to fatty deposition rather than excess interstitial fluid, then liposuction should be considered.

The excessive growth of adipose tissue associated with lymphoedema led to the proposal that lymph is adipogenic, but there has been limited evidence to support this until now. A landmark study from Harvey *et al.* described a mouse model of lymphoedema that progresses to obesity.⁶⁹ They have suggested that a factor normally present in chyle or lymph cooperates with insulin to drive adipocyte differentiation.

Non-pitting, non-fibrotic lymphoedema treated with liposuction has resulted in some excellent volume reduction outcomes.⁷⁰ Hakan Brorson from Sweden is a leading proponent of this and is renowned for his regime of lymphoedema management. This involves an initial intensive course of compression, using custom-made garments, which is termed 'controlled compression therapy'. Liposuction is undertaken under tourniquet control, with the aim of removing all excess tissue from the arm and this is followed by maintenance compression therapy in the same manner as before. Although labour intensive, this regime has shown dramatic reductions in volume. One prospective study combining liposuction and compression therapy in this manner showed oedema reduction figures of 104% compared with 47% for controlled compression alone.⁷¹ It has also been shown that the aspirate removed in this manner under tourniquet control contains up to 93% adipose tissue.⁷²

There is concern that the instrumentation of the surgery further damages the lymphatics of the limb, although lymphoscintigraphic studies have shown that it may not further decrease the already impaired lymph transport capacity.⁷³ However, concerns that the intervention may worsen the fibrosis and so exacerbate the condition have not been fully realized.

Liposuction does not address the cause of the lymphoedema, but simply reduces the volume of the limb. It cannot be used in

isolation but requires the use of lifelong maintenance compression therapy, which is a significant disadvantage for some.

Reconstructive procedures

These techniques involve the use of a conduit (usually lymphatic collector or an interposition vein) to restore lymphatic continuity in lymphoedema resulting from an anatomical interruption. The volume reduction achieved in some cases is reported to reach a level of 80% and the transport index, as demonstrated by imaging methods, has shown an improvement of 30%.⁷⁴ The technique is said to imitate the normal physiology and has shown long-term patencies of more than 10 years.⁷⁵

Autologous lymphatic grafts used to bridge obstructed lymphatic segments in this manner may be useful in some cases, but data are lacking. The method necessitates the harvest of the conduit from a healthy limb, and there are concerns regarding the donor site morbidity that need to be addressed in further studies. It has also been shown that LVAs are less susceptible to thrombosis than lympholymphatic where the pressure within the lymphatics is very low.⁷⁶

Physiological/derivative procedures

The pathogenesis of lymphoedema is related to several physiological factors including increased lymph load, lymphatic obstruction, the number and pattern of lymphatic/lymphaticovenous (reduced compensatory capacity) communications and lymph vessel obliteration. Physiological surgical strategies for lymphoedema are predicated on these principles of pathogenesis in an attempt to restore physiological lymphatic function.

Omental transfer has been used whereby a pedicled portion of omentum is transposed to bridge an area of lymph vessel hypoplasia causing obstruction to the affected limb drainage but omentum lymphatics were found not to generate sufficient collateral drainage. Bridging procedures, initially popularized in the setting of lymphoedema by Sir Harold Gillies in 1935,⁷⁷ have generally failed because lymphatic communication was not achieved. However, the enteromesenteric flap was initially thought to be a breakthrough in the lymphoedema management.⁷⁸ This bridging procedure required covering transected iliac or inguinal nodal basins with a segment of ileum. However, the fact that it involved major surgery and carried the risk of small bowel obstruction means that such procedures have now been abandoned.

Lymph node transfer

The surgical technique of transplanting a healthy, vascularized lymph node into a lymphoedematous limb was initially investigated in the rat⁷⁹ and canine models.⁸⁰ Superficial lymph nodes and perinodal tissue were moved as a free vascularized transfer and this resulted in reduction of the lymphoedematous legs compared with controls. Performing simultaneous lymphaticolymphatic anastomoses to re-establish lymphatic circulation was shown to convey no benefit, and it had previously been

shown that lymph glands will spontaneously re-establish afferent and efferent continuity following division if the vascular supply is retained.⁸¹

Subsequent to these animal studies, there have been a number of *in vivo* studies suggesting that lymphoedema can be treated by lymph node transfer. In order to minimize donor leg lymphoedema, superficial inguinal lymph nodes located along the superficial circumflex iliac artery (SCIA) were selected for transplantation. These more external superolateral nodes had been previously shown to receive drainage from the lower limb in a minority of cases. Corinne Becker and colleagues showed that these nodes based on the SCIA drained mainly the lymph from the abdominal wall and could be safely transplanted with a skin island supplied by the same vessel.⁸² This group has published modest improvement in cases of post mastectomy⁸³ and primary lymphoedema⁸⁴ with this technique, although others have struggled to produce similar results. What is not clear is whether the transplanted node confers benefit in isolation or whether it is the axillary scar release and vascularized transfer of tissue that confers benefit.

The recipient site for lymph node transfers is usually the affected nodal basin, so as to re-establish drainage routes so far as is possible. However, recipient vessels for anastomosis can be challenging in the setting of a scarred and possibly irradiated nodal basin. Hence other options for recipient sites have been sought, such as the wrist, which has yielded reasonable improvements in limb size and lymph drainage.⁸⁵ Although this technique resulted in statistically significant mean reduction rates there are concerns regarding the cosmetic outcomes of such transfers.

Nodal transfers and autologous breast reconstruction with the deep inferior epigastric artery perforator (DIEP) flap have been performed simultaneously. The concept of performing a breast reconstruction at the same time as attempting to manage the lymphoedema is certainly an attractive one and has had success.⁸⁶ However it may be that breast reconstruction itself has an impact on lymphoedema.⁸⁷ A review of 574 cross-matched patients showed that patients who did not undergo reconstruction (implants and autologous in equal numbers) were significantly more likely to develop BCRL.⁸⁸ Further evidence for this comes from a recent large study wherein breast cancer patients who underwent modified radical mastectomy with immediate autologous breast reconstruction had a significantly lower incidence of lymphoedema than those in the non-reconstruction group.⁸⁹

To date, the technique of lymph node transfer has been the source of some controversy. The suggestion that the transplanted node encourages lymphangiogenesis (development of new lymphatic connections) is countered by the argument that this may happen even in the absence of a transplant. Hence the mechanism as to the success of the technique is unclear, as is the optimal recipient site for the transplantation (axilla/wrist etc.), whether a skin flap is necessary in addition to the node itself and whether a lymphatic anastomosis is required.

Donor site morbidity is perhaps the largest area of controversy for this technique. Given the fact that removing a single lymph node from a lymphatic basin carries a risk of lymphoedema (sentinel node biopsy), it follows that harvesting the node for transplantation must also carry the same risk. Lymphoscintigraphy has shown that postoperative lymphatic vessel function of the donor limb may be impaired.⁹⁰ A more recent review from Paris showed significant complications in 38% of patients who underwent autologous lymph node transplantation.⁹¹ These were not only chronic lymphoedema in the donor limb, but also lymphocoeles, a hydrocoele requiring surgery and persistent donor site pain.

It is well established that the development of the lymphatic system is mainly regulated by the VEGF-C/VEGF-D/VEGFR-3 signalling system. Knowledge of the different molecules involved in lymphangiogenesis has rapidly accumulated in recent years. It has been suggested that combining growth factor therapy with vascularized lymph node transfer will result in increased lymphangiogenesis around the implanted node and therefore improved drainage of the limb. However there are a number of potential technical and oncological obstacles. The role of growth factors in cancer upregulation is one such concern, as numerous studies have also shown a direct correlation between VEGF-C and VEGF-D expression in human cancers and tumour metastasis, suggesting that lymphangiogenesis has an important role in promoting the metastasis of human tumours.⁹²

There have been some promising early results from animal studies in Finland using such growth factor therapy in combination with lymph node transfer.^{93,94} Growth of lymphatic channels around the transferred nodes was seen and results from initial clinical trials are keenly awaited.

Lymphaticovenous anastomosis

The concept of lymphatic reconstruction by connecting obstructed lymphatic channels onto veins in order to improve drainage remains an attractive one.

This lymphaticovenous anastomosis (LVA) surgery was first performed in the late 1960s^{95,96} with perhaps the most well-known initial work published by O'Brien and colleagues.⁹⁷ Early studies proved the technique to be advantageous for sufferers from postsurgical lymphoedema, although results were modest and variable.⁹⁸ With the advent of recent advances in supermicrosurgery, such techniques have become more popular.

One prospective study showed that performing this LVA procedure on patients with BCRL could result in symptom improvement for 95% of patients and a quantitative improvement in 65%.⁹⁹ An impressive series of results from an Italian team found that, of those patients followed up, 85% were able to discontinue the use of conservative measures such as compression sleeves. With an average follow-up of more than 10 years an average reduction in excess volume of 69% was achieved.¹⁰⁰ A large series from Poland has also shown benefit from lymphovenous shunt procedures using the femoral vein, although this recipient vein is not widely used.¹⁰¹

Many researchers have had conflicting results, with significant variation between patients in terms of the amount of reduction in size of the limb that occurs. Indeed some small series have had very limited success.¹⁰² It appears, therefore, that patient selection is crucial in order to select those patients who will benefit from surgery. This may be due to a number of factors, including the severity of lymphoedema-related fibrosis and the availability of viable lymphatic vessels.⁹⁹ It is for this reason that imaging techniques such as indocyanine green lymphography have been employed.¹⁰³

Dynamic imaging techniques are used to delineate functioning lymphatics to be used for anastomosis, and this combination of imaging with surgery has had more favourable results.¹⁰⁴ Once the lymphatics and venules have been isolated, the anastomoses are generally performed using 12/0 Ethilon on a 50 μ m needle, using supermicrosurgical instruments (Figures 47.2, 47.3 and 47.4).

One series combining this technique with ultrasonography to identify veins, reported 78% of patients having at least a 50% reduction of the proximal, distal or whole limb.¹⁰⁵ Further studies have refined the technique by using shorter incisions,¹⁰⁶ performing anastomoses at multiple sites simultaneously¹⁰⁷ and using intravascular stents.¹⁰⁸

If there is a dermal backflow pattern whereby no linear lymphatics can be found, some surgeons have advocated the use of predictive lymphatic mapping, whereby the linear pattern of lymphatics on the unaffected limb are mapped onto the affected limb, and this technique is used to guide the site of surgical incision for lymphatic surgery.¹⁰⁹

Several reports have described the effect of such microlymphatic surgery on peripheral lymphoedema, but details of the exact treatment protocols used are limited. Many of the series published are thought to combine DLT/complex decongestive therapy (CDT) with LVA bypass surgery and thus the separate net effects of surgery versus DLT/CDT have not always been made clear. A recent publication sought to address this and considered that oedema can be reduced using DLT/CDT before surgery. The authors evaluated the net effect of DLT/CDT and then evaluated the net effect of subsequent LVA surgery.¹¹⁰ The approximate reduction achieved by preoperative DLT/CDT in affected limbs was significantly better than that achieved by surgery, but the net effect of LVA surgery on volume reduction was confirmed. They also indicated that the surgical effect should include not only the amount of oedema reduction but also changes in skin stiffness, subjective symptoms and the frequency of cellulitis. The series included some patients who required no DLT/CDT after surgery and many for whom the class of pressure in the elastic stockings could be decreased. Both of these outcomes should also be evaluated when considering the outcomes of any surgical technique.

The anatomical configuration of the lymphaticovenous anastomosis varies between series (i.e. whether to perform an end-to-end or end-to-side anastomosis and whether to use the proximal or distal ends of the lymphatic and venule). The

Figure 47.2 Lymphatic and vein prior to anastomosis, with 1 mm gradations on background.

Figure 47.3 Lymphaticovenous anastomosis immediately after completion.

Figure 47.4 Lymphaticovenous anastomosis 2 s later, showing flow of dye from lymphatic into vein.

majority of series comprise end-to-end anastomoses between the distal stump of the lymphatic and the proximal stump of the vein but good results have also been achieved with multiple alternative configurations.^{108,100}

The number of anastomoses performed may also be relevant to the success of the surgery. One large retrospective review has suggested a relationship between the numbers of anastomoses and volume reduction achieved,¹¹¹ but not all centres have shown similar findings. However the patency rate of the anastomoses decreases over time and thus it may be reasonable to suggest that many anastomoses are needed to achieve good long-term outcomes.

The timing of surgical intervention is critical, but there are some conflicts between pathophysiology and clinical indication. The concept of undertaking LVA at a much earlier stage to restore some of the disruption/blockage of superficial lymphatics is based on the physiological rationale that this will reduce increased hydrostatic pressure in other parts of the lymphatic system and promote absorption of fluid back into the lymphatic vessels. However, performing LVA surgery at the time of lymph node clearance in a non-selective fashion would be difficult to justify as only about one-quarter of patients would be expected to subsequently develop lymphoedema. On the other hand, the procedure may be less effective when done following onset of established lymphoedema and of course this entails an additional surgical procedure.

It has been proposed that LVA surgery should be performed at the same time as axillary node clearance (ANC), in order to attempt to prevent the onset of lymphoedema in the first place. The LYMPHA technique, conceived by Corradino Campisi in Genoa, is such a technique and consists of performing LVA between the arm lymphatics and collateral branches of the axillary vein at the same time as axillary dissection.¹¹² In a recent series from this group, one cohort of patients had ANC and LVA during the same operation, whereas the others had the best conservative treatments.¹¹³ The study has short follow-up and small numbers, but the results showed that 30% of the control group developed lymphoedema whereas only 4% of the treatment group were affected.

The surgical technique used by this group varies slightly from the standard LVA. Usually, the divided end of a single lymphatic is anastomosed to a similar-sized venule. Campisi's group insert multiple lymphatics into the divided end of larger veins, using their 'sleeve technique'. Although there are strong data to support LVA surgery on its own, some find it difficult to justify prophylactic LVA surgery at the time of an axillary clearance if only 20–30% of those patients treated would have developed lymphoedema.

A technique designed to mitigate the damaging effects of axillary surgery is axillary reverse mapping. The lymphatic drainage of the arm is mapped with blue dye prior to surgery, so that the identified lymphatics can be preserved.¹¹⁴ However, to truly preserve the lymphatic flow of the arm, not only the afferent lymphatics but also the lymph nodes belonging to the

arm lymphatic pathways must be preserved. There remains controversy regarding the oncological safety of preserving lymph nodes during an axillary clearance in this manner. Similarly, the identification of efferent lymphatic pathways in order to bypass the axilla is hindered by the fact that these join the common lymphatic pathways draining the breast. For these reasons further studies are required to confirm the feasibility and long-term efficacy of this technique.

Lymphangiosarcoma

Lymphangiosarcoma is a rare tumour that presents with localized swelling and multiple, subcutaneous nodules occurring in chronic lymphoedematous limbs. It is an aggressive tumour that is rapidly fatal unless extensive surgery is performed.

Summary

Both excisional and lymphatic reconstruction surgical techniques have been employed to treat lymphoedema but published results have been variable and difficult to assess in terms of efficacy due to small numbers and limited statistical analysis.

Despite the exciting potential of combining imaging with lymphatic diversion surgery, there is a clear need for an unbiased scientific assessment of these techniques with larger randomized studies. Research is needed to understand which patients are most likely to benefit from surgical techniques and the optimal timing. This can only be achieved with standardization of diagnosis, classification, assessment and outcome measures with international consensus.

Clearly, it would be preferable to prevent development of more established forms of lymphoedema by intervening at an early stage to impact on pathogenic mechanisms.

CHAPTER 48

Hand examination and investigations

J. Henk Coert,¹ Peter Hoogvliet² and Willem D. Rinkel¹

¹Department of Plastic, Reconstructive and Hand Surgery, Erasmus University Medical Center, Rotterdam, The Netherlands

²Department of Rehabilitation Medicine, Erasmus University Medical Center, Rotterdam, The Netherlands

The medical student adage of 'look, feel and move' applies to hand examination at all clinical levels. Having been put in harm's way more than any other part of the body, this extension of our mental will into the external world doubles up as a tactile organ as well. A thorough knowledge of its anatomy and biomechanical principles assists the clinician in narrowing down the pathology. Recognition of patterns of pathology and injury are as important in examining the hands as they are in any other form of clinical examination.

Examination principles: 'look, feel, move'

Inspection ('look')

Prior to the physical examination a medical history should have been taken. The inspection is an important part of the examination as the appearance may give valuable information prior to the palpation of the hand and wrist, especially in cases of pain or discomfort. In this phase patients – especially children – will be more relaxed. It is important to compare the involved hand and/or wrist with the contralateral side.

The inspection should include:

- colour,
- deformity, including alignment,
- swelling,
- muscular appearance (atrophy, hypertrophy, spasm),
- trophic changes (e.g. sweating, hair growth),
- skin creases.

Specific appearances should be noted.

- For rheumatoid arthritis a well-known pattern can be seen in advanced disease. This includes radial deviation of the wrist and ulnar deviation of the metaphalangeal joints with swollen joints and dorsal aspect of the wrist in case of active disease. Attention should be given to potential loss of extension of the thumb and the fingers.
- For nerve palsies, specific postures can be seen: 'dropping hand' indicates radial nerve palsy with loss of wrist and finger extensors.

- 'Preacher's hand' is caused by pathology of the proximal median nerve. The index and middle finger are in a relative extended position, whereas the ring and little finger are in more flexed position. The flexor digitorum of the ring and little fingers are innervated by the ulnar nerve and are the only functioning long finger flexors.
- 'Claw hand' or 'spinster's claw' is an abnormal hand position that develops due to pathology of the ulnar nerve. The hand will show hyperextension of the metacarpophalangeal (MCP) joints and flexion at the distal and proximal interphalangeal (IP) joints of the 4th and 5th digits (ring and little fingers). The clawing will become most obvious when the person is asked to extend their fingers. The pathogenesis is a partial or complete denervation of the two ulnar lumbricals as well as the interosseous muscles to these fingers. The ulnar paradox is so called because the more distal ulnar palsy sparing the flexor digitorum profundus (FDP) supplies to the ring and little fingers is more pronounced.
- Dupuytren's contracture can present itself as a small, hard nodule at the base of the finger. It predominantly tends to affect the ring and little finger as puckering and adherence of the palmar aponeurosis to the skin. Progression may lead to a flexion contracture of the MCP and IP joints of the affected digits.
- The clinical presentation of osteoarthritis may vary from swollen joints to abnormal joint position.

Palpation ('feel')

The first orientation should be the evaluation of:

- temperature,
- oedema,
- tenderness, pain,
- passive (joint) stiffness,
- presence of skin lines,
- stability of joints (specific tests will be discussed later in this chapter).

Range of motion ('move')

Evaluation should include:

- measurement of the active range of motion of the hand and wrist joints;

- relation of movement with pain or discomfort;
- presence of snaps, clicks and clunks;
- specific tendon tests (see below Clinical tests);
- specific nerve tests (see below Clinical tests).

Clinical tests

Tendon testing

The Bouvier test

The Bouvier test or manoeuvre is generally used to assess the nature of a claw hand. This test was named after the French orthopaedic surgeon Sauveur Henri Victor Bouvier (1799–1877). In 1851 he described¹ the observation of one of his patients, the carpenter Henri Marlier, who was suffering from a temporary, effort-induced, left-sided ulnar palsy, that passive flexion of his 4th and 5th MCP joint enabled him to actively extend the proximal interphalangeal (PIP) and distal interphalangeal (DIP) joints in these fingers. A comparable phenomenon was later described by Beevor² in 1903 and even later by several other distinguished hand surgeons.³ The biomechanical basis of this test is that blocking extension of the MCP joint increases the tension in the finger's extrinsic extensor mechanism up to a level that, when besides the ulnar nerve palsy all other systems are working properly, it is able to fully extend the PIP and DIP joints. In this situation the test is considered to be positive. In a negative test additional factors such as insufficiency (rupture, adhesion, lengthening) of the central slip or a volar subluxation of the lateral bands also play a role in the origin of the claw hand.

(a)

(b)

The Bunnell test

The Bunnell test assesses the length of the intrinsic muscle-tendon units to the fingers. The test was named after the American surgeon Sterling Bunnell (1882–1957), one of the founding fathers of hand surgery and the first president of the American Society for Surgery of the Hand (ASSH). This test is also named the Finochietto test, the Finochietto–Bunnell test and the Bunnell–Littler test. The underlying biomechanical phenomenon was first described⁴ in 1920 by the Argentinean surgeon Ricardo Finochietto (1888–1962), who later became the head physician for Eva Perón, the wife of Juan Perón the tenth president of Argentina. Later descriptions are by Parkes in 1945⁵ and Bunnell in 1948,⁶ albeit apparently without knowledge of and therefore reference to their predecessor(s).

The biomechanical basis of this test is that when the MCP joint is held in extension, the tension in the MCP joint capsule and the aforementioned tendons as well as the more distal portion of the extensor apparatus increases, allowing less flexion of the PIP and DIP joints. Conversely, when the MCP joint is held in flexion, the tension in the MCP joint capsule and the aforementioned tendons as well as the more distal portion of the extensor apparatus decreases, allowing more flexion of the PIP and DIP joints (Figure 48.1).

The Boyes test and the Elson test

The former test was named after the American surgeon Joseph Henry Boyes (1905–1995), one of the founding fathers of the ASSH, its first secretary–treasurer and its ninth president.⁷ In this test the PIP joint is held passively extended and an attempt is made to flex the DIP joint (Figure 48.2a). In a normal finger

Figure 48.1 (a) Bouvier test. (b) Bunnell test.

Figure 48.2 (a) Boyes test. (b) Elson test.

Figure 48.3 Finkelstein test.

this is possible and the test is negative. When the central slip has been ruptured, the tension in the lateral bands is increased and DIP flexion becomes increasingly difficult. This test is not very sensitive and only becomes positive later when the proximal part of the ruptured central slip has become retracted and adherent to the surrounding tissues.⁸

In more acute situations, when the Boyes test is less sensitive, other tests can be used, of which the Elson test was found the most reliable.⁹ This test is named after the British orthopaedic surgeon Reginald A. Elson MB BCh Cambridge, FRCS (1930). In this test the PIP joint is flexed 90° over the edge of a table, and the patient is asked to extend the joint against resistance. In a healthy finger the examiner can feel the pressure of the extending PIP joint and the DIP remains flail. In case of a central slip lesion, the possibility of active PIP joint extension is severely diminished and the lateral bands remain proximal and consequently taut, rendering the DIP joint rigid with a tendency to extension (Figure 48.2b).

The Finkelstein test

The Finkelstein test for de Quervain's disease was first described by and named after the American surgeon Harry Finkelstein (1865–1939). In the original implementation of this test the

examiner grasps the patient's thumb and deviates the hand ulnarly. The test is positive when this movement elicits excruciating pain over the tip of the radial styloid. Another test for de Quervain's disease was described earlier by the German surgeon Erich Eichhoff.¹⁰ In the Eichhoff test the patient's thumb is placed in the patient's hand and the other fingers closed around the thumb, holding it tightly. Then the examiner bends the hand severely in ulnar abduction. The test is positive when an intense pain is experienced on the styloid process of the radius. Often the Eichhoff test is assumed to be the Finkelstein test. This is probably due to the fact that both are being mentioned in Finkelstein's original paper in which the quoted description of the Eichhoff test takes up an elaborate 236 words while the description of Finkelstein's own test takes up only 19 words and is therefore easily overlooked.

A disadvantage of both Eichhoff and Finkelstein tests is that they can elicit pain in healthy subjects and therefore have a high sensitivity but a low specificity. This is the reason that nowadays more subtle versions of the latter are being used with a more staged loading of the involved first dorsal extensor compartment and tendon (Figure 48.3).¹¹ Quantitative information about the sensitivity, specificity or the positive or negative predictive value of the Eichhoff and Finkelstein tests or their more sophisticated offspring is not yet available.

Nerve (specific nerve testing)

Many techniques for evaluating sensibility have been described. Interestingly, even today consensus is lacking. How do we test sensibility in the hand? This may appear an easy question to answer. However, simplicity may deceive, in many hand surgery departments different tests scoring gnostic modalities are being used. If we unravel the problem, it can be brought down to the following: there are a number of requirements for adequate testing.¹²

- The test should have a quantitative outcome. Simply asking 'Do you feel this, does it feel different from over here or different from the same area of the other hand?' is not sufficient. This may all seem exaggerated, but we are often confronted with information about the sensibility of the hand that resembles this. It can be even worse: 'We already applied local anaesthesia, but I think that the sensibility was normal'.
- It should be a test that correlates with function of the hand. For example, the fact that touch is being perceived does not mean that that sensibility is useful in daily living and in the workplace.
- It should be tolerable for the patient. Testing sensibility with a needle is cruel to the patient, especially if the sensibility is not abnormal! In children, introducing such an instrument will

directly end any cooperation and repeated tests will not be accepted.

- The test should be reproducible in time and it should be reproducible between different technicians.
- Especially nowadays, the test should be affordable and it should not be time consuming.

Tests can be divided into innervation density and touch threshold tests. The *innervation density test* scores the number of available and working axons and receptors, whereas the *threshold test* gives information on the required force of the stimulus to elicit a response by the mechanoreceptors. Innervation density is tested by static and moving two-point discrimination tests. Temperature and pain are seen as protective sensibilities: temperature thresholds can be measured and pain is scored on a visual analogue scale to demonstrate the severity. The use of these different modalities is demonstrated by evaluating the results of median nerve reconstruction as an example. Numerical grading scales to evaluate the function of sensory and motor nerves have been described. Different aspects of combined sensory and motor recovery will be scored as a number. Its applicability is demonstrated by comparing pre- and postoperative results of ulnar nerve decompression at the elbow.¹³

(b)

(c)

(d)

Figure 48.4 Hoffman/Tinel's examination. (a,b) In carpal tunnel syndrome. (c) In cubital tunnel syndrome. (d) Sensory branch of radial nerve.

Tinel/Hoffmann sign

The Tinel sign is named after the French neurologist Jules Tinel (1879–1952). Both he and, only months before him, the German physiologist Paul Hoffmann (1884–1962) described the generation of paraesthesias radiating into the area of distribution of a particular nerve due to putting pressure on it or tapping on it respectively. The hypothesis is that the sign occurs because the incompletely myelinated sprouting fibres of damaged or compressed nerves are increasingly sensitive to mechanical stimuli.

The Hoffmann/Tinel's test is a specific test for carpal tunnel syndrome and can be used as indication for medical management (Figure 48.4). The Hoffmann/Tinel sign is positive in 51–54% of cases of symptomatic carpal tunnel syndrome and is 80% positive in pronator syndrome. No numbers are known for cubital ulnar neuropathy.^{14–17}

For carpal tunnel syndrome:^{18–24}

- Sensitivity: 23–73%
- Specificity: 87–94%
- Positive predictive value: 0.75
- Negative predictive value: 0.41
- Level of evidence (Oxford Centre for Evidence-based Medicine): 1c.

Phalen's test

Phalen's test is named after the American orthopaedic surgeon George S. Phalen (1911–1998) and is used to aid in the diagnosis of carpal tunnel syndrome. Phalen's test consists of passive flexion of the patient's wrist for 15–60 s. The test is considered positive when the patient experiences tingling or numbness in the median nerve distribution. This test increases carpal tunnel pressure (CTP), and therefore the pressure on the median nerve, which is believed to be one of the causes of carpal tunnel syndrome. The increase in CTP during Phalen's test is probably caused by a decrease of the cross-sectional area of the carpal tunnel.

The reverse Phalen's test consists of passive extension of the patient's wrist for 15–60 s. The test is considered positive when

the patient experiences tingling or numbness in the median nerve distribution. The increase in CTP in this test is higher than the normal Phalen's test. A possible explanation for this is that wrist extension not only results in a decreased cross-sectional area of the carpal tunnel at the pisiform level but also a constriction of the proximal end of the carpal tunnel due to the incursion of the flexor digitorum superficialis and flexor digitorum profundus muscle bellies.

Phalen's test is positive in 48–87% of cases of symptomatic carpal tunnel syndrome, with a mean time of 18.4 s.^{24–26}

- Sensitivity: 10–80%
- Specificity: 55–86%
- Positive predictive value: 0.78
- Negative predictive value: 0.49
- Level of evidence (Oxford Centre for Evidence-based Medicine): 1c.

The Phalen's manoeuvre has been found to be more sensitive than Tinel's sign.²⁷

Reverse Phalen's test

This test can be performed by having the patient maintain full wrist and finger extension for 2 min (Figure 48.5). The reverse Phalen's test significantly increases pressure in the carpal tunnel within 10 s of the change in wrist posture and the CTP has the tendency to increase throughout the test's duration. In contrast, the change in CTP noted in the standard Phalen's test is modest and plateaus after 20–30 s.

Froment's sign

Froment's sign is used to evaluate the motor function of the ulnar nerve. The patient is asked to hold a piece of paper between the volar side of the thumb and the radial side of the index finger. The examiner pulls on the paper while instructing the patient to hold on it. Patients with adequate function of the first dorsal interosseous and adductor pollicis muscles will keep the IP joint of the thumb in an extended position. In case of weakness, the patient will need to flex the IP joint to be able hold on

(a)

(b)

Figure 48.5 (a) Phalen's test. (b) Reverse Phalen's test.

to the paper using the flexor pollicis longus (and also (hyper) extending the thumb MCP joint to stabilize it: Jeanne's sign).

Jeanne's sign

Jeanne's sign is used to evaluate the motor function of the ulnar nerve. In case of pathology of the ulnar nerve, the patient needs to hyperextend the MCP joint of the thumb to create lateral stability to compensate for the thumb adductors.

Wartenberg's sign

This is used to evaluate the motor function of the ulnar nerve. The patient is instructed to keep the fingers extended. If the patient has pathology of the ulnar nerve, the little finger deviates ulnarly because of dysfunction of the third palmar interosseus and the ulnar directing force of the extensor digiti minimi. This is not present in all the patients. This is related to the eccentric insertion and pull of the extensor digiti minimi onto the 5th digit abducting the digit unopposed by intrinsic hand adductors.

Scratch collapse test

This is a new diagnostic test for carpal tunnel syndrome and cubital tunnel syndrome in which the examiner scratches the patient's skin lightly over the area of nerve compression, while the patient performs resisted shoulder external rotation bilaterally.

The test is performed as follows: patient facing examiner, arms adducted, elbows flexed, hands outstretched and wrist neutral (Figure 48.6). The examiner gently pushes against both the forearms, asking the patient to sustain steady resistance. With the fingertips, the examiner scratches/swipes the skin overlying the potentially compressed nerve. A positive test is recorded if the patient demonstrates a loss of resistance in the affected side after 'scratching' the respective tunnel. Loss of resistance is brief, with the patient regaining strength essentially immediately.

The positive predictive value for all tests was high for carpal tunnel syndrome, with the scratch collapse test having the highest value (99%), followed by wrist flexion/nerve compression (98%) and Tinel's (96%). Negative predictive values were also highest for the scratch collapse test (73%) followed by wrist flexion/nerve compression (65%) and Tinel's (59%). For cubital tunnel syndrome, the scratch collapse test had the highest positive predictive value (99%), followed by Tinel's (98%), and elbow flexion/nerve compression (96%). Negative predictive values, however, were highest for Tinel's (98%), followed by the scratch collapse test (86%) and elbow flexion/nerve compression (78%). Data analysis showed that the scratch collapse test was reproducible, with excellent interrater reliability, and had higher sensitivity than the other tests performed, for both carpal and cubital tunnel syndromes. The accuracy rate was 82% for diagnosing carpal tunnel syndrome and 89% for cubital tunnel syndrome.²⁸

Traditional nerve tests

Traditional tests are also divided into innervation density and touch threshold tests.

Figure 48.6 Scratch collapse test.

One-point discrimination test (Von Frey hairs)

The cutaneous threshold can be evaluated by the static and moving one-point discrimination tests and vibration. A static one-point discrimination test can be performed by either Semmes Weinstein filaments or quantitative sensory testing (QST) (Figure 48.7). Other tests that are available are combined tests that will score both sensory and motor function, for example the pick-up test and the Moberg recognition test.

Semmes Weinstein filament test, and its variant the Weinstein Enhanced Sensory Test (WEST, e.g. WEST-hand), present nylon monofilaments of roughly the same length (38 mm) but of varying diameters. The diameter and length are used to control the force applied. Whereas Dr Weinstein used three-digit numbers to reflect the force of the Semmes Weinstein aesthesiometer (three-digit number equals the common log of the force measured in tenths of a milligram), the WEST aesthesiometers (also created by Weinstein and group) use grams (e.g., 0.70 g) to describe the force.

There is a low correlation between pressure sensitivity and spatial threshold (divergent validity) and between pressure threshold and cortical area. However, the Semmes Weinstein monofilaments correlate with object recognition time and object identification.^{29–32}

- Level of evidence (Oxford Centre for Evidence-based Medicine): 3a.

Two-point discrimination test

This test will demonstrate the innervation density. Originally described by Weber and modified by Moberg, it will evaluate the slow-adapting fibres. In compressive neuropathies the reproducibility has been difficult due to bias in the application forces of the two prongs.

The test can be performed as a static or dynamic test. In static two-point discrimination the device will be applied to a small area and will require near-normal sensation to be discerned by the patient. In the moving variation a larger area is tested. This can still be felt after static two-point discrimination is not being detected. If the prongs can only be felt at a wider interval, the innervation density is diminished.^{33–35}

There is a strong correlation between two-point discrimination and object identification. Poor two-point discrimination can be functionally limiting. The cutaneous pressure threshold is

inversely related to static two-point discrimination (regardless of age or presence of compression or neuropathy).^{36–40}

Quantitative sensory testing

Quantitative sensory testing (QST) has been described as the result of subjective tests of sensibility that require conscious recognition of the stimulus in contrast to electrodiagnostic testing. It can be used to evaluate thermal, pressure and vibration perception. Advantages of QST over traditional nerve testing are the uniform non-logarithmic scale for one-point discrimination and the known application force for two-point discrimination (see Figure 48.7). The multiplication of the distance between the prongs and the application force can be used as a constant factor (e.g. if the prongs are at the 4 mm distance the force to discern may be 6 g/mm, if the prongs are wider apart, to 6 mm, the application force needed will be smaller: 4 g/mm. However, the multiplication will remain constant.⁴¹

Unfortunately we need more evidence from future studies that the use of QST for the non-invasive assessment and quantification of sensory nerve function is more accurate than conventional tests. Cutaneous pressure threshold measurements with QST had a statistically significant correlation with the small-object subset of the Mayo Dexterity Test and with the object recognition test, demonstrating that QST is a valid tool for evaluating the sensory aspect of hand function. Also QST has a high sensitivity but a low specificity when compared with electrodiagnostic testing for diagnosis of peripheral nerve entrapment.^{42,43}

Moberg pick-up test

This test will evaluate motor and sensory function. The Moberg recognition test has also been described. Both tests will score the handling and recognition of small objects within a certain time frame.

Figure 48.7 Sensibility testing. (a) Monofilament. (b) Disk-Criminator. (c) Pressure-specified sensory device.

In the pick-up test, small objects used in daily life, such as buttons, keys, paperclips, screws, bolts etc., are picked up and placed into a small box. This can be performed with or without visual aid. The times that are needed to complete the tasks are recorded. For the recognition test, the number of objects identified without visual support in a given time frame is scored.³⁵

Electrodiagnostic testing

In 1666 Francesco Redi described the first experiments in clinical neurophysiology. He discovered that a specific muscle in an eel created electricity. It was Luigi Galvani who described in his publication ‘De viribus electricitatis in motu musculari commentaries’ the fact that electricity could cause muscle contraction. It was not until 1960 that electrodiagnostic testing (EDT) testing could be used clinically.

EDT is critical in the diagnosis of many neuromuscular and peripheral nerve problems (Table 48.1).

EDT can be divided into nerve conduction velocity (NCV) and electromyography (EMG). NCV describes the speed with which an electric pulse is transmitted along a sensory or motor nerve, and the strength of the conducted impulse: amplitude height. If two different sites along the nerve or two different nerves are being compared, this can be used to obtain the conduction velocity. If only one site can be recorded for the impulse to travel distally over the nerve, this is called distal latency.

Table 48.1 Main indications and disadvantages of electrodiagnostic testing

Main indications	
Localization of nerve lesion	Radiculopathy
Progression of nerve lesion	Resolution neuropraxia
	Reinnervation following nerve repair
	Progression inflammatory neuropathy
	Status brachial plexus
Evaluation of systemic disease	Peripheral neuropathy
	Drug toxicity
	Neuromuscular dysfunction
	Myopathy
	Inability of patient to communicate
Verification of suspected nerve problem	Suspected malingering
	Martin–Gruber connection
Disadvantages	
Neurophysiology	Large myelinated fibres preferentially recorded
Pathophysiology	Sparing central fibres
	Uneven fibres loss among fascicles
	Incomplete remyelination
Anomalous innervation	Radial sensory nerve to thumb
	Overlap lateral antebrachial cutaneous nerve with radial sensory nerve
	Lateral sural nerve entrapment
	Temperature
Technique	Patient age
	Patient height
	Site along nerve

EMG evaluates the status of innervated muscle through a needle placed into the muscle. A normal muscle will display an M-wave, which is a depolarization with a short interval. If there is no or diminished activity, this suggests a denervated or fibrotic muscle, or both. A normal muscle is electrically quiet, however in denervated muscle spontaneous depolarization will occur, showing fibrillation potentials. These are, in fact, small M-waves.³⁵

In a third of the clinically symptomatic patients for carpal tunnel syndrome, the EDT is normal.

For ulnar nerve compression at the elbow, the results of the EDT do not predict the results of conservative or surgical management.^{44,45}

Neuropathic pain: diagnostic blocks

Diagnostic blocks are used to obtain information about the source of a patient’s pain. As such they differ in principle and in practice from regional anaesthetic blocks. In order to be valid, diagnostic blocks must be precise and target-specific. The involved nerve should receive a field block proximal to the point of maximal pain. Lidocaine (lignocaine) is most frequently used due to its early action and its short duration. We have shown that that a positive nerve block can predict a successful denervation.⁴⁶

Ligament (systematic exam) – scaphoid–lunate interval

Scaphoid shift test (Watson)

This test is used to diagnose insufficiency of the scaphoid-lunate (SL) ligament, scaphoid fracture and radio-scaphoid osteoarthritis. The arm is resting on the elbow. The examiner places his or her index and middle finger on Lister’s tubercle, with the thumb is on the distal pole of the scaphoid (Figure 48.8). The wrist is in a neutral position for flexion and extension. The wrist is in ulnar deviation and is brought to radial deviation. The scaphoid will move from an extended position to a flexed position. If the SL ligament is insufficient, the scaphoid will move dorsally in relation to the scaphoid fossa of the radius. Releasing the pressure on the scaphoid will cause a clunk. If this clunk is painful, a ligament tear is suspected. If the test is painful without a clunk, pathology of the scaphoid or the radiocarpal joint is possible.⁴⁷

Ballottement test

This is used to detect pain over the SL interval indicating a complete or partial rupture or occult ganglion. The examiner fixes the lunate palmar and dorsal with the thumb and index and the scaphoid with the same fingers of the other hand. When moving in opposite directions this will cause translation over the SL interval. The test is positive if pain and/or increased movement is present.

Finger extension test (Schuck test)

This test is used to detect pain over the SL interval, which indicates predynamic instability or occult ganglion. The examiner holds wrist and MCP joints in flexion. The patient is asked to extend the PIP and DIP joints of all fingers against resistance. If pain is elicited, the test is considered to be positive.⁴⁸

Figure 48.8 Watson test.

Ligament (systematic exam) – lunotriquetral interval

Ballottement test (Reagan's test)

Reagan's test is used to detect pain over the lunotriquetral (LT) interval, indicating a complete or partial rupture or occult ganglion. The examiner fixes the lunate palmar and dorsal with the thumb and index and the triquetrum with the same fingers of the other hand (Figure 48.9 top). When moving in opposite direction this will cause translation over the LT interval. The test is positive if pain and/or increased movement is present.

Lunotriquetral shuck test (Kleinman's shear test)

This is used to detect pain over the LT-interval, indicating a complete or partial rupture or occult ganglion. The patient's elbow is positioned on the table in a neutral position. The examiner fixes the lunate palmar and dorsal with the thumb and index, while the examiner pushes the pisiforme dorsally.

Midcarpal instability (Lichtman's test)

Lichtman's test is used to diagnose midcarpal instability. The examiner fixes the all metacarpals with one hand and the forearm with the other hand. Under axial loading the wrist (neutral for flexion and extension) is brought from ulnar to radial deviation. The test is positive if a painful clunk is felt.

Distal radioulnar joint translation test

This is used to evaluate the integrity of the volar and dorsal radioulnar ligaments (RUL). The patient's elbow is flexed 90° resting on a table. The wrist is neutral in regard to pronation and supination. The radius and the ulna are both stabilized between a thumb and an index finger. The amount of translation is

evaluated in neutral, full pronation and supination. The latter two are used for evaluation of both dorsal and volar RULs, respectively (Figure 48.9, lower panels). A test is considered positive if a clear difference with the contralateral side is detected.

Ulnar abutment

The ulnar abutment test is used to evaluate the integrity of the volar and dorsal RULs. The examiner stabilizes the patient's hand and places his or her thumb on the distal ulna. The other hand is used to stabilize the forearm. Then the patient's wrist is fully deviated in ulnar direction and the forearm is supinated and pronated. A test is considered positive if a pain and/or a click is present.

Pisiform grind test

This is used to diagnose pathology in the piso-triquetral (PT) joint. The examiner holds the hand while palpating the pisiform, applying shear force pushing it into the triquetrum. The test is positive if pain is present during the manoeuvre.

Trapeziometacarpal joint translation test

Test used to assess the laxity of the trapeziometacarpal (TMC) joint. The base of the first metacarpal is fixed between thumb and index and translation should be evaluated and compared with the contralateral side.

Grind(ing) test

The grind test or grinding test of the carpometacarpal (CMC) joint of the thumb implies a combination of rotation and axial compression of the joint. The test is considered positive if it

Figure 48.9 Distal radioulnar joint test.

elicits pain in the examined joint. The test can be executed by grasping the basal phalanx but this also stresses the MCP joint. To pressure only the thumb CMC joint, the thumb metacarpal should be grasped instead.

When the grind test is compared with the Eaton and Glickel system for radiologic staging of CMC osteoarthritis as the gold standard, the interrater reliability and the criterion validity of the grind test are as follows:

- Kappa value: 0.48
- Sensitivity: 42–53%
- Specificity: 82–93%
- Positive predictive value: 91–96%
- Negative predictive value: 68–70%.⁴⁹

Motor assessment

The Medical Research Council scale

In 1911 the Parliament of the United Kingdom passed the National Insurance Act, proposed by David Lloyd George as Chancellor of the Exchequer. Although its primary purpose was to provide the British working classes with their first contributory system of insurance against illness and unemployment, it also created a national fund for medical research. The Research Committee and Advisory Council that was set up in 1913, later in 1919 becoming the Medical Research Council (MRC), coordinated this research. Against the background of the vast numbers of nerve injuries in World War I and the start of World War II in 1939 the MRC formed a Nerve Injuries Committee that in 1942

published the first edition of *Aids to the Investigation of Peripheral Nerve Injuries*.⁵⁰ This atlas shows doctors how to examine limbs for peripheral nerve lesions and also contained the MRC scale for muscle strength. This scale divides strength into grades 0–5:

- Grade 0 – No contraction
- Grade 1 – Flicker or trace of contraction
- Grade 2 – Active movement, with gravity eliminated
- Grade 3 – Active movement against gravity
- Grade 4 – Active movement against gravity and resistance
- Grade 5 – Normal power.

Contrary to what these numbers suggest, this scale is not linear but more of an exponential nature because most muscles only need a minor percentage of their normal strength to overcome gravity. This percentage is different for every muscle, being about 2% for the biceps muscle and about 24% for the hip abductors.⁵¹ Consequently, for these muscles grades 0–3 cover respectively 2% and 24% of the normal muscle strength and grades 4 and 5 cover the remaining 98% and 76%, respectively. This means that only two grades (4 and 5) are available to describe the entire functional range of muscle strength. Knowing that manually tested muscle strength in the higher ranges is often overestimated⁵² up to a level that patients having only 50% of their normal muscle strength can be judged as normal,⁵³ it can be concluded that the MRC scale has its limitations with respect to the assessment of the percentage of normal strength. For this purpose dynamometry seems to be more suitable, except in clinical situations where a dynamometer cannot be used.

Grip strength

A sufficient amount of grip strength is necessary for the independent execution of the activities of daily living. When grip strength is going to be measured it should be noted that not all grip types are equally relevant. When measuring strength after carpal tunnel surgery, tip pinch dynamometry is more sensitive to median nerve function because it specifically targets the thenar musculature.⁵⁴ Maximum grip strength is achieved with the wrist in 35° extension.⁵⁵ In the case of five different hand dynamometer grip sizes the graph of the strength measurements at the five handle positions forms a bell-shaped curve with the greatest strength in the middle position. In the widest handle position the force is predominantly generated by extrinsic muscle action and in the smallest handle position predominantly by the intrinsic muscle action. When the strength of one hand is compared with the healthy contralateral one there is usually assumed to be a 5–10% difference in favour of the dominant hand. However, in 20–30% of the normal population the non-dominant hand is equally strong or stronger than the dominant hand.^{56,57}

Imaging

Plain film

Plain films are the basis of the work-up for pathology of the hand and wrist. Correct positioning of the hand and forearm is critical to obtain the required information.

For the fingers, views in three directions are needed in order to be able to evaluate pathology: posterior–anterior (PA), lateral and three quarters views.

The hand should be evaluated using PA and three quarters views. In most instances the lateral is not useful, but may be required on indication (e.g. carpal bossing, dorsal avulsion fracture of carpus, etc.).

For plain films of the hand and wrist, the shoulder should be abducted 90° and the elbow flexed 90°. This ensures a true posterior–anterior view of the wrist.

Special views can be obtained on indication, for example:

- Robert's view (to evaluate the TMC joint);
- carpal tunnel view (to evaluate fracture of the hook of the hamate);
- special fist view, ulnar/radial deviation (to evaluate the intercarpal ligaments of the proximal row: SL and LT).

There is only anecdotal evidence to be found on the clenched fist view for X-radiographs when SL ligament injury is suspected. One study comparing different views of the SL ligament concluded that a clenched fist view with 30° ulnar deviation (AP) resulted in the biggest SL gap: a Terry-Thomas sign of 4.55 mm (same as in a clenched pencil view).^{58–61}

- Level of evidence (Oxford Centre for Evidence-based Medicine): 4.

Ultrasound

Today musculoskeletal ultrasound offers quick, safe and relatively cheap visualization of the musculoskeletal system and the accompanying vessels and nerves. Initially the hospital's radiology department performed the majority of all ultrasound examinations. Nowadays gynaecologists and cardiologists perform their own ultrasound examinations and the rheumatologists are about to follow. According to this development it seems logical that in medical centres specializing in the treatment of patients with disorders of the hand and wrist, just as hand surgery became a specialism separate from orthopaedic or plastic surgery, the ultrasound examination of the extremities becomes a separate field of study. One of the major advantages of this is that the person performing the ultrasound examination can not only make a nice picture of the field or anatomical structure of interest but can also, because he or she is knowledgeable with respect to the disorder(s) the patient has or may have, confirm or deny diagnostic assumptions and actively pursue new diagnostic or therapeutic pathways. An additional advantage is the availability of more complex procedures such as the localization of nerves or other structures prior to operation, diagnostic ultrasound-guided nerve blocks using less local anaesthetics⁶² and ultrasound-guided palpation for a more precise localization of pressure-dependent pain.

CT scan

This modality is an important imaging technique for the hand and wrist. It was initially primarily used to evaluate fractures in three planes and in a three-dimensional fashion. Fractures of

Table 48.2 Comparison of MRI and MR arthrography for diagnosis of triangular fibrocartilage complex (TFCC) tears

	MRI				MRA			
	Sens (%)	Spec (%)	PPV	NPV	Sens	Spec	PPV	NPV
TFCC central	70.3	100	100	50.0	95.0	100	100	85.0
TFCC peripheral	60.0	100	100	85.0	93.0	97.0	88.0	97.0
TFCC full thickness	75.0	81.0			84.0	95.0		
1.5T	70.0	79.0			83.0	95.0		
3.0T	86.0	100			100	100		

MRI, magnetic resonance imaging; MRA, magnetic resonance arthrography; Sens, sensitivity; Spec, specificity; PPV, positive predictive value; NPV, negative predictive value.

the carpal bones can be visualized especially well (e.g. avulsion fractures of the triquetrum).

In osteoarthritis of hand and wrist, a CT scan can show the exact extent of the damaged cartilage in a multiplanar fashion. The distal radial ulnar joint is difficult to evaluate on plain films due to the configuration of the joint. For example, we have shown that CT will show the extent of scaphotrapezotrapezoidal joint arthritis in more detail than plain films. Other areas for CT scans are, for example, bone tumours and vascular pathology (CT angiography). For soft tissue and in the presence of metal implants CT scanning has clear limitations.

With the use of intra-articular dye, CT arthrography has been shown to be useful for detecting SL ligament, LT ligament and central triangular fibrocartilage complex (TFCC) tears with high sensitivity and specificity. It is not as accurate at identifying peripheral tears.^{63,64}

MRI scan

In the last decade MRI has earned its place in the care of the hand and wrist. It is the scan of choice for soft tissue pathology. The improvement in the quality of the coils and the scanners has catapulted the modality forward. Also, avoiding radiation has clear health benefits.

Clinical applications are soft tissue tumours: ganglion cysts, giant cell tumours, lipomas, vascular tumours and bone tumours (e.g. enchondromas).

Occult fractures of the forearm, wrist and hand can be detected by a cortical break with bone bruising. In case of suspicion of a fracture non-union, MRI is better at showing this than plain films. Also ulnocarpal abutment can be seen by the early bone marrow oedema prior to the formation of cysts.

Infections can be detected, especially (chronic) osteomyelitis in the absence of clear abnormal infectious parameters.

In case of avascular necrosis of bone, MRI can demonstrate reduced vascularization in the early stages, making it useful in the diagnosis of Kienbock's and Preiser's disease.

The use of intra-articular dye has improved MR imaging for ligamentous injuries in the wrist, ligamentous injury to the thumb, MCP collateral ligaments, SL and LT ligaments and the TFCC.

When ulnar wrist pain exists without clinical instability on the ulnar side, additional work-up should be considered. MRI with or without intra-articular contrast is the choice. Pathology of the TFCC, LT interval, extensor carpi ulnaris and subsheath, quality of cartilage on the lunate fossa, lunate, distal radioulnar joint and distal ulna and synovitis can be seen. High-resolution MRI was able to diagnose distal radioulnar ligament, palmar radioulnar ligament or ulnolunate ligament injuries accurately.⁶⁵ The major limitations are asymptomatic tears in the central and/or peripheral TFCC and the LT ligament due to normal wear. For pathology of Palmer class 1B or 1C, MRI may give false-negative results.

Rüeggger reported that these tears often appear as non-communicating tears extending from the distal radioulnar joint into the triangular fibrocartilage.⁶⁶

With regard to the diagnostic accuracy of MRI and MR arthrography in the diagnosis of TFCC tears (central and peripheral), overall we can state that MR arthrography has a better prognostic value in diagnosing TFCC tears (Table 48.2).⁶⁷⁻⁶⁹

- Level of evidence (Oxford Centre for Evidence-based Medicine): 1a.

Bone scan

A bone scan or bone scintigraphy or three-phase radionuclide bone imaging (TPBI) is a technique in which a phosphorous-based compound attached to a radioisotope is administered to the patient by an intravenous injection. The most popular radioisotope is technetium-99m, which has a short (6h) half-life, limiting the radiation exposure of the body. Although the exact mechanism by which the phosphorous-based compound is metabolized and associates with the bone is unknown, three phases can be discerned in its distribution through the body. In the first phase, the first seconds after the injection, which is called the intravascular radionuclide angiogram phase, the tracer predominantly occupies the blood vessels. This phase can be used to check for the presence of vascular abnormalities with decreased or increased perfusion. In the second phase, 5–8 min after injection, which is called the blood pool or tissue phase, the tracer predominantly occupies the extravascular, extracellular spaces. This phase can be used to assess the relative vascularity to the area of interest, which can be useful in inflammatory lesions. In the third phase, 3–4h

after the injection, which is called the delayed or metabolic image phase, the majority of the radioisotope has been metabolized. This phase can be used to assess the location of areas with an increased level of bone turnover, such as fractures or osteomyelitis. Sometimes fourth-phase images can be made, 18–24 h after the injection, showing further increased uptake. This phase can be used to diagnose osteomyelitis in patients with delayed metabolism of the tracer due to decreased perfusion, such as in diabetes mellitus and/or peripheral vascular disease.⁷⁰

When radioactive substances are administered to a patient the resulting amount of ionizing radiation is always an important issue. A bone scan for a 70 kg adult results in a total body radiation load of about 1.3 mSv, which is about 216% of the worldwide average annual artificial radiation exposure of about 0.6 mSv. This being said it should be noted that the ovaries load (2.4–3.4 mSv), the testes load (1.6–2.2 mSv) and especially the bladder wall load (26–62 mSv), are considerably higher, although the latter disappears with voiding after 2–5 h.⁷¹

Dynamic conventional X-ray/fluoroscopy

The first fluoroscopic image was observed on 8 November 1895 by Wilhelm Röntgen when he saw a barium platinocyanide screen lighting up while being exposed to X-rays. The earliest fluoroscopes consisted of nothing more than an X-ray source and a fluorescent screen, hence the name fluoroscopy or fluorography. Unlike conventional X-ray examination, fluoroscopy allows the visualization of movement of structures within the body, although at the expense of a prolonged exposure to X-rays. The detrimental effects of the latter were already known to Thomas Alva Edison, who therefore in 1903 terminated his research on fluoroscopes. Nevertheless, between 1930 and 1950 fluoroscopes could be found in shoe shops in the United States, Canada and the United Kingdom to aid in the fitting of shoes.⁷² The mediocre quality of the created image and the relatively high radiation exposure initially limited the usefulness of fluoroscopes in the medical context. Later the invention of the X-ray image intensifier and the more sensitive flat-panel detector solved the first problem and, together with the invention of mini C-arms, decreased the second one, allowing fluoroscopy to become a generally accepted technique in hand surgery. Nevertheless, the longer exposure times in fluoroscopy and therefore the increased exposure to artificial radiation compared to conventional roentgenograms remained a controversial issue.

In patients with an SL distance of ≤ 3 mm, the sensitivity and specificity of cineradiography for ligament injury of the wrist^{73–75} is high (accuracy 0.93). This accuracy is higher than that for radiography alone (0.81). The accuracy of cineradiography is 0.90 when the SL distance is ≥ 3 mm (on conventional radiography).

- Sensitivity: 85–90%
- Specificity: 95–97%
- Positive predictive value: 0.94–0.98

- Negative predictive value: 0.86
- Level of evidence (Oxford Centre for Evidence-based Medicine): 2b.

Safety issues

During hand surgery with an average fluoroscopy time of 51 ± 36.9 s the surgeon's hands are exposed to an average $\pm$ SD of 0.2 (range 0.05–0.8) ± 0.12 mSv/case. This means that it will take an annual average of 2500 fluoroscopy-assisted operations to reach the 500 mSv/year limit for hand exposure. It can be concluded that it is virtually impossible for a hand surgeon to even approach this limit. That being said, one should know that the given annual dose limits have been calculated by extrapolation of data from medical occupational exposures, atomic bomb survivors and nuclear accident survivors and are not based on hard science. Consequently, the risk of low-dose exposure resulting in life shortening, somatic and heritable mutations is difficult to calculate. Currently most radiation biologists and geneticists assume that no dose of radiation can be considered completely safe and its usage must be determined on a risk-versus-benefit analysis. As a result of this it is advisable to use the as low as reasonably achievable (ALARA) principle with respect to the fluoroscopy-related radiation exposure by following the generally available suggestions regarding the settings of the mini C-arm and the distance and the position relative to the fluoroscope.

CHAPTER 49

Congenital hand differences

Bran Sivakumar, Jonathan Adamthwaite and Paul Smith

Department of Plastic Surgery, Great Ormond Street Hospital, London, UK

Embryology of congenital hand differences

Introduction

The upper limb bud develops from the flank of the developing embryo from day 26.¹ Somatic lateral plate mesoderm forms the skeleton and mesoderm from somites migrates in to form the musculature and contributes to the vascular system. Fibroblast growth factors initiate development along three axes with the interaction of signalling centres: *proximodistal* axis controlled by the apical ectodermal ridge (AER);^{2,3} *anteroposterior* (radioulnar) controlled by the zone of polarizing activity (ZPA); and the *dorsoventral* (or dorsovolar) controlled by the wingless gene encoded protein (Figure 49.1). Genes and their encoded proteins control growth and differentiation and act as messengers between signalling centres and developing cells. Mutations, whether inherited or spontaneous, disrupt secreted proteins, ligand factors and transcription factors. Environmental factors including drugs (e.g. thalidomide), radiation, nutrition and infection can also disrupt molecular pathways.

Timeline

The limb bud contains a core of proliferating mesenchymal cells covered by ectoderm which thickens at the tip to form the AER. The spinal nerves grow into this and an initial capillary network coalesces into a main stem artery, which drains into a marginal vein. The mesoderm organizes into the ZPA and a progress zone (PZ). By day 33, there is a paddle-shape limb with pre-chondrogenic condensations at sites where cartilaginous skeletal elements will form. Chondrogenesis takes place and myoblasts migrate into the limb and aggregate into ventral and dorsal muscle masses by day 36. At six weeks, digital rays form, giving the hand a webbed appearance and at seven weeks the upper limb rotates by 90° and the elbow flexes, bringing the palm anteriorly. Ossification occurs in parallel and apoptosis between rays leads to tissue involution and digital separation. Thus by week 8 a miniature adult upper limb is formed¹ (Table 49.1).

Limb patterning

Research into the developing chick embryo has provided a great deal of information on the process of limb patterning. In the proximodistal axis, the AER drives proliferation and bud outgrowth, secreting fibroblast growth factors, in particular FGF 2, 4 and 8.^{4,5} AER resection leads to a truncated limb, whereas AER grafting extends the limb. In the anteroposterior (radioulnar) axis, the ZPA is on the ulnar side between the polarizing region (posterior limb bud mesenchyme) and limb bud tip mesenchyme. This secretes Shh, which is the product of the *sonic hedgehog* gene.⁶ If the polarizing region is grafted anteriorly, a mirror set of digits results. In the dorsoventral axis, the somite provides a dorsal signal to the mesenchyme, which dorsalizes ectoderm. Right ectoderm transplanted onto a left limb results in a right hand developing. *Wnt7a* from the dorsal ectoderm and *LMX1B* from the mesoderm coordinate tendon and ligament formation.^{7–9} Other important genes in limb patterning include *HOXD* (*HOXD13* mutations are associated with central polydactyly) and *GLI3* (mutations lead to polydactylies).^{2,10–12}

Classification of congenital hand differences

Although there have been multiple attempts to classify congenital hand differences, an entirely inclusive system remains elusive. A largely morphological system, first proposed in 1968¹³ then refined in 1976¹⁴ and 1983¹⁵ by Swanson, was adopted as the standard by the International Federation of Societies for Surgery of the Hand in 1976 and remains the most widely used (Table 49.2). However, approximately 10% of congenital hand differences do not fit into this classification, and some anomalies fit into more than one category. Extensions to this classification include those by Knight and Kay in 2000¹⁶ and Upton in 2006.¹⁷

In 2013, Tonkin¹⁸ presented a classification system based on causation, taking into account the growing body of knowledge

Figure 49.1 Development and patterning centres of the upper limb. Limb patterning is coordinated along three axis that are intimately linked through feedback loops. Outgrowth of the limb from proximal to distal is driven by the apical ectodermal ridge (AER). The anteroposterior axis is controlled by the zone of polarizing activity (ZPA) through the morphogen sonic hedgehog (*SHH*). Dorsal (D) and ventral (V) patterning is controlled via engrailed-1 (*EN1*), which is expressed in the ventral ectoderm and *WNT7A* whose expression is limited to the dorsal ectoderm.

Table 49.1 Timetable of upper limb development

Time point	Upper limb development
Day 26	Limb bud first appears
Day 33	Paddle-shaped hand present
Day 42	Digital rays present
	Hand assumes a webbed appearance
7th week	Upper limb rotates 90° laterally to bring the palm anteriorly
	Elbow begins to flex
	Ossification begins
	Involution of tissue between fingers occurs by apoptosis
8th week	Upper extremity resembles miniature adult upper limb

from molecular biology. He categorizes anomalies into malformations (an abnormal formation of tissue resulting from abnormal cell function), deformations (an insult to cells which have already formed normally) and dysplasias (a lack of normal organization of cells into tissue). Disruptions (alteration of tissue that is already formed) are considered alongside deformations. However, from a clinical point of view Swanson's system has proved the most practical to hand surgeons.

Syndactyly

A normal web ends at the midproximal phalanx on the volar side¹⁹ and an abnormal continuation beyond this level is termed syndactyly (from the Greek *syn*, together, *dactylos*, digit). Syndactyly is the commonest congenital hand abnormality with an incidence of 1 in 1000 live births. It is more common in white populations than in black and affects males more than females (46–84%). It is familial in 15–40% and can be unilateral or bilateral (25–50%).^{20,21} Syndactyly may affect the fingers and/or toes and most commonly presents as an

Table 49.2 Swanson classification of congenital hand differences

Failure of formation	Transverse arrest	Complete deficiencies
	Longitudinal arrest	Intercalated deficiencies
Failure of differentiation	Soft tissue	Radial (preaxial) longitudinal deficiency
	Skeletal	Central longitudinal deficiency
Duplication	Ulnar polydactyly	Ulnar (postaxial) longitudinal deficiency
	Central polydactyly	Syndactyly
Overgrowth	Radial polydactyly	Camptodactyly
	Ulnar dimelia	Trigger thumb
Undergrowth	Macrodactyly	Clasped thumb
	Brachydactyly	Clinodactyly
Constriction ring syndromes	Thumb hypoplasia	Symphalangism
	Groups 1–4	Synostosis
Generalized skeletal abnormalities	Achondroplasia	Arthrogryposis
		Windblown hand

First proposed in 1968 and adopted as the standard by the International Federation of Societies for Surgery of the Hand in 1976.

incomplete second web syndactyly in the foot. In the hand, the third web is most frequently involved (50%) (Figure 49.2a,b), followed by the fourth (30%), second (15%) and first (5%).^{19,20} A failure of apoptosis or programmed cell

Figure 49.2 Images of different types of syndactyly. (a) Incomplete, (b) complete, (c) complex, (d) complicated, (e) acrosyndactyly.

death is thought to be responsible during digit separation from days 41 to 53.²²

Syndactyly may occur in isolation. However, it is also associated with a number of syndromes including Poland's, Apert's and Greig's syndromes. It can also occur in conjunction with other limb deformities such as polydactyly and constriction rings.

Classification

Syndactyly is classified as follows²⁰ (see Figure 49.2)

- Incomplete or complete (extending to the distal phalanx)
- Simple (soft tissue only) or complex (with bony synostosis)
- Complicated (a haphazard arrangement of bones with loss of normal ray patterning)

- Acrosyndactyly (fusion of digits distally, from the Greek *acro*, meaning tip, with proximal fenestrations commonly associated with constriction ring syndrome).

Clinical examination

Inspect the syndactylized digits. With complete syndactyly, the nails may be fused with an inward rotation of the digits, which suggests the presence of a complex distal bony union (Figure 49.2c). The degree of skeletal disruption within a syndactyly tends to parallel the degree of soft tissue abnormality, including that of tendons and digital neurovasculature structures. It is important to examine for the presence of digital creases, which provides valuable information about the passive

and active joint range of motion which may also be abnormal. The status of the joints pre-separation must be established to ensure adequate counselling of patients and their families with regard to postoperative motion and function. Often a child and family will opt for the correct complement of digital number over function in equivocal cases.

In complicated syndactyly there is more than a just a bony synostosis, with a haphazard arrangement that can include extraskkeletal elements concealed within a digit with associated fusions, rudimentary bones, missing bones, abnormal joints and sometimes cross bones, which may span several rays²³ (Figure 49.2d). It can be uncertain which bones best match with which digits. In acrosyndactyly, there is a complex syndactyly characterized by fusion of the bone distally but not proximally with often fenestrations or sinuses proximally (Figure 49.2e). This is discussed later under Constriction Ring Syndrome.

Surgical principles and management

Timing of surgery

Timing is controversial. With a minor syndactyly the later the release the less likely there will be recurrence in the form of web creep.²⁴ To reduce anaesthetic risk most surgeons operate over the age of 1 year. Delaying separation in this way has the added advantage of larger anatomy, including that of the vasculature. Indications for earlier surgery include syndactyly involving the border digits (i.e. between the thumb and index and the little and ring fingers) where tethering of growth can occur due to marked discrepancy in digital length. This can result in compromised function, and, in neglected cases, flexion contractures. Early release is also advised in cases of complex and acrosyndactyly, where bony

fusions can also affect growth.²⁵ The aim is for all possible separations to be complete by the age of 5.²⁴

Technique

The aim is to achieve both optimal function and cosmesis. Release involves separation of conjoined skin and subcutaneous tissue, ligaments and bony synostosis while preserving the integrity of the neurovascular bundles. Subcutaneous fat may be removed in effort to facilitate closure and contouring.

Separation can be divided into reconstruction of the web, sides of the digits and tips including the paronychia folds.

Web reconstruction

Multiple techniques have been described using volar, dorsal or a combination of flaps of varying sizes and designs.^{26–31} The web is generally reconstructed with a proximally based dorsal flap. Grafts are best avoided in the webspaces as they can lead to problems of poor pliability and delayed healing with associated web creep. Large triangular flaps are practical and versatile (Figure 49.3). They allow for adjustments to be made around abnormal distal branching of digital vessels and avoid transverse scars that can recontract in the future. They must be designed in such a way as to create a gentle slope from dorso-proximal to volar-distal.

Release of the first web involves the use of Z-plasties (four-flap (Figure 49.4), double, double opposing, five-flap), transposition flaps (from the dorsum of the hand and index or thumb), pedicled and free flaps depending on the defect size following thumb and index separation.^{32,33} It is important to release the fascia on the first dorsal interosseous and the adductor muscles. Sometimes it is necessary to reinsert the adductor muscle more proximally.

Figure 49.3 Author's preferred technique for syndactyly release using interdigitating triangular flaps. Design of interdigitating flaps marked on volar and dorsal sides of simple complete syndactyly.

Reconstruction of the sides of digits

Most commonly, interdigitating flaps from the volar and dorsal aspects are used to close the defects along the borders of the digits (see Figure 49.3). Straight-line incisions along the borders should be avoided as they have a high incidence of scar contracture and subsequent digital deformity. A skin graft is usually needed in all but the most minor cases, as even in a simple syndactyly skin shortage is at least 36% of the circumference.³⁴ The graft should be full thickness from the groin, inner arm or antecubital fossa. Thick split-thickness grafts from the instep can be used in some cases of toe separation. Graft take may be improved with quilting onto the underlying soft tissues, and in the case of complex, directly onto bone. Graftless techniques tend to reduce abduction. Withey *et al.* described an open technique with

Figure 49.4 Preferred method of first web release using a four-flap Z-plasty.

thick split-thickness grafts used at the base of the inner sides of the released digits with a large number of triangular flaps. Any open areas were left to heal by second intention with good cosmesis.³⁵

Single-stage releases of both sides of a digit should be avoided as this may jeopardize digital vascularity in cases of anomalous vascular anatomy. For example, in short multiple syndactylous fingers, dominant digital vessels can only exist on the lateral sides of the conjoined fingers. Sometimes it is necessary to sacrifice one of the vessels in a distal bifurcation. The digital nerves can usually be gently separated more proximally.

Tips

In a complete syndactyly with separate nails or partly fused nails, on separation of the pulps the skin can generally be advanced to close the resultant defects. In conjoined nails without a ridge, the lateral nail fold requires reconstruction, most commonly with interdigitating flaps from the hyponychium (e.g. Buck-Gramcko 'stiletto' flaps)³⁶ (Figure 49.5). Care must be taken to ensure these paronychia reconstructions are not too bulky and do not leave an excessively narrow tip.

Clinodactyly

Clinodactyly (from the Greek *clino*, deviated, *dactylos*, digit) is a congenital deformity in the radioulnar plane at the phalangeal level. Incidence is reported as 1–19.5% depending on the degree of angulation used to define it.³⁷ It is inherited as an autosomal dominant trait with incomplete penetrance though the exact aetiology is unknown. The angulation commonly occurs as a result of a triangular-shaped 'delta' or

Figure 49.5 Buck-Gramcko stiletto flaps used for reconstruction of paronychia folds.

Figure 49.6 Formation of a trapezoidal phalanx as a result of a longitudinal bracketed epiphysis. (a) Growth on the side of the bracketed epiphysis is compromised. (b) Radiograph of a clinodactylous digit with a trapezoidal proximal phalanx.

trapezoidal middle phalanx (Figure 49.6), though more rarely the proximal phalanx can be involved. This is formed by an abnormal C-shaped epiphysis (longitudinal bracketed or comma-shaped), the arm of which extends onto the ulnar side of the middle phalanx (Figure 49.6a). The articular surface of the phalanx does not lie perpendicular to the longitudinal axis of the finger.^{38–41} The middle phalanx ossifies later than the other phalanges and latest in the little finger, hence clinodactyly occurs most commonly in the little finger. The thumb is the second most common. Clinodactyly most frequently occurs as an isolated familial abnormality. However it may also be linked to syndromes including Apert's syndrome (thumb), Trisomy 21, Poland's syndrome, Treacher Collins syndrome and Klinefelter's.⁴²

Clinical assessment

The most common presentation congenitally is in the little finger with radial deviation of more than 10°, seen at the proximal interphalangeal (PIP) and distal interphalangeal (DIP) joints, and a positive family history.⁴³ An acquired deformity may occur due to growth plate injury or deviation following syndactyly release. Kirner's deformity may be mistaken for clinodactyly. However Kirner's deformity represents a volar and radial curvature at the DIP joint. It most commonly affects females and appears between the ages of 7 and 14 years, often presenting as a painless swelling at the base of the nail.⁴⁴

A common presenting complaint with clinodactyly is cosmesis, as milder forms are not associated with any functional impairment. However with worsening angulation, function can become impaired. Radiographic assessment allows identification

of an abnormal or bracketed epiphysis. The status of the growth plate is an important factor in deciding treatment.

Surgical principles and management

As the abnormality is primarily skeletal and not corrected with growth there is little role for splintage or stretches. The main indication for surgery is worsening deviation with associated functional impairment. This commonly occurs with deviations of over 20–30°. Age and the status of the epiphysis are critical factors. If growing physiolysis with resection of the lateral physis and interposition of a fat graft can achieve good results with reliance then on the finger growing straight and correcting itself.⁴⁵ This is best done before the age of 6 years. Durability of this procedure is influenced by the extent of soft tissue release at the time of surgery.⁴⁶ Epiphyseal bar resection with fat grafting is best avoided in small triangular-shaped bones with minimal growth potential and best not repeated to avoid premature epiphyseal closure.⁴⁷ With persistent deformity or after completion of growth, correction is best achieved via osteotomy procedures. These include a closing wedge osteotomy where bony wedge is removed from the longer side in order to correct angulation. If length preservation is more critical an opening wedge, reverse wedge or dome osteotomy (Figure 49.7) may be more appropriate. However in this form of correction the soft tissue deficit on the shorter side must be addressed in order to facilitate correction and prevent recurrence in the long term. This can be achieved through techniques such as Z-plasties or local transposition flaps. Our preference whenever possible is for an opening wedge or dome osteotomy (see Figure 49.7) with longitudinal K-wire fixation.

Figure 49.7 A dome osteotomy for correction of clinodactyly. The dome is created via multiple K-wire holes in an arch configuration linked through of the use of osteotome or fine side cutting burr.

Camptodactyly

Camptodactyly (from the Greek *kampylos*, arched, *dactylos*, digit) is a congenital flexion deformity of the PIP joint (Figure 49.8). There are approximately 1 million cases in the United Kingdom per year. The little finger is affected most commonly (70%), then the ring (20%) and then the other digits (10%). Bilateral involvement is common and multiple digits can be affected.⁴⁸ Two common patterns of presentation exist. First, in the newborn age group, worsening during the 1–4 year growth spurt. In this group males and females tend to be equally affected. Second, in the adolescent growth spurt between 10 and 14 years of age, in which there is a female preponderance. The condition tends to not progress beyond skeletal maturity. Most cases are sporadic. However in 30% of cases it is inherited as an autosomal dominant trait.^{49,50}

Pathology

Virtually every structure crossing volar to the PIP joint has been implicated in the condition. However abnormalities can be divided into primary causal anomalies and those that are secondary effects. The primary causes are commonly abnormal flexor digitorum superficialis and lumbrical anatomy. Tightness and aberrant distal insertions lead to a flexor–extensor imbalance. Secondary effects include abnormalities of the retinaculum cutis, volar plate, collateral ligaments lateral bands, central slip and skeletal changes.⁵¹ Skeletal changes such as joint space narrowing, flexion of the proximal phalangeal head and flattening of the base of the middle phalanx augur a poorer response to treatment and prognosis⁴⁹ (Figure 49.9).

Figure 49.8 Image of a camptodactylous little finger. A web can be seen across the proximal interphalangeal joint.

Clinical assessment

Functional impairment can occur when the flexion contracture exceeds 60° and multiple digits are involved. Otherwise issues tend to be more cosmetic. Foucher described four types⁵² (Table 49.3).

Factors associated with a poor response to treatment include skeletal changes, older patients (teenagers) with stiff joints and those who demonstrate poor compliance with hand therapy.⁵²

Surgical principles and management

The mainstay of initial management is stretching and splintage. We reserve surgical intervention for patients with a progressive condition despite compliance to hand therapy and flexion contractures of more than 60°. Outcomes from surgery range

Figure 49.9 Radiographic image of camptodactylous digits, demonstrating narrowing of the joint space in the proximal interphalangeal joint, flattening with volar curvature of the head of the proximal phalanx and flattening of the base of the middle phalanx.

Table 49.3 Foucher classification of camptodactyly⁵²

Grade	Description
1a	Early and stiff
1b	Early and correctable
2a	Late and stiff
2b	Late and correctable

from 14% to 35% improvement.^{51,53} Outcomes from hand therapy in young children in the Japanese population have been excellent with an 80–92% improvement reported^{54,55} though poorer in white population series (mean improvement of 40°).^{52,56}

Preferred method of surgical correction

All abnormal structures, both primary and secondary, must be addressed. We use a volar longitudinal approach with Z-plasty lengthening as required. Steps include

- Release of the retinaculum cutis, lateral digital sheets and Grayson's ligaments.
- Release of any abnormal insertions of the lateral bands and interosseus.

- The lumbricals are inspected and abnormal insertions are released.
- If the flexor digitorum superficialis (FDS) is functional and traction on the lateral bands produces PIP joint extension, an FDS transfer to the extensor mechanism via the lumbrical canal can be performed.
- If the FDS is deficient proximally and not usable it is released.
- If the flexor digitorum profundus (FDP) or FDS musculotendinous units are short but functional they can be fractionally or step lengthened in the forearm.
- Joint release may be necessary, including release of the check-rein ligaments, accessory collaterals and volar plate in turn as required.
- Our preference is to avoid skeletal correction as this leads to further stiffness of the PIP joint and a poorer outcome.

However, no single procedure has proved to be universally successful. Other techniques described include Glicenstein's subperiosteal release,⁵⁷ angulation osteotomy and arthrodesis.

Duplication

Duplication may involve the whole limb or part of a limb. Polydactyly occurs when greater than five digits or toes are present. It may occur as an isolated anomaly, either sporadic or inherited, or syndromic with a multitude of associated syndromes described. Syndromic polydactyly may occur in combinations such as radial with ulnar and may coexist with other hand and foot anomalies. The aims of surgical intervention are to improve function, especially in terms of glove and shoe fitting, and cosmesis. Upper limb polydactyly is the focus of this section.

Radial polydactyly

Radial, or preaxial, polydactyly occurs in 1 in 3000 live births.³⁷ It is usually unilateral and sporadic with no associations. The expanded Wassel classification with contributions from Wood in 1978 and Hung in 1996 is generally the most widely used system^{58–60} (Table 49.4). A significant proportion of cases may not fit completely into this classification and so additional terms such as deviation or triphalangism can be used. Chromosome 7q36, harbouring the regulatory element of the SHH protein, is implicated in the rarer dominantly inherited radial polydactyly.²⁴ Typically there is some degree of hypoplasia of both duplicates, with the radial usually the smaller of the two (Figure 49.11a). The ulnar-innervated intrinsics to the thumb typically insert onto the ulnar-most duplicate and the median-innervated onto the radial duplicate.

Clinical examination

Other anomalies may be present and so it is always important to examine all four limbs. More specifically, in radial polydactyly the thenar musculature may be hypoplastic, especially with increasing Wassel grade.⁴³ The extrinsics are usually Y-shaped

Table 49.4 The expanded Wassel classification system of thumb duplication based upon radiographic appearance^{58–60}

Grade	Description
Type I	Bifid distal phalanx
Type II	Duplicated distal phalanx (approximately 20%)
Type III	Bifid proximal phalanx
Type IV	Duplicated proximal phalanx (commonest, approximately 50%)
Type V	Bifid metacarpal
Type VI	Duplicated metacarpal
Type VII	Triphalangeal, in either or both thumbs (approximately 12%)

and asymmetrical with hypoplasia or absence involving the smaller digit. Simultaneous flexion or extension may occur with or without deviation. The joints may be stiff, hypermobile or hypoplastic. Note the presence of creases and hence the chance of active movement following surgery. There may be asymmetry of the pulps and nail beds. The first web may be tight, especially with more proximal duplications.

Surgical principles and management

Our preference for timing of surgical correction is between 12 and 18 months of age as long as other, more pressing comorbidities have been addressed. In an unbalanced duplication the thumb to be retained and reconstructed should be first determined. Different parts from each thumb may need to be used in order to provide the best complement of structures for stability and function.^{24,43} Careful dissection of intrinsic, extrinsic muscles and tendons and ligamentous structures must be carried out. Pollex abductus – an abnormal deviating radial connection between the flexor and extensor apparatus – must be looked for and divided if present to allow for unrestricted motion and growth.^{61,62} Preservation of an optimal neurovascular supply is important for thumb viability and the preservation of sensibility. One-stage reconstruction, including osteotomies to ensure correct skeletal alignment, is recommended.

Correction of distal duplications (Wassel types I–III)

Unbalanced distal duplications

In unbalanced distal duplications where one side is larger with a well-formed nail, excision of the deficient partner, most commonly the radial, is best. The preserved duplicate – usually the ulnar – is augmented with tissue salvaged from its radial partner. Incisions are planned high in the axial line dorsal to the junction of glabrous and non-glabrous skin. The radial border of the ulnar thumb is excised to allow inset of the flap. During the dissection, the radial nail and bone are excised, and the tendons are sectioned at the level of their division. Only one nail is preserved. A broad proximal phalangeal head can be trimmed. Residual deviation of the thumb can be corrected via a closing wedge osteotomy of the distal phalanx in type II duplications or

proximal phalanx in type III. Reconstruction of a radial collateral ligament using local tissue is important in this technique.

Balanced distal duplications

Decision making becomes more complex when the duplications are hypoplastic but of equivalent size (balanced type). One approach in this situation is a modified Bilhaut–Cloquet procedure using asymmetric skeletal elements from each phalanx in an effort to preserve joint surface integrity and an entire nail bed from one duplicate to avoid a nail ridge.^{63,64} However, this approach can still result in a broad and aesthetically suboptimal thumb so the aforementioned method of retaining one duplicate and augmenting it with tissue salvaged from the other is preferred whenever possible.

Correction of type IV duplications

In general, the best approach for these, the most common of preaxial duplications, is the preservation of the ulnar-more developed thumb and reconstruction of motion and stability using elements from its radial partner. The principles and steps are similar to those in type II reconstruction with also initial detachment and subsequent reattachment of the intrinsic muscles. Incisions are planned around the radial duplicate to be excised, preserving skin to allow for soft tissue recontouring of the retained thumb. Decisions around which duplicate to retain becomes more complex in a balanced duplication (Figure 49.10). Skeletal work is often necessary to achieve long-term correction of alignment.⁶⁵ The bifid head of the metacarpal must be trimmed to prevent residual exostosis distorting the radial contour of the reconstructed thumb. An additional osteotomy of the metacarpal may be necessary to correct any residual clinodactyly. This involves the removal of a triangular wedge of metacarpal neck to create a perpendicular articular surface. The osteotomy is fixed with a longitudinal K-wire and the radial collateral ligament should be reconstructed if possible. The latter may not be possible due to the extensive dissection required for skeletal realignment and stability relies upon correct re-insertion of intrinsic musculature, in particular the abductor digiti minimi.

Correction of proximal duplications (Wassel types V, VI and VII)

The basic principles outlined above also apply to type V, VI and VII duplications. The ulnar-more developed thumb is usually retained and reconstructed (Figure 49.11). The intrinsic muscles must be repositioned, the lax radial collateral ligament must be tightened and the extrinsic tendons centralized if necessary.⁶⁶ Adduction contractures in the first web must also be released to improve function. In type VI duplications where both the metacarpophalangeal (MCP) and carpometacarpal joints are abnormal, an epiphyseal sparing chondrodesis at the MCP joint will provide the necessary stability for a functional thumb. In type VII duplications the thumb with the two phalanges is retained if it

Figure 49.10 Wassel IV thumb duplication. (a) Radiographic image of a balanced Wassel type IV duplication demonstrating duplication from the proximal phalangeal distally. (b) Image of a patient with a Wassel type IV thumb duplication.

Figure 49.11 Reconstruction of a Wassel type VII duplication. (a) Preoperative image of an unbalanced type VII duplication. (b) Preoperative radiograph demonstrating smaller triphalangeal radial duplicate. (c) Postoperative image of corrected type VII duplication after removal of radial duplicate.

is the more stable and components of the triphalangeal duplicate used for reconstruction. If the thumbs are comparable in size and functionality then preference should be given to that with the more stable ulnar collateral ligament at the MCP joint.³⁷ In some instances triphalangeal thumb reconstruction may require an on-top-plasty, whereby the distal portion of one thumb is transferred to the proximal part of the other with the better basal joint.

Ulnar polydactyly

Ulnar, or postaxial, polydactyly occurs in 1 in 500 live births (37). It is the most common congenital hand anomaly. It is often bilateral and usually of autosomal dominant inheritance. Temtamy and McKusick in 1969 divided ulnar polydactyly into

type A duplications which were more developed and substantial and type B which were rudimentary and pedunculated.⁶⁷ Type B are ten times more common in black populations.⁶⁸ Whereas type A is rarer and its incidence is more common across races.⁶⁹ Ulnar polydactyly, in particular the more substantial type A, is associated with a number of different syndromes, especially in white and Asian populations. These include chromosomal abnormalities such as Trisomy 13 and 18 and bone dysplasias such as Ellis-van Creveld.

Classification

Stelling and Turek in 1963 classified ulnar polydactyly into three types based on the degree of duplication as shown in Table 49.5⁷⁰ (Figure 49.12). Type I within this classification is the most common (Figure 49.12a). However, clinically there is a spectrum

of complexity and the common small pedunculated digit usually has at least a nail and distal phalanx. A neurovascular bundle is always present, however rudimentary the appendage. The digit may auto-infarct and auto-amputate prior to presentation.

Clinical examination

Clinical assessment follows the principles of radial polydactyly. The most common site of attachment when a more developed digit is present is at the MCP joint level. It is often abducted

Table 49.5 Stelling and Turek classification of ulnar polydactyly⁷⁰

Grade	Description
Type I	Soft tissue mass without skeletal structure and skin bridge only (pedunculated)
Type II	Digit with all normal components and articulating with a normal or bifid metacarpal or phalanx
Type III	Complete digit articulating with an extra metacarpal

at the MCP joint and radially deviated at the PIP joint. The extrinsic tendons are usually Y-shaped and asymmetrical as in radial polydactyly.⁴³

Surgical principles and management

Type I

We find ligaclip ligation or crushing with diathermy to the neurovascular bundle at the base in an outpatient setting effective, being less likely to leave a residual nubbin than the more traditional tying off (Figure 49.12a). Alternatively, formal excision under local anaesthetic can be performed within the first three months of age.

Type II

The ulnar duplicate is usually the most hypoplastic and is therefore removed with preservation of the ulnar collateral ligament at the MCP joint if required and re-insertion of any aberrantly positioned hypothenar musculature (Figure 49.12b, c). Trimming of a broad metacarpal head may be required to create

Figure 49.12 Images of three Stelling grades of ulnar polydactyly.⁷⁰ (a) Type I – pedunculated soft tissue digital mass. (b, c) Type II – complete digit articulating with bifid phalanx or metacarpal. (d, e) Type III – complete digit along with extra metacarpal.

the optimal ulnar contour. Resection of the metacarpal head and MCP joint reconstruction may be necessary.

Type III

Principles detailed above with reference to type II corrections apply in particular with unbalanced type III polydactyly (Figure 49.12d,e). In balanced type III situations it is preferable to retain the ulnar ray with its intact complement of hypothenar muscles.

Central polydactyly

Central polydactyly is rare condition. The ring finger is most often involved, followed by the middle then the index. A complete extra independent digit is rare. Often the situation is more complex, involving more than one digit with aberrant bones and abnormalities of the extrinsics, intrinsics and neurovascular supply.²³ Examples include duplication of the middle finger proximally at the metacarpal level, which shifts to an aberrant duplication of the ring finger within the digit. Duplication of the ring finger is often partial and hidden by a syndactyly with the middle digit. Polysyndactyly can be associated with *HOXD19* gene mutations with involvement of the little toe of the foot, together with a suppressed polysyndactyly of the ring finger.⁷¹ Surgical management should be considered carefully in central polydactyly as involved digits are often deficient, with significant soft tissue anomalies with poor function upon release.⁷²

Macroductyly

Macroductyly involves the localized enlargement of all structures of an affected digit (Figure 49.13 and 14). This distinguishes it from conditions where only part of the digit is involved

Figure 49.13 Image of a patient with macroductyly affecting predominantly the central two rays with an associated syndactyly.

(e.g. vascular malformations). It is rare, with an estimated incidence of 0.2 per 10 000 births. It affects the index most commonly and is usually unilateral.⁷³

The enlarged area often corresponds to the cutaneous distribution of specific nerves (i.e. nerve territory-orientated macroductyly).⁷⁴ If one digital nerve is affected, the macroductyly on that side will push the unaffected side away from the midline, causing a clinodactyly. If the common digital nerve is affected, both sides of adjacent fingers will be involved, leading to divergent clinodactyly.⁷⁵ Macroductyly tends to follow two patterns of progression: a *static form*, where growth is commensurate with the child's limb, and a *progressive form*, in which the growth is out of proportion (see Figure 49.13).⁷⁶ It can also be classified into five types according to specific disease entities, as described by Flatt and expanded by Upton.^{37,77} Type I is associated with lipofibromatosis (see Figure 49.14), II with neurofibromatosis, III with hyperostosis, IV with hemi-hypertrophy and V with additional conditions linked to overgrowth.⁷⁷ Conditions associated with overgrowth include Proteus and Beckwith-Wiedemann syndromes.⁷⁸

Surgical principles and management

Management of these cases is challenging due to the extensive nature and relentless progression of the condition. Surgery can be complicated by problems of delayed healing, infection

Figure 49.14 Intraoperative image of a case of macroductyly demonstrating harmartomatous overgrowth of all tissues.

and hypertrophic scarring.⁷⁸ The aims of treatment are to reduce bulk, maintain sensation and preserve joint motion whenever possible.⁷⁹ Careful counselling and the individualization of treatment is crucial. Psychological support is important as the psychosocial distress macrodactyly causes to patients and their families should not be underestimated.⁸⁰ The main surgical options are epiphyseal ablation (epiphysiodesis), soft tissue debulking with or without skeletal reduction (see Figure 49.14) and finally amputation. Nerve stripping or resection has also been recommended by some authors in an effort to suppress the neurotrophic drive seen in cases of nerve-orientated or neurofibromatosis type overgrowth.⁸¹ However, the long-term results of nerve exision/neurolisis are unpredictable and do not reliably prevent overgrowth.⁸² Epiphysiodesis is carried out to control longitudinal growth.⁷⁵ It is best carried out when the size of the affected digit reaches that of the parents. Destruction of the growth bar can be achieved with a needle, burr or osteotome under radiographic guidance. This often requires repetition and can be combined with debulking procedures to control circumferential girth. However, results from serial debulking surgery can be frustrating and despite early and repeated intervention the endpoint is often amputation, particularly in cases with a progressive growth pattern. Amputation should not be considered a treatment failure as it can significantly unencumber the hand, thereby improving overall function and cosmesis. Careful joint decision making with the patient and family must be carried out to avoid a protracted course with repeated hospital admissions and surgical procedures.^{78,79}

Thumb hypoplasia

Thumb hypoplasia can significantly impact on hand use as the thumb contributes to at least 50% of overall hand function.⁸³ Thumb hypoplasia represents a spectrum of abnormalities that range from structurally normal but small thumbs, through varying degrees of skeletal and soft tissue deficiency to complete thumb aplasia. It can exist as an isolated entity but is commonly seen as a component feature of radial ray deficiency. Its true incidence is hard to ascertain as thumb hypoplasia is present in a multitude of congenital malformations, in particular central and transverse deficiencies. Incidences of up to 37% of all congenital hand anomalies have been reported.⁸⁴ The aetiology is complex, encompassing multiple genetic and environmental factors.⁸⁵ This is confirmed through links to many different conditions, each with distinct aetiologies, including Fanconi's anaemia, thrombocytopenia with absence of radius (TAR) syndrome, Holt–Oram syndrome and the vertebral, anal, cardiac, tracheal, oesophageal, renal and limb association (VACTERL).^{86,87} Therefore involvement of a geneticist is advised.

Table 49.6 The modified Blauth classification of thumb hypoplasia^{89–92}

Grade	Features
1	Mild hypoplasia with all structures present
2	Moderate hypoplasia Thenar muscle hypoplasia First webspace adduction contracture MCP joint laxity Modified by Smith: 2A = ulnar collateral ligament laxity only 2B = global instability of MCP joint
3	Severe hypoplasia Metacarpal hypoplasia Thenar muscle hypoplasia Extrinsic hypoplasia Modified by Manske and McCarroll: 3A = Relatively stable CMC joint present 3B = unstable CMC joint
4	No metacarpal present Floating thumb (<i>pouce flottant</i> in French or <i>Pendeldarmen</i> in German)
5	Complete absence

Classification

The classification of thumb hypoplasia has evolved since that first proposed by Muller in 1937.⁸⁸ Currently the most widely accepted is the Blauth classification,⁸⁹ which has been refined through contributions from Buck-Gramcko in 1981,⁹⁰ Manske *et al.* in 1995⁹¹ and Smith in 2002⁹² (Table 49.6). Complete assessment of thumb hypoplasia must incorporate detailed analysis of its size and position in relation to the other digits, the first webspace, intrinsic musculature, extrinsic tendons and quality and stability of the thumb osseo-articular column to ensure optimal management. Accurate classification of anatomical and functional deficiency allows planning of surgical treatment.

Grade 1

There may be hypoplasia of the phalanges and metacarpal with weak intrinsics. The first web may be marginally tight. Joints are all present and stable. There is excellent function and parents may be unaware of any hypoplasia. This form is common in those with a contralateral more severe radial dysplasia.

Grade 2

The metacarpal and phalanges are present but may be narrower and smaller than usual. In addition the radial carpus particularly the trapezium, trapezoid and scaphoid may be hypoplastic.⁹³ A large spectrum of soft tissue abnormalities can occur, affecting both the extrinsic and intrinsic radial musculature. The median innervated thenar muscles, in particular the opponens pollicis and abductor pollicis brevis, are underdeveloped and weak. In contrast the ulnar-innervated intrinsics, particularly the adductor pollicis, are strong, which results in an abnormal adduction of the thumb and resultant narrowing of the first webspace.⁹³ Hypoplasia of the thenar intrinsics leads to a

weakness of thumb opposition, another defining feature of grade 2 hypoplasia. This, in combination with instability of the MCP joint, further compounds thumb dysfunction. In particular, laxity of the ulnar collateral ligament leads to radial collapse of the thumb during pinch. Grade 2A thumbs are defined by uni-axial (ulnar) instability and IIB by multiaxial instability of the MCP joint.⁹² Pollex abductus may also be present, causing radial deviation distal to the MCP joint through abnormal connections between the flexors and the extensor mechanism.⁶¹

Grade 3

Features of grade 2 thumbs are present but with more pronounced osseo-articular and extrinsic musculature deficiency. The osseous deficiency is most significant at the proximal metacarpal level, rendering the thumb even more unstable.^{90,94–96} There is in addition a degree of hypoplasia of the radial carpus, in particular the scaphoid, which is often absent. The distal radius is smaller and there is hypoplasia or total absence of the radial styloid.⁹³ The thumb MCP joint is unstable in all directions with severe underdevelopment of the collateral ligaments and volar plate. Intrinsic and extrinsic muscle abnormalities are pronounced. Flexors and extensors are usually present but are markedly weak. Abnormal tendinous interconnections can be present, producing a pollex abductus deformity.⁶¹ Intrinsic muscles are similarly underdeveloped, particularly those innervated by the median nerve, whereas ulnar-innervated adductor is relatively spared, compounding the first web adduction contracture.^{94,97} Manske *et al.* subdivided this category into grades 3A and B.⁹¹ In grade 3A thumbs the metacarpal, although hypoplastic, is present, forming a relatively stable articulation at the carpometacarpal (CMC) joint, whereas in the grade 3B thumb the proximal end of the first metacarpal is absent, which leads to instability of the CMC joint. More recently, in 2002, Smith suggested that all hypoplastic thumbs with a metacarpal present should be classified as grade 2. In other words Manske grade 3A should be classified as a grade 2C. He further suggested that Grade 3 should be divided into 3A where there is loss of the proximal one third of the metacarpal and 3B where there is a loss of the proximal two thirds.⁹²

Grade 4

These 'floating' thumbs arise most commonly distally along the radial midaxial line of the hand. They usually comprise two hypoplastic phalanges within a pedunculated soft tissue envelope that is connected to the hand by a narrow skin bridge containing a neurovascular pedicle. There are no metacarpal or intrinsic muscle insertions into the phalanges. A first dorsal interosseous may, however, be present.^{89,97}

Grade 5

This is defined by complete absence of the thumb and in 50% of cases there is a degree of radial deficiency.³⁷ The degree of radial hypoplasia correlates with deficiency within the index finger.⁹⁷ Hence those with a normal radius may try to 'auto-pollicize'

their index finger by pronating and abducting it and widening their second intermetacarpal space.^{37,97}

Surgical principles and management

Grade 1 function well and no intervention is required. The aims of reconstruction in grade 2 thumbs is widening of the first webspace, stabilization of the MCP joint and the provision of opposition. All three aims can be achieved through one surgery. Release of the adduction contracture allows the thumb to passively abduct and oppose, utilizing the shape of the CMC joint. Simultaneous opponensplasty adds the active ability to do so.

Addressing the first web contracture must ensure adequate release of all structures limiting thumb abduction, including the tight investing fascia over the adductor and first dorsal interosseous musculature. In addition, in severe cases release of the musculature itself from its origin or insertion may be required. Resurfacing the new opened web can be achieved in a number of ways depending on the degree of skin deficit. Mild to moderate contractures can be dealt with adequately using a single or four-flap Z-plasty technique. These also allow access to the MCP joint to facilitate joint stabilization and opposition transfers. More severe contractures may necessitate a large dorsal rotation-advancement flap to resurface the first web.^{98–100} More complex options include regional pedicled flaps such as the radial forearm or posterior interosseous flap or free tissue transfer with thin pliable flaps such as the groin flap.^{33,101}

Management of the lax MCP joint and the provision of opposition should be guided by the type of joint instability seen.¹⁰² Uni-axial (usually ulnar) instability of the MCP joint (grade 2A) can be corrected in the majority of cases as part of an FDS opposition transfer⁹⁵ (Figure 49.15a). The two slips of the FDS, usually from the ring finger, can be split and passed through drill holes in the base of the proximal phalanx and the head of the metacarpal, in a square configuration, as originally described by Lister.⁹⁵ Our preference, however, is to place the tendon repair on the radial side of the MCP joint so that in pinch tension is taken off it¹⁰² (Figure 49.15b). The use of the superficialis transfer in this way enables both MCP joint stabilization and thumb opposition using the distal border of the carpal tunnel as a pulley. In contrast, those with poor bone stock and instability in all planes (grade 2B) require an epiphyseal plate-sparing fusion of the MCP joint – a chondrodesis – in combination with an abductor digit minimi opponensplasty¹⁰³ (Figure 49.16) in order to produce equivalent functional results.^{102,104,105}

Grade 3A thumbs are generally reconstructable following the aforementioned principles outlined for grade 2 thumbs. But beware that even though the CMC joint may be present, it may be unstable or may appear stable at rest but may not be so in pinch. This is further exacerbated by MCP joint stabilization with increased force through the joint.

Grade 3B thumbs and onwards are best treated with ablation and substitution through pollicization of the index finger.^{62,96,97} Despite the advantages of a pollicization in grade 3B, some cultural and parental beliefs may preclude the use of the index

Figure 49.15 Flexor digitorum superficialis tendon combined collateral ligament reconstruction and opposition transfer. The two slips of the flexor digitorum superficialis are split and passed through drill holes in the base of the proximal phalanx and the head of the metacarpal in a 'box-like fashion'. The tendon repair is placed on the radial side of the MCP joint so that in pinch, tension is taken off the repair site. (a) Two slips of the flexor digitorum superficialis used to stabilize the MCP joint. (b) A schematic of the 'box-like' arrangement of the superficialis tendon around the MCP joint.

Figure 49.16 Abductor digiti minimi opposition transfer. Insertions of the abductor digiti minimi muscle into the base of the little finger are released. The muscle is then transferred, maintaining its origin on the pisiform and proximally based blood supply, to the thumb to provide opposition.¹⁰³

finger and demand alternative forms of reconstruction to preserve total digit number. These alternatives include staged reconstruction with both vascularized and non-vascularized tissue transfers. These approaches, despite yielding some good results, are more unpredictable and generally suboptimal when compared to index finger pollicization.^{106–110}

Pollicization

Pollicization is the transposition of the index as a vascular island into a functional thumb position. Excellent functional and aesthetic results can be achieved through careful planning and surgical execution but there will be compromises due to lack of

a true CMC joint, weaker intrinsic muscles and differences in phalangeal lengths.¹¹¹ Power is diminished to approximately 30–50% of the normal thumb. The key determinant of outcome is the quality of the index finger to be transferred. The principal stages are as follows:

- 1 Incisions – we prefer those described by Buck-Gramcko.¹¹²
- 2 Neurovascular dissection – commonly requires freeing of a neural ring, splitting the common digital nerve and division of the radial digital artery to the middle finger.
- 3 First dorsal and first palmar interossei detachment from their insertions.
- 4 Second metacarpal resection from the distal physis to the CMC joint. The physis is ablated to prevent future growth of the neotrapezium. Metaphyseal periosteum is removed to avoid new bone formation and painful bony spicules.
- 5 Fixation of the index MCP joint in maximal hyperextension to compensate for loss of the volar plate and provide stability in pinch.
- 6 Correct fixation of the neo-thumb into 100° pronation and 30° of abduction to allow for a degree of derotation during healing and rehabilitation.
- 7 Musculo-tendinous unit reattachment and balancing as follows:
 - Extensor digitorum communis becomes the new extensor pollicis brevis as it is the more radial.
 - Extensor indicis proprius becomes the new extensor pollicis longus.
 - The extensors are routinely both shortened, advanced and sutured at the level of the thumb MCP joint. The degree of shortening is proportional to that of the index metacarpal.
 - After adjustment of the extrinsic tendons, the intrinsic are inserted and tensioned appropriately. The first dorsal interosseous becomes the new abductor. The first palmar interosseous becomes the adductor.

- Balancing of the intrinsics is critical to correct posturing of the neo-thumb. The thumb is placed into maximal flexion at the interphalangeal joint and the intrinsics inserted on each side at maximal tension.
 - Long flexor shortening is only required over 7 years of age. Otherwise it tightens with growth and use.
- 8 Decompression of the tourniquet to allow for haemostasis and to check viability of the transfer.
 - 9 Skin re-draping and closure to contour the new thumb and first webspace.
- Revisional procedures are necessary in a significant proportion of patients and usually involve first web releases, extensor tenolysis and transfers to supplement opposition.

Radial longitudinal deficiency

Radial longitudinal deficiency (RLD), previously referred to as radial club hand, represents a spectrum of abnormalities along the preaxial side of the upper limb. As a result of both skeletal deficiency and soft tissue abnormalities the hand adopts a radially deviated, flexed and pronated position at the distal end of a shortened forearm³⁷ (Figure 49.17a). This may be associated with abnormalities along the whole length of the upper limb including the shoulder, elbow down to the thumb and radial digits. There may only be a mild thumb hypoplasia or, in its severest form, complete absence of the thumb and radius. The condition may be unilateral or bilateral but is rarely symmetrical. The right side is affected twice as often as the left. RLD also occurs slightly more frequently in males.¹¹³ The incidence is reported at 1:30 000–1:100 000 live births.^{114,115}

Aetiology

Environmental and genetic factors play a role though the exact aetiology is unknown. Environmental causative factors include thalidomide,¹¹⁶ valproic acid,¹¹⁷ phenobarbitol¹¹⁸ and ethanol.¹¹⁹ Bilateral cases are more likely to be linked to a syndrome. Most are due to sporadic mutations but some have a genetic basis and can be transmitted as either autosomal dominant or recessive disorders. Experimentally, radial dysplasia can be created in chick wings and the ZPA identified as responsible for anteroposterior limb patterning.¹²⁰ Expression of the sonic hedgehog gene⁶ and retinoic acid¹²¹ have been shown to be critical in regulating the function of the ZPA. This is influenced by several factors including the homeobox genes and is only induced due to signalling from the AER,² probably through fibroblast growth factor.¹²² Abnormal limb development may be related to several different interruptions within this pathway.

Associated syndromes

There are multiple associated syndromes, which confer a poorer prognosis. Syndromes that require early exclusion include those with haematological conditions, cardiac abnormalities and renal defects. It is therefore important to seek early input from a clinical geneticist.

Haematological

Fanconi's anaemia is an autosomal recessive pancytopenia, which is fatal without bone marrow transplantation. It is identified through a chromosomal breakage study which is recommended for all children with radial dysplasia. TAR syndrome is a rare autosomal recessive disorder characterized by bilateral absence of the radii in the presence of both thumbs and

(a)

(b)

Figure 49.17 (a) Image of a patient with type IV radial dysplasia showing radial deviation at the wrist and shortening of the forearm. A Blauth grade IV 'Pouce Flottant' thumb hypoplasia is also present. (b) Radiograph of the same patient demonstrating complete absence of the radius with absence of a wrist joint and bowing of the ulna.

hypomegakaryocytic thrombocytopenia.¹²³ The presence of functional thumbs distinguishes TAR syndrome from other conditions with radial aplasia which are usually associated with severe thumb hypoplasia or aplasia.^{123,124} In TAR syndrome the platelet count usually improves with age so intervention is best delayed until levels normalize.

Cardiac

Holt–Oram syndrome is autosomal dominant condition, which commonly exhibits atrial and ventricular septal defects.¹²⁴

VACTERL association

This is the largest individual syndromic group with associated radial dysplasia. Patients within this group vary in the severity of their presentation demonstrating a wide spectrum of associated anomalies. The diagnosis is made on the basis of a minimum of three of the following abnormalities – vertebral, anorectal, cardiac, tracheoesophageal, renal, limb and a single umbilical artery. Limb malformations are reported in 40–50% of cases and mostly represent radial deficiency.¹²⁵

Classification

Bayne and Klug classified RLD based on the degree of radial hypoplasia on radiographic assessment¹²⁶ (Table 49.7). This classification system does not encompass the degree of carpal or hand involvement.

Clinical findings

RLD is usually identified on a routine neonatal check. Investigations should then be instigated to exclude associated anomalies. The most profound changes in radial dysplasia are seen in the hand and wrist but it is important to examine the entire upper limb. Type I cases can be easily missed but are often heralded by the presence of associated thumb hypoplasia. Bilateral involvement is often asymmetrical in terms of severity so careful examination of both upper limbs is important.

Upper arm

The upper arm may be shorter than the opposite side with distal humeral epiphysis involvement. The humeral involvement parallels the degree of radial hypoplasia.

Table 49.7 Bayne and Klug classification of radial longitudinal deficiency¹²⁶

Grade	Description
Type I	<i>Short distal radius</i>
Type II	<i>Hypoplastic radius with distal and proximal epiphyses present but defective</i>
Type III	<i>Partial absence of the radius – most commonly of the distal one or two thirds</i>
Type IV	<i>Complete absence of the radius</i>

Elbow

The elbow may demonstrate bony abnormalities. There is usually full extension but flexion is sometimes limited initially. However this has been observed to improve over time if the wrist deformity is controlled with splintage.¹¹⁶ In addition, active pronation and supination are compromised. Patients tend to compensate for this by using shoulder rotation to turn their hands.

Forearm

The forearm is short with varying degrees of radial deficiency. The ulna is also hypoplastic and often bowed – growing to a maximum of two thirds the length of the contralateral side (see Figure 49.17). Without treatment ulna bowing can worsen. If some form of proximal radius is present its distal portion is replaced by a fibrous condensation or anlage. An additional deforming force is the presence of an abnormal combined radial muscle mass of flexor carpi radialis, extensor carpi radialis longus and brevis and brachioradialis which inserts into the anlage and on occasion the carpus. Soft tissue abnormalities, including those of musculotendinous units and neurovascular structures tend to parallel the degree of skeletal deficiency. Affected structures such as the median nerve tend to favour an aberrant radial course towards the distal forearm, hence complicating treatment and surgical correction.^{37,127}

Carpus

The radiocarpal articulation is often non-functional and may not even be present, with a hypoplastic or absent trapezium and scaphoid (Figure 49.17b). With ossification, increasing carpal coalitions are seen.

Hand

The thumb is often either hypoplastic or absent (Figure 49.17a). The ulnar side of the hand is the least affected, with worsening hypoplasia and stiffness in the radial digits. Motion at the MCP joints is restricted, although a degree of hyperextension is present. There are often flexion deformities of the PIP joints, particularly affecting central digits and in syndromic cases.¹²⁸

Surgical principles and management

The aims of treatment in radial club hand are to provide stable realignment of the carpus and hand on the distal ulna, improve function of the limb as a whole and maximize growth potential.^{36,116,126} The soft tissue structures on the radial side of the wrist are short, therefore treatment begins with stretching and splintage carried out by the parents with the guidance of a hand therapist. Physiotherapy aims to correct wrist deviation and to improve and maintain range of motion of the digits. In type I cases where the wrist is stable and easily corrected to neutral no intervention is required. But if a tendency for radial deviation remains, a tendon transfer of the tight combined dorsoradial muscle mass to the ulnar side of the carpus may be required.

(a)

(b)

Figure 49.18 Soft tissue distraction with a uniplanar mini-fixator device. (a) Image of a patient with type IV radial dysplasia with a Pennig Uni-planar Mini-fixator device with a central coaxial hinge *in situ* on the radial aspect of the limb. (b) Radiograph of the same patient demonstrating two-pin fixation across the second and third metacarpals distally and into the ulna proximally.

Type II cases are some of the most challenging to treat. Attempts have been made to distract and lengthen the radius with or without a bone graft.¹²⁹ This, however, often needs to be repeated as a child grows and results are unpredictable. In type III cases we advocate removal of the radial anlage and treatment as for type IV cases as detailed below.

Soft tissue distraction

The benefits of stretching and splinting on addressing radial deforming forces should not be underestimated. However these manoeuvres alone have proven insufficient in completely addressing radial tension prior to wrist correction particularly in severe type III and IV cases. As a result, Kessler proposed the idea of soft tissue distraction.¹³⁰ Since its conception, soft tissue distraction has revolutionized the treatment of radial dysplasia and has evolved through the use of a variety of different uniplanar and multiplanar devices. Our preference is a uniplanar device with a central coaxial hinge, which is placed on the radial side of the limb and secured by pin fixation into the ulna proximally and into the index metacarpal through to third metacarpal distally (Figure 49.18). On-table distraction yields a significant amount, after which incremental distraction is taught to parents to perform at a rate of approximately 1 mm per day. Maximizing this latter slower distraction is crucial in minimizing long-term radial tension and pressure on the ulna physis. Distraction is stopped once the third metacarpal base is aligned with the distal ulna, at which point the soft tissues are allowed to adapt to their new position prior to a wrist corrective procedure. We have noted that this 'consolidation' period of stress relaxation facilitates wrist stabilization and can produce some remodelling and straightening of the ulna.

Wrist correction

This can be achieved through a centralization with a proximal row carpal notch or a (non-notched) stabilization procedure. Centralization involves alignment of the third metacarpal with

Figure 49.19 Intraoperative image of a centralization procedure demonstrating creation of a carpal slot. The ulna is placed into the carpal notch and a tendon transfer is carried out of the dysplastic combined dorsoradial muscle mass.

the ulna through the creation of a notch in the carpus, producing a fusion or fibrous union to the proximal carpal row (Figure 49.19). This is more stable than a stabilization but inherently immobile. A stabilization procedure, also known as a radialization, involves rebalancing the carpus on the end of the ulna in line with the second metacarpal without a carpal slot. Both procedures are combined with a tendon transfer of the dorsoradial muscles mass into the base of the fifth metacarpal or

Figure 49.20 Intraoperative image of a radialization procedure showing transfer of the combined dorsoradial muscle mass. No carpal slot is made in a radialization (stabilization). Stability relies upon transfer of the combined dorsoradial muscle and congruency of the ulna and carpal joint surfaces.

extensor carpi ulnaris tendon to rebalance forces at the wrist and prevent recurrence into radial deviation (Figure 49.20). A dorsal approach via a longitudinal incision is all that is required, rendering complex incision patterns or flaps to address skin shortages obsolete. Repositioning through a radialization, although it preserves motion, is inherently more unstable than a centralization.

Review of our series shows there is a tendency for more long-term recurrence in radialization cases. As a result we would favour a stable centralization in cases where the quality of the dorsoradial muscle mass or ulna joint congruity does not lend itself to the stable equilibrium that is required for a radialization. Both types of correction are supported with longitudinal K-wire fixation for a period of six months to a year.

Alternative procedures in radial dysplasia

We consider the outcomes from soft tissue distraction followed by centralization or radialization with a tendon transfer satisfactory and have not pursued other methods. Vascularized and non-vascularized fibular head transfers have been used to replace the radius as well as vascularized metatarsophalangeal joint transfer.¹³¹ The cohorts in these series have been smaller and their take-up so far limited worldwide.

Following wrist correction, thumb hypoplasia can be addressed and later forearm lengthening. Forearm lengthening requires stability at the wrist and is fraught with potential complications. In highly selected patients it may bring functional and cosmetic gains that they consider worthwhile.^{132,133}

Constriction ring syndrome

Constriction ring syndrome is a rare condition of unknown aetiology. Numerous names have been used to describe this entity in the past, including annular band syndrome, constriction

Figure 49.21 Right hand showing constriction rings affecting the index, middle and ring fingers. Circumferential ring affecting the distal index finger and further constrictions producing acrosyndactyly of the middle and ring fingers.

band syndrome, Streeter dysplasia, Torpin dysplasia, amniotic band disruption sequence, acrosyndactyly, fenestrated syndactyly and congenital amputation syndrome.¹³⁴ The syndrome is characterized by bands of ranging severity, always present at birth, that can affect any part of the body with a particular predilection for the upper or lower extremities¹³⁵ (Figure 49.21). The reported incidence in the literature varies from 1 in 1200 to 1 in 15 000 live births depending on the population sampled and the diagnostic criteria used.^{135,136} When found in conjunction with significant limb involvement its incidence has been recorded as low as 0.19 per 10 000.¹³⁷ No genetic inheritance pattern has been identified but some environmental associations have been postulated. These have included possible links with abnormal gestational histories¹³⁸ and oligohydramnios.¹³⁹

Aetiology

Several theories have been postulated, including an intrinsic theory of localized areas of imperfectly formed tissue due to 'defective areas of germ plasm'^{135,140} and an extrinsic theory due to the formation of mesodermic strands because of rupture of or damage to the amnion during the first or early second trimester.¹⁴¹ These amniotic strands become entangled with the fetus, in particular the extremities, within the sac. In addition, resultant transient oligohydramnios caused by a loss of amniotic fluid can lead to abnormal pressure on developing limb buds, resulting in associated deformities such as talipes equinovarus – clubfoot.¹⁴² Anomalies such as cleft palate as part of Pierre Robin sequence also appear closely linked to the effects of oligohydramnios.¹⁴³ Similarly, there is a strong

association between limb ring constrictions and rare craniofacial clefts, again supporting the idea of a common causality.¹⁴⁴

Clinical presentation

No two cases of constriction ring syndrome are identical. The deformities are always present at the time of birth and prenatal ultrasonographic techniques enable early diagnosis.^{145,146} More than one limb is usually affected and associated musculoskeletal anomalies are commonly present^{135,147,148} (Table 49.8). There is a predilection for the more distal extremities – in particular the longer central three digits and longer great toe¹⁴⁹ (Figure 49.21). In line with an extrinsic aetiology, involvement of the thumb is rare due to its flexed adducted posture during intrauterine development, making entrapment more difficult. More proximal rings do occur but with much less frequency. However, it is rare for only one ring to be present as an isolated abnormality.³⁷

The severity of the deformity can vary dramatically, even between affected limbs of the same individual. The depth of the groove can range from mild indentations with minimal involvement of subcutaneous tissue to deep deficiency with associated disruption of lymphatic channels, nerves and blood vessels.^{148,150,151} Generally the rings tend to be deeper on the dorsal surface of affected extremities. Deep volar involvement can be associated with tendon involvement and joint contractures.¹⁵² Skeletal involvement is rare because in these cases auto-amputation tends to have already occurred.¹³⁴ Amputations can

occur at any level and stumps tend to be tapered.¹⁴⁷ Sensation tends to be normal and despite the presence of rings and amputations, function is generally good as proximally all soft tissue and skeletal anatomy remain unaffected.¹⁵³

Fusion of distal parts is also common in cases of constriction ring syndrome in the form of acrosyndactyly¹³⁵ (see Figure 49.2e). Distal fusions can be either simple or complex with bony fusions present between adjacent digits. Proximal fenestrations tend to lie characteristically distal to the level of the commissure.

Classification

A number of classification systems have been proposed for constriction ring syndrome. The most widely used of these is that described by Patterson,¹³⁵ a clinically useful system of four different groups which reflect a range of severity (Table 49.8).

Surgical principles and management

The timing of surgery is dependent on the type and severity of presentation. In the neonatal period the main treatment that may be required is the division of small soft tissue bridges between digits and the thumb to ensure unrestricted growth.¹³⁴ In some instances it may be possible to see fibrous bands encircling the fingers and toes of newborns. These can be simply removed or unwound to release the tethered digits.¹⁵⁴ Occasionally, ring constrictions can produce severe distal oedema and vascular compromise, particularly in cases of delayed healing in the postnatal period. These cases represent an emergency situation which requires expeditious decompression in the early neonatal period in order to prevent impending tissue ischaemia.¹⁵⁵ Hemi-circumferential decompression can yield a dramatic improvement in the status of the distal extremity. Once the decompression has had time to take effect, resultant redundant skin and the remaining half of the ring can be dealt with as a delayed second stage.

Simple constriction rings can be dealt with non-urgently prior to school age using principles described below. Syndactyly separation is best carried out early if it involves the border digits

Table 49.8 Classification of constriction ring syndrome¹³⁵

Grade	Description
Type 1	Simple ring constrictions
Type 2	Ring constrictions accompanied by deformity of the distal part with or without lymphoedema
Type 3	Ring constrictions accompanied by fusions of distal parts ranging from mild to severe acrosyndactyly
Type 4	Intrauterine amputations

Figure 49.22 Schematic demonstrating excision margins for correction of ring constriction. Transverse incisions are made on the shoulders flanking the constriction to ensure complete removal of all scarred tissue from within the ring.

and is tethering growth. Otherwise it can be dealt with after 1 year of age. Bilateral procedures and those treating upper and lower limbs simultaneously are possible but best performed before the child is ambulatory. More complex procedures such as toe-to-hand transfers, skeletal lengthening and digital transpositions can be delayed to optimize patient and family compliance and the size of surgical anatomy.¹³⁴

Methods of constriction ring correction

Traditional methods of correction involved excision of grooves, mobilization of adipose tissue and re-approximation of skin using Z-plasty- or W-plasty-based techniques.^{37,156} However, resultant scars have a tendency to indent with time and occasional partial loss of flaps and resultant delayed healing can result in a conspicuous depressed saw tooth appearance.¹⁵³

The ideal correction of a deep constriction ring should address the tight scar at the base of the indentation, atrophic tissue along the side walls and indurated fatty tissue within the distal swollen segment.¹³⁴ Transverse incisions are first marked on the either side of the depressed area on the limb or digit. These are marked on the shoulders flanking the constriction to ensure complete removal of all scarred tissue from within the ring (Figure 49.22). Gentle compression of one marked side against its opposing unmarked partner guides correct incision placement. All scarred tissue is then excised from within the depth of the ring, preserving large dorsal veins, volar neurovascular structures and tendons. Excess fatty tissue, usually most apparent distally, can then be excised and the remaining deeper tissue can be redraped to fill the annular contour defect. In this way final closure of the layers can be staggered to minimize the effects vertical scar contracture. If the ring is circumferential, one or two Z-plasties can be incorporated to break up the scar and are best placed in the mid-lateral axes to avoid the most socially visible areas of the limb or digit.¹⁵³

Toe-to-hand transfers

Constriction ring amputations of the thumb and digits are ideal candidates for vascularized toe-to-hand transfers as proximal anatomy including the neurovasculature is normal.^{106,157,158} These techniques can dramatically improve hand function through the reconstruction of a sensate mobile thumb or digits which will show a degree of commensurate growth with the child^{159,160} (Figure 49.23). However, this approach can occasionally be limited by a lack of usable toes in the context of constriction ring syndrome.

Distraction lengthening

An alternative approach is the use of distraction lengthening.^{161,162} This method is very effective at restoring a functional prehensile unit but can be very involved process that requires a great deal of patient and family commitment. Indications for surgery must be carefully considered.¹⁶³ This method appears to be more effective when used at the metacarpal and forearm levels as the distracted tissue is surrounded by more soft tissue

Figure 49.23 Image of a free vascularized toe-to-hand transfer to reconstruct a thumb intrauterine auto-amputation secondary to constriction ring syndrome.

with greater vascularity.¹³⁴ Distraction at the phalangeal level is possible but is extremely challenging due to problems of poor skeletal stock and soft tissue coverage.

Digital transposition

Transposition of a redundant digital tip based on its neurovascular pedicle as an 'on-top' plasty including its proximal phalanx can lengthen digits, improving length for prehension.¹⁶⁴ Transposition of a short non-functioning index finger in this way can also broaden a first webspace.

Arthrogryposis

Arthrogryposis (from the Greek *arthron*, joint, *grint*, hooking) is an umbrella term encompassing more than 300 disorders in which there are congenital contractures affecting at least two or more different areas of the body.^{165,166} The overall prevalence of arthrogryposis is around 1 in 3000 live births.¹⁶⁷ The inheritance, natural history, optimum management and prognosis varies across the disorders. Therefore ensuring a specific diagnosis and individualized treatment plan is key.^{166,168} When the results of neurological examination are normal, the most common causes are amyoplasia, one of the distal arthrogryptic syndromes, a generalized connective tissue disorder or fetal crowding.¹⁶⁸ An abnormal neurological examination points towards a CNS disorder or a neuromuscular disease (peripheral nervous system, motor endplate or muscle).¹⁶⁸

Amyoplasia, also known as classic arthrogryposis or arthrogryposis multiplex congenital (AMC), is a specific disease entity characterized by congenital joint contractures and muscle

wasting without evidence of any progressive neuromuscular disease. Distal arthrogryposis exhibits primarily hand and foot involvement but is a heterogeneous subset of autosomal dominant disorders.^{168–170} For the purposes of this chapter we will focus on amyoplasia.

Aetiology

Amyoplasia is sporadic, occurring in 1 in 10 000 live births.¹⁶⁶ Its exact aetiology remains unclear but evidence points towards a likely cause being patchy damage of the anterior horn cells of the spinal cord in the developing fetus.¹⁷¹ Genetic factors are not significant as twin cohort studies have demonstrated discordance¹⁶⁹ and no clear environmental factors have been identified.¹⁶⁷

Clinical findings

The vast majority have both upper limbs and both lower limbs affected (84%). They appear fusiform, wasted and without flexion creases (Figure 49.24). Lower limb involvement alone occurs in 11% and upper limb involvement alone in 5%.¹⁷² The joint contractures tend to be symmetrical. Characteristic features of amyoplasia include the following:^{169,173}

Figure 49.24 Image of patient demonstrating the common features of amyoplasia. The upper limb is internally rotated at the shoulder with the elbows extended, forearms pronated and the wrists flexed and ulnar deviated.

- *Upper limbs* (Figure 49.24)
 - Shoulders adducted and internally rotated
 - Elbows extended
 - Forearms pronated
 - Wrists flexed and ulnarly deviated
 - Thumbs adducted, laxity of UCL, absence of abductor pollicis brevis
 - Fingers partially flexed
- *Lower limbs*
 - Hips flexed and abducted with dislocation of one or both sides in 30%
 - Knee usually fixed in extension
 - Feet held in rigid equinovarus contractures in the majority
- *Other common features*
 - Deformities of face and jaw: asymmetry, flat nasal bridge, haemangiomas (frontal midline capillary haemangioma in 90% of those with all limbs involved), micrognathia and trismus
 - Genital deformities, umbilical or inguinal hernias are common.

Surgical principles and management

Most often affected children are of above average intelligence with the potential for independence.^{173,174} The priorities are communication, activities of daily living and mobilization.¹⁷⁵

Timing of surgery

We advocate a coordinated multidisciplinary approach parallel upper and lower limb surgery where possible to reduce the number of operations the child has to endure and ensuring greatest benefit especially as in both early surgery confers a better outcomes. A protracted course of lower limb surgery focused on ambulation alone, which may involve addressing clubfeet, knee contractions and hip dislocations for example, may result in significant delays to upper limb treatment.¹⁷⁶

Aims of treatment of the upper limb

The aims of treatment are to:

- maintain and improve joint range of motion, focusing on passive as this may improve function with passive assistance manoeuvres;
- maintain and improve muscle strength;
- preserve bimanual function; and
- optimize upper limb positioning to reach table tops.

These can be achieved initially with gentle manipulation and splintage with the help of occupational and physical therapy. Occupational therapy also teaches adaptive skills, trains caregivers to provide home therapy and tailors assistive equipment to meet individual patient needs.^{92,177} Therapy is an ongoing process which in the majority of patients extends at least into their teenage years.¹⁷⁸ Surgical intervention in the upper limb is recommended for fixed joint contractures that interfere with upper limb function.

Surgical options by region

Shoulder

This is rarely indicated unless there is significant shoulder internal rotation to preclude functional positioning of the limb in space. In these cases a humeral rotational osteotomy to around 45° will facilitate midline functioning of the hand.¹⁷⁴

Elbow

The main goal is to enable elbow flexion to allow hand-to-mouth reach. Improvement of passive range allows assistance techniques such as trunk swaying and table top propping. A posterior elbow joint release with a Z- or W-plasty to regain 90° of passive flexion with a tricepsplasty works well.¹⁶⁵ If active flexion is poor, an elbow flexorplasty transfer can be carried out at the same time. A variety of different options have been described for this purpose including the use of pectoralis major, latissimus dorsi¹⁶⁵ and triceps.¹⁷⁹ However, care must be taken to avoid development of a unwanted flexion contracture that can impair of pre-existing function. In this regard, transfer of the long head of triceps alone as a functional unit has been shown to produce reliable anti-gravity flexion while preserving active extension with minimal donor site morbidity.¹⁸⁰

Wrist

Early carpectomy prior to ossification of the carpal bones facilitates removal of a trapezoidal wedge from the mid carpus without damage to the radius or ulnar articular surfaces. This resection allows for correction of the wrist flexion contracture to around 40° of hyperextension and relaxes volar soft tissues, including the neurovascular structures and flexor tendons. This permits the fingers to adopt a more functional flexor-empowered position.¹⁸¹ The wrist position is initially maintained with K-wire fixation and recurrence is prevented through the transfer of the flexor carpi ulnaris and radial tendons to augment the dorsal pull on the metacarpals. Early surgery achieves more active flexion and allows greater bone remodelling.^{165,181}

Thumb

Patients with tight adduction contractures who do not respond to stretching and splintage may benefit from a first webspace release and either an extensor indicis transfer to improve extension or an epiphyseal sparing chondrodesis of the MCP joint. In some cases an opposition transfer is required at the same time.¹⁷⁴

Fingers

Finger position can be significantly improved with early stretching and splintage. Further improvement can be achieved through functional repositioning of the wrist contracture through wedge carpectomy, as mentioned above. In rare instances digital flexion, contractures require surgical release with full-thickness skin graft reconstruction.¹⁶⁵

Trigger thumb

Trigger thumb occurs due to obstruction of the flexor pollicis longus tendon at the A1 pulley as a result of stenosing tenovaginitis.¹⁸² Unlike the intermittent triggering seen in adult cases, children most commonly present with their thumbs locked in flexion at the IP joint. A small minority present locked in extension.

Notta's node is palpable proximal to the A1 pulley in a fixed flexion deformity. Most authors view this as secondary to bunching up of the tendon, as it appears to resolve following A1 release, rather than as a primary lesion. When the thumb is locked in extension, the failure to glide through the A1 pulley occurs distal to proximal, with Notta's node abutting the distal end.

Aetiology and presentation

Trigger thumb usually presents between 6 months and 2 years. There is debate as to whether this is in fact an acquired rather than congenital condition. Most studies reporting presence at birth depend upon a retrospective history from the parents. Prospective studies with early postnatal assessment report very few cases.^{183,184} However, diagnosis in the newborn is unreliable as they tend to clasp their thumb, and clicking or triggering is more difficult to elicit in a child than in an adult. A congenital basis is supported by the presence of trigger thumb in twins, the frequency of bilateral trigger thumb (25%) and the association with Trisomy 13.^{185–188} Trigger thumbs occur 14 times more frequently than trigger fingers. It is usually pain free, unless attempts are made to straighten the digit. A missed diagnosis of dislocation may be made with rapid recurrence following attempted reduction.

Surgical principles and management

Trigger thumbs tend not to resolve spontaneously in most cases. However there is some evidence that resolution is higher in those diagnosed prior to the age of six months.¹⁸⁸ Trigger fingers have even higher rates of spontaneous resolution. This recovery may be assisted by splinting and passive stretching programmes. However, we have found compliance difficult in this age group. Furthermore, we do not advocate treatment with steroid injections in paediatric cases.

Surgical release of the A1 pulley of the thumb is very successful.¹⁸⁹ We advise release prior to the age of 3 years,¹⁸⁸ due to a risk of permanent joint deformity. Access is via a transverse incision at the base of the thumb within a skin crease. Care must be taken to avoid damage to neurovascular bundles, which tend to sit more anteriorly when compared to the digits. However, direct visualization of the bundles is not required, only care in their protection. The radial part of the A1 pulley is divided under direct vision to allow unobstructed tendon gliding and to prevent damage to the oblique pulley. Trigger fingers, however, usually do not respond to A1 division alone, requiring sacrifice of one slip of FDS also.

CHAPTER 50

Finger tip injuries

Donald Sammut¹ and Robert Pearl²

¹Hand Surgeon, Circle Bath Hospital, Bath, UK

²Department of Plastic Surgery, Queen Victoria Hospital, East Grinstead, UK

Introduction

The hand is in harm's way. It is at the frontier of all work and contact with the environment. The finger tips, as a collective functional unit, bear the statistical brunt of such injuries. Hand injuries constitute the single most frequent surgical presentation in an average emergency department.¹

The hand is unique in its dual role as a considerable gatherer of information about the environment and also as an executor. Unlike the other major sensory organ, the eye, the hand is also able to act on the information gathered, constantly modifying action by feedback of sensation and proprioception. The gathering of information about the environment is especially developed in pulp and palmar digital skin, which is not to be regarded merely as skin covering, but as a specialized organ in its own right. The dense population of sensory end organs is housed in skin with specialized, mechanical properties. The skin is robust and yet deformable – the nail complex and the skeleton provide a fixed stop, against which the pulp and palmar skin complex are deformed; without such a rigid stop, one would obtain less meaningful information about the contour and texture of a held object or touched surface.

The aesthetic importance of the hand is not to be underestimated and is an important consideration in all reconstruction. Irrespective of custom and attire, in virtually all societies, the hand is always on display (the hand is exposed even in societies where the face is concealed). The back of the hand, in particular, is a significant aesthetic unit. In this regard, function and appearance are closely interlinked. The hand which behaves fluently and efficiently attracts little attention, even if it carries significant scar, or is missing anatomical parts. Smooth, healthy-looking skin cover, as well as fluid, natural behaviour form important aspects of social acceptability. Hand gestures reinforce facial expression and in some spheres, hand movement and posture constitute a very specific vocabulary, interpretable by those who converse in that language. Aside from the obvious example of signing for the deaf, the orchestra conductor's hand gestures speak a clear language to musicians and culture-specific hand

gestures convey meaning over distance beyond that possible through sound. Convention and social context convey specific messages with hand gestures – the extended index finger held vertically over the lips is universally interpreted as a request for quiet, for silence. It is also relevant that the hand is the most frequent acceptable point of contact; in most societies, the handshake is considered a permissible intrusion into personal space, and a permitted form of contact, irrespective of the difference in social standing of those shaking hands.

The hand is an integral part of one's identity for any individual but specific professions imbue the hand with an additional importance. The musician, for instance, has a special relationship with the hand since this forms an integral part of his or her identity and 'voice'. The same can be said of the craftsman or in sports that use the hand. Although these aspects form an important element of management, one must not overrate the contribution of profession to the decision-making process. Although some methods of reconstruction may entail an unacceptable period off work for, say, the manual worker, whose main concern may be for strength and durability, all will require a large measure of pain-free, sensate dexterity. Irrespective of work or leisure pursuits, all will still need to perform delicate, precise tasks, such as writing and doing up fastenings and buttons, touching spouse and offspring. Most will be disturbed by an unattractive extremity on display.

Since the hand is the part most frequently involved in work-related injuries,² the issue of personal injury claims and the cloud of possible compensation frequently hangs over the outcome of repair and reconstruction.

In the case of injuries in children, the growing hand presents special challenges on a number of fronts. Any repair must take into account the facilitation of growth of soft tissues and skeletal elements. Scarring and contracture, a perennial problem in the hand, assume an added importance. To these factors must be added the factor of parental anxiety and elements of guilt and regret centred on the occurrence of the injury in the first place. In general, the management of the child's hand involves the management of the family.

These various factors should all figure in the assessment of injury, the 'feel' of patient compliance and cooperation, the choice and planning of repair and reconstruction and the required aftercare. All too often these injuries are downgraded in the queue of surgical priorities – many still consider that 'all soft tissue injuries of the pulp heal' without regard to the quality of function of such healing. Injuries that can lead directly to significant loss of function, persistent pain and compromised appearance are still, regrettably, considered trivial and merit little surgical input. They are often misguidedly delegated to inexperienced members of the surgical team with little appreciation of their complexity and functional significance.

Assessment

The challenge of reconstruction in the hand lies primarily in the assessment and decision making, not in the technique, however immaculately executed. In assessing any injury (and the patient) one brings to bear experience and a big repertoire so that, as far as possible, questions are answered before the start of surgery. This is not to say that plans may not change when the examination reveals more detail, but it is the planning and selection of technique that is the focus and essential to a good outcome.

In the field of reconstruction, there are no recipes, only principles. In the management of reconstruction challenges of the digits, one vital principle is the appreciation that not all areas of the hand are of equal functional value. Observation of the hand in action soon reveals that all digits have leading and trailing aspects. Although one would not suggest that any part of the hand is of lesser importance, in reconstructive terms these could also be considered 'high premium' and 'low premium' territories (Figure 50.1).

The leading edge is the more commonly used in contact with a held object or contact with a surface. The trailing edge is less often in contact, and tends to have less developed discriminatory abilities or needs. This principle is most true of the thumb. The ulnar pulp 'leads' and is involved in virtually all dextrous activity and certainly all precision actions, since it is this area which faces the long digits most effectively. By contrast, the radial pulp 'trails' during most tasks, coming into play with relatively unspecialized tasks such as tapping on a horizontal surface or keyboard. The principle is least true of the index, both of whose aspects are frequently involved in common activity.

Once this principle is accepted, one can start to assess the functional significance of a specific defect and the availability of suitable methods of reconstruction:

- High premium areas require the best possible reconstruction, preferably sensate, glabrous pulp skin taken if possible from the same digit.
- Injury to a low premium area may be reconstructed acceptably and reliably with relatively non-specialized cover, such as a skin graft or an insensate skin flap.

Figure 50.1 The leading aspects of the digits. Source: Donald Sammut. Reproduced with permission.

- Low premium areas can be considered for transfer to high premium areas, preferably on the same digit, as for instance the reconstruction of ulnar pulp in the thumb using radial pulp (Figure 50.2).

These observations are proposed as factors to be taken into account, and are certainly not absolute. They are among many that should be considered, including the requirements of the patient overall, likelihood of compliance, as well as special requirements for a particular patient, such as the playing of musical instruments or professional sport.

In few other areas of reconstruction is collaboration with the patient as essential. This element needs careful assessment if one is to obtain a good outcome, which, in this situation, is the maximum restoration of function (and hence appearance) and an acceptance by the patient of any limitations consequent on the injury.

Detailed informed consent also needs to take into account the time and effort investment required of the patient, particularly in the more complex reconstructions. The extension of the site of injury and/or the involvement of distant donor sites are all factors to be included in the detail of the process of informed consent.

Figure 50.2 Pulp exchange flap. (a) The defect involves the entire leading (ulnar) surface of the thumb pulp. (b) The trailing (radial) aspect of pulp is intact and an island flap is designed on this pulp. (c) The flap is entirely islanded leaving ample fat around the nerve and artery. (d) The island is transposed to reconstruct the ulnar pulp. (e) The secondary defect is resurfaced with a skin graft, in this case a full-thickness graft taken from the amputated part, which was defatted. (f, g) Final result at three months. Source: Donald Sammut. Reproduced with permission.

Finally, in the process of assessment, the surgeon must also have a realistic and honest assessment of his or her capabilities. Many methods of reconstruction are attractive to the surgeon since they fulfill a natural mechanical neatness and challenge of construct. The seduction of such methods must be resisted in the absence of expertise or adequate guidance (and, preferably, also assistance) by those more experienced.

It cannot be overemphasized that the method selected must suit the defect and the level of expertise of the surgeon. In this regard one must mention that it may be entirely appropriate to select a temporary method known to be insufficient for long-term wear and restoration of function (such as a dressing or a split skin graft on pulp), leaving all options open for reconstruc-

tion with the availability of appropriate expertise. If this approach is selected, it is wise to present this to the patient as a two-stage procedure so that he or she is prepared for the second surgery and it does not come as a 'salvage', or adjustment, of the first.

Healing by secondary intention

Both pulp and palmar skin have remarkable powers of regeneration, as evidenced by the reliable healing of the open palm technique advocated by McCash.³ Large defects of pulp will heal reliably provided a number of important criteria are observed:

- The defect must be suited to this method. No vital structure, such as tendon, bone, or joint, must be exposed. Severely contaminated or crush defects must be thoroughly debrided of all contamination or necrosis.
- The hand must be elevated.
- The patient must understand that the method requires careful adherence to instruction and compliance with treatment (many patients will only remember that 'It needs no surgery' and this is rapidly translated into 'It needs no care').
- Non-adherent dressings require regular change, preferably on alternate days. Exception is made for children where it is routine to leave a dressing undisturbed for a week, after which the wound can be left exposed, in order to avoid the trauma of painful dressings.

The dressing in direct contact with the wound is a matter of personal preference. tulle gras (paraffin-impregnated gauze) is traditional. It is cheap and easily available or can be improvised, but dries rapidly and tends to adhere more than one might expect. Many superior alternatives are available, such as thin, perforated silicone sheeting (e.g. Mepitel®, Mölnlycke Healthcare), which is resistant to all adherence. Chitin (Beschitin®, Unitika) and other natural substances have their advocates. The important aspects are: non-adherence, a barrier to contamination and assiduous care and compliance.

Surgical options for cover

Amputation

In cases where a significant part of the digit is crushed, with accompanying disruption of the nail complex and/or the distal interphalangeal joint, amputation with closure of locally available skin, may be the indicated option. In this situation, it may be appropriate to elect to ablate any nail elements which, regenerating, will be unsupported, non-adherent, unattractive or likely to lead to functional problems such as snagging on clothing.

Much morbidity results from amputation performed without proper regard to indications and points of technique. There is a natural tendency to preserve length at all costs. The aim should be to achieve a non-tender digit covered by good-quality skin, irrespective of length. It is better to elect for a slightly shorter length, with good-quality, mobile skin cover, than to preserve length at all costs but with a tight and painful digit end. A digit with tense, painful skin cover may well be excluded from function, resulting in an effective loss of all useful length. This is particularly true of the index, which is readily substituted by the middle finger and regularly requires subsequent revision. It is a wise surgeon who seeks to prevent the cycle of pain, tenderness and exclusion.

There are three generally indicative levels of amputation of the finger tip (Figure 50.3):

- **Level 1** involves loss of skin and only a minimal loss of nail and distal phalanx. In this case all of the tip vital structures are preserved and skin cover is indicated.

Figure 50.3 The levels of amputation. Level 1: There is a skin defect with minimal loss of nail and no significant loss of supporting distal phalanx. Indication: Dressing or, if bone exposed, advancement of skin flap. Level 2: A significant portion of nail and supporting bone is lost. Indication: Ablation of nail remnant and trimming of bone so as to preserve the next vital structures, the insertion of extensor and flexor, while achieving tension free cover (direct closure or flap). Level 3: The tendon insertions are disrupted. Indication: Trimming of bone and removal of articular cartilage to achieve skin cover with appropriate cover (direct closure or flap). Source: Donald Sammut. Reproduced with permission.

- **Level 2** involves loss of skin and most of the distal phalanx/nail complex. In this case the nail should be ablated and the next proximal structures to preserve are the tendon insertions. Just enough bone should be left to preserve these insertions which will preserve power and elements of proprioception.
- **Level 3** has lost all nail elements and the tendon insertions. The condyles of the middle phalanx can be removed to prevent an unattractive, spatulate stump shape. The phalanx is shortened to a level where tension-free, good skin cover can be achieved. One should not be tempted to anchor the tendons, or to suture them to each other. This invariably leads to an imbalance and most frequently to a flexion contracture.

All amputations require attention to the nerve ends. One should take the opportunity of any skeletal shortening to keep the nerve ends long and to transpose them dorsally, away from contact areas.

Options for skin cover

If skin cover is required, either *skin grafts* or *flap cover* can be used. Reconstruction most often involves moving tissue around from one site to another, with the added, vital, phrase 'and keeping it alive'. Blood supply is paramount. A skin graft requires a bed capable of angiogenesis, the essential process of 'take'. 'Take' is the establishment of a blood supply to support a graft. A flap requires no such bed – it brings its own blood supply and can be placed over any surface, including metalwork. Provided this principle is observed, the decision can then be taken on what form of cover will best restore function and structure. The concept of the

'reconstructive ladder,' with its implications that one chooses the simplest reconstruction available, is outdated – one chooses what is appropriate and best restores form and function.

It follows that the surgeon must have in his or her repertoire, as large a variety of reconstructions possible, in order to match the reconstruction to the defect and patient, and not the other way around. This, incidentally, is another strong reason for involvement of experienced, senior surgeons. All too often this process is left to those with one or two methods at disposal – this invariably results in the dispensation of a method which the surgeon knows, rather than that which is appropriate.

Skin grafts

Provided the bed will ensure take, a split skin graft provides excellent temporary cover or permanent cover of a 'low priority' area, including a secondary defect, from flap harvest. Many wounds involve crushing or bursting mechanisms and it is difficult, at first view, to be sure of viability unless one is wastefully radical with excision. In such situations, a flap may be the appropriate skin cover but its territory may itself lie in the area of trauma. Proceeding with immediate flap cover may lead to flap loss and failure with waste of a reconstructive option. A skin graft may provide comfort, initiate healing, resolve inflammation and will keep all other options open.

In some situations, skin graft provides good definitive cover. These include the trailing aspects of digits and the secondary defects from the raising of a flap. It need hardly be added that a flap donor source is chosen from an area that can be closed directly, can take a skin graft or can be left to heal by secondary intention. Skin grafts do not provide good definitive cover in the pulp, where accurate, pain-free sensibility and good mechanical properties are required. In such a situation, the skin graft will lead to unacceptable hyperaesthesia, poor cosmesis and troublesome long-term fissuring.

The choice between split skin graft (SSG) or full-thickness skin graft (FTSG) is a matter of balance of various factors. A full-thickness graft requires a better quality bed, since there is a larger cell population for nourish. Take of a split skin graft is more reliable on a poorer bed. Conversely, split skin grafts contract more significantly than full-thickness grafts – an important factor in cover of mobile areas crossing joint creases and anywhere in the growing hand.

Points of technique

Split skin graft

- *Donor site:* Small grafts can be taken from the hypotenar mound. The skin here is thick enough to permit harvest of the dermis while replacing the epidermis.⁴ Larger grafts can be taken from the proximal inner aspect of the forearm, where it can be unattractive and/or tender or from the thigh. With both SSG and FTSG, the opportunity to harvest skin, or indeed any other element, from a finger which is to be discarded should not be lost (the concept of the 'bank digit').⁵

- A guarded skin graft knife is used, such as the Watson, Humby, Silvers knife or, for larger areas, the electric dermatome.

Full-thickness graft

- *Donor site:* Avoid harvest from the wrist skin crease – scars here can be misinterpreted as the outcome of self-inflicted wounds and can prove tender and troublesome with the wearing of watches or bracelets. The cubital fossa provides ample skin for most needs in the hand and digits. It is usually hairless, and is in the same bloodless field, which speeds up proceedings and makes harvest more accurate. Hairy donor sites should be avoided – harvest from the groin crease in children before the distribution of pubic hair is evident provides a common pitfall.
- The graft should be taken thin, without subcutaneous fat, or thinned just before final detachment.
- The graft should be sutured tense over the recipient site (suture of a graft provides the only instance when suture under tension is permissible) and larger areas require a tie-over dressing.

Finally, one may mention the composite graft as a form of skin grafting. This is particularly applicable in the child's hand, when the section is clean and the segment uncrushed. It is more successful the fresher the injury and the younger the child. The amputated part should be applied rapidly, with minimal dissection of either surface and with as accurate alignment of landmarks, such as nail fold and even print ridges. Parents are warned that the method is not guaranteed and that reconstruction may be required if it fails. The part often appears to necrose and perish, only to reveal accurate resurfacing some three weeks later when the carapace falls off or is peeled off.

Flap cover

Flap cover is indicated when bone, joint and tendon are exposed, or when metalwork needs cover. In some situations there is no choice but to apply a skin graft to intact tendon sheath or paratenon, or even direct to cancellous bone where, somewhat surprisingly, it frequently takes. These are relative indications: in general, exposure of such structures requires flap cover.

Flap cover is also indicated when deeper structures are not exposed and the defect is capable of nourishing a graft, but sensibility, mechanical quality or cosmesis are relevant requirements.

Flaps have been classified in various ways. In the hand, the basis of the blood supply and the presence of sensibility provide the most relevant classifications:

- *The basis of the blood supply:* Preservation of continuity of blood supply is paramount. This may be either left unidentified in the flap base (e.g. the Hueston flap⁶ or the cross finger flap⁷) or formally dissected free, as in the islanded flaps. In general, the latter type of designs are the more mobile and versatile, but demand a higher level of technical expertise.
- *The presence of sensibility:* For classification purposes, one may consider 'sensate' flaps those which maintain pulp quality

Table 50.1 Classification of commonly available flaps

Relatively insensate flaps:	Kite flap Delayed flaps: cross finger, thenar, distant flaps (e.g. groin flaps, random flaps) Free venous flaps
Relatively sensate flaps:	V-Y advancements (e.g. Atasoy flap) Thenar advancement Bipedicle homodigital Homodigital islands ^{10,11,12} Heterodigital ¹³ Free flaps (e.g. hemipulp transfer from toe or from a bank digit). The recovery of sensation is inversely proportional to age in these examples

and replace lost pulp with sensate pulp. One should not consider adequately 'sensate' the cross finger flap which regains some sensibility despite the numerous reports of recovery of 'excellent' two-point discrimination.^{8,9} Nor should one consider that the transfer of an island of dorsal skin (e.g. the kite flap) replaces adequate pulp quality sensibility. On this basis, the commonly available flaps can be classified as shown in Table 50.1

This definition of sensate/non-sensate is a working classification serving to underline the importance of replacing like with like. It sorts out flaps rather too harshly on the basis of restoration of pulp quality sensation. Many studies report recovery of two-point discrimination approaching normal in flaps that cannot transfer nerve continuity, such as the cross finger flap.^{9,14} In this context, one should note that our methods of assessment of sensory discrimination remain relatively crude and subject to significant operator variability and subjectivity.

The description of flap qualities is not intended to label any flap superior or inferior to others. All are useful in context and the wise reconstructive surgeon will master all, and will amass a large repertoire on which to draw when analysing each individual defect. It cannot be repeated too often that each defect will have qualities which will be met by this or that flap, and one should have all at one's disposal so as to be able to produce a flap that matches the defect, not the other way around. In this regard, one should resist the tendency to refer to this or that flap as a 'workhorse' or to apply the same, favourite, flap to a wide variety of defects. Conversely, it is also ill advised for the inexperienced to be captivated by a clever flap and to resolve to 'try' it.

The account below cannot be exhaustive. Representative flaps in each category have been selected which illustrate the principles of selection, technique, flap attributes which form part of the analysis, planning and execution of skin cover of the digit.

The kite flap (Figure 4)

The kite flap was originally designed with a wide base pedicle by Holevitch (Figure 50.4).¹⁵ Vilain and Michon developed the design, narrowing the pedicle to about 1 cm, including the vascular axis; this design was christened the 'flag flap'. It was

Figure 50.4 Kite flap raised on the dorsum of the index. Source: Donald Sammut. Reproduced with permission.

Foucher who islanded the skin flap, denuding the pedicle of skin and conferring a greater degree of mobility as well as the potential for tunnelling of the pedicle.¹⁶ The island of skin is raised in a plane just superficial to the extensor tendon paratenon (which must be left intact so as to receive a graft). The pedicle includes the first dorsal metacarpal artery, local veins, as may be found (usually plentiful), and any superficial branches of the radial nerve that are identifiable.

The radial nerve branches provide sensation but the density of end organs in the dorsal skin never matches the density required to provide pulp quality sensation and it is for this reason that this flap is included in the 'insensate' category.

Although it is tempting to use it for resurfacing of the leading edge of thumb pulp, its use should be reserved to areas with less demanding sensory qualities, such as the dorsum of the thumb and the radial aspect.

Important points of technique

- The first dorsal metacarpal artery should be identified early since it may follow a course part way through the substance or fascia of the first dorsal interosseous muscle.
- It is prudent to include any veins which can be gathered into the pedicle – a surfeit of veins makes for a healthier flap.
- Terminal branches of the radial cutaneous nerve are fine and must be sought and preserved.
- If the flap is tunneled, the tunnel must be generous and without sharp kinks in its course.
- The donor area must be carefully protected and the paratenon left intact so as to receive a graft.

Advantages

The technique is relatively unchallenging and the flap is robust, provided important points of technique are observed. The loss of skin from the dorsum of the index produces no functional impairment. Care with the dissection should ensure full and immediate take, so that the cosmetic defect is minimized. The pedicle is mobile and long and permits placement of the flap in a wide radius of reach.

Disadvantages

The quality of the thin, poorly sensate, transferred skin cannot replace glabrous skin with its myriad of end organs and special mechanical qualities. This limits its application. The transferred skin may be hairy, particularly in males and, in black skin, will be darker than palmar skin. The skin graft applied to the donor site may pigment.

Delayed staged flaps

Delayed flaps have a random design (i.e. they are not planned over a known vascular pedicle). They are inset into a recipient defect and their relative ischaemia (which can be encouraged by judicious clamping) encourages ingrowth of vessels from the recipient site. The flap can then be detached from the donor site.

The period required before the flap can be safely detached from its original vascular supply varies, but generally depends on the quality of blood supply in the recipient bed and the volume of flap that must be nourished. The principle of delay is discussed in more detail elsewhere.

The cross finger flap

Gurdin and Pangman⁷ are credited with the first description of this flap which uses a well-established principle. It is still one of the most commonly used (and abused) flaps used for skin cover in the digits. In principle, dorsal skin from a digit is raised and turned over like the page of a book (Figures 50.5 and 50.6). A palmar defect in an adjacent digit can be inset and receive cover. The secondary defect receives a graft. There are a number of variations, including the innervated neurovascular cross finger flap and the reverse dermis cross finger flap.

Important points of technique

- The recipient defect should be thoroughly debrided *before* planning of the flap.
- It is best, if possible, to design the flap over the dorsum of the finger between the interphalangeal joints.
- The flap must be raised carefully so as to preserve its dermal plexus but also to leave behind a graftable defect.
- The skin graft (usually full thickness) is best secured and inset into the donor defect before the flap is sutured to the recipient. It is easier to gain access to all the borders of the graft while the fingers are still unattached.

Advantages

The flap is reliable, simple to perform and versatile – the same digit can act as donor, giving a flap to a neighbour and as recipient, receiving a second flap from another neighbour (e.g. dorsum of middle finger to palmar index combined with dorsum index to palmar thumb).

Disadvantages

The enforced delay produces stiffness particularly in the proximal interphalangeal (PIP) joint of the recipient finger, which is kept flexed for some 2–3 weeks. Pigmented or hairy dorsal skin may be unsightly on the palmar surface (Figure 50.7).

A skin graft is required and may pigment. The flap is totally insensate unless modified in one of the described methods (e.g. Venkataswami), which are technically more demanding. Its lack of sensation should restrict its use to more proximal defects where the pulp has been preserved.

Distant delayed flaps

The limited indications and disadvantages of locally sourced delayed flaps hold true for distant flaps with the added problems of immobilization and difficulties with elevation of the hand. Nevertheless it is occasionally necessary to raise and use a random flap from abdomen or arm or an axial pattern, delayed flap from the groin. The groin flap has its application, delayed or

by immediate free transfer, in larger defects, especially in staged reconstructions such as multi-digit loss which may later receive free toe transfers, at which time it is a bonus to be able to transplant into good-quality trophic skin rather than dense scar.

The Atasoy flap¹⁷

Some elements of the literature have likened this V-Y advancement of pulp flap described by Atasoy in 1970 to the Tranquili-Leali flap¹⁸ described in 1935 to which some even attribute precedence. There is no connection between the two other than the original triangular shape of the flap. The Tranquili-Leali flap involved division of both vascular pedicles and flap survival

depended on direct supply from the vertical connections between skin and deeper surfaces. This was sheared forward rather like a jelly and its advancement was very limited. In contrast, the Atasoy flap is a bipedicle island flap, raised on both, intact, vascular pedicles and nerves (Figure 50.8).

Important points of technique

- Selection is crucial. Only transverse or dorsally inclined defects should be considered. At least half of the distal phalanx should be preserved to provide adequate nail support.
- The width of the advancing edge must correspond precisely to the width of the nail plate. Too narrow a flap produces

(c) It is important that the flap be entirely islanded free from its bed and attached only by the pedicles with a generous sheath of fat. (d) The flap is advanced and inset. The secondary defect can be closed as a V-Y or left to heal. (e) In selecting an appropriate defect it is important that the amputation be angled transversely or, preferably, with a dorsal angulation. Source: Donald Sammut. Reproduced with permission.

Figure 50.9 The Moberg flap. The flap is raised in the plane of the flexor pollicis longus sheath and includes both digital bundles. The original flap simply advanced by 'creep', aided by some flexion of the thumb, and with no secondary defect. Further advancement can be obtained by transecting (and islanding) the base (O'Brien), and grafting or closing as a V-Y (Carroll). (a) The defect. (b) The flap raised in classical design. (c) The Carroll V-Y modification to close. (d) Design of the classical Moberg flap and the Carroll modification (islanding the flap and closing the base as a V-Y). Source: Donald Sammut. Reproduced with permission.

unattractive 'shoulder pads' either side. Too wide a flap produces an unattractive spatulate result.

- The flap must be completely islanded (i.e. it must remain attached only by the neurovascular pedicle).
- The proximal V apex need not be limited to the distal interphalangeal (DIP) joint crease. The flap should be designed of the dimensions required and the crease line is an irrelevant landmark.
- If, postoperatively, there seems to be tension, or congestion, only the side sutures should be considered for release. The leading edge sutures must be left intact; their division will

result in retraction of the flap proximally, exposure of bone and healing with a tender, dimpled scar.

The Kutler flaps,¹⁹ double VY advancements with each flap on either side of the digit tip, are mentioned because they bear a superficial resemblance to the Atasoy V-Y but, once again, the main point in common is the shape. They are technically challenging and generally unreliable, not least because the anatomy of the vasculature on this area is variable. The vascular arcade in the pulp may be U-shaped, Y-shaped or H-shaped²⁰ and one cannot rely on an axial vessel on either side in the flap triangle. In practice, Kutler flaps are raised without islanding, left attached to

their bed, and teased forward to obtain modest advancement, a process made more difficult by the presence in the flap of Cleland's ligament, which must be teased apart or divided.

The thenar advancement flap

This flap consists of the entire palmar surface of the thumb, raised off the flexor sheath and skeleton, and stretched distally to cover a distal transverse defect (Figure 50.9). It enjoys the advantage of perfectly sensate, homodigital cover, which requires no re-education.

In essence, this flap 'creeps' distally, the division of septa and tethering fibres enabling the skin to cover a larger area by stretching. In practice, there is also an element of flexion of the interphalangeal joint in most instances, so that the defect comes to meet the flap as much as the flap advances to cover the defect. Flexion contracture of the interphalangeal joint is a common sequel to this flap and is, fortunately, not a significant functional impairment.

The flap, originally described by Moberg,²¹ is applicable only to the thumb, which enjoys a dual vasculature, dorsal and palmar, so that the two can be separated. Application in other, long digits, as advocated by Snow, runs a significant risk of necrosis of the dorsal skin.

Important elements of technique

- The neurovascular bundles in the thumb lie apposed to the flexor pollicis longus (FPL) tendon sheath either side and not down the midlateral lines.
- The parallel incisions must be strictly in the midlateral axis if one is to avoid subsequent flexion contracture.
- If the flap does not advance enough and/or is too tense, one can join the two parallel incisions on the palmar aspect, effectively islanding the flap on its bundles as advocated by O'Brien²² (Figure 50.10) or close the base as a V-Y (Carroll) (Figure 50.9c).

The advancement rotation flap

This flap is based on one digital bundle, without islanding, rotating to cover a terminal defect. It was described by Hueston⁶ (Figure 50.11) as a square, or rectangular flap, raised

Figure 50.10 The O'Brien islanded flap. O'Brien modified the Moberg flap by transection of the base and islanding. Source: Donald Sammut. Reproduced with permission.

by an L-shaped incision. It excludes the neurovascular bundle from the leading edge and is nourished by the neurovascular bundle in the base. This means that the leading half of the flap is insensate.

Important points of technique

- Selection is best reserved for transverse amputations or for oblique loss slanted towards the base. This minimizes the required arc of travel.
- Cleland's ligament should be divided in the static base of the flap, since this base also is involved in the stretch and rotation required.
- The distal end of the base will produce a dog-ear and this should be dealt with in the manner described by Foucher, by excision of a square of skin *on the dorsum* (Figure 50.12) without reducing the width of the base pedicle.
- The secondary defect, a raw triangle at the proximal border, can be left to heal by secondary intention or may accept a split skin graft.
- Provided the underlying bone is not wide (for instance including phalangeal condyles) one should not trim the skin to coat the skeleton too closely. A looser skin pocket will contract to conform to the skeleton without tension.

The issue of loss of sensation of the leading half has been addressed in various ways:

- Souquet described a modification which included the leading neurovascular bundle in the flap and teasing it so as to permit some stretch. This maintains sensation but greatly limits the ease of rotation and movement (Figure 50.13).
- The flap can be based on the leading edge of a digit, so that the insensate half comes to be placed on the trailing edge and is of lesser functional consequence.
- The two techniques, Hueston and Souquet, can be combined in the manner described by Lloyd and Sammut (Figure 50.14),²³ which includes both bundles in the flap, but mobilizes the leading neurovascular bundle to obtain better movement.

Figure 50.11 The Hueston flap. The flap is square, raised palmar to the leading edge neurovascular bundle, in the plane of the flexor sheath and nourished by the neurovascular bundle in its base. The leading half of the flap is insensate since the leading edge bundle is not included. Source: Donald Sammut. Reproduced with permission.

Figure 50.13 The Souquet flap. Like the Hueston flap, the design is square but includes the neurovascular bundle in the leading edge. The flap will rotate less but remains sensate in all areas. Source: Donald Sammut. Reproduced with permission.

The island flaps, homodigital and heterodigital

Numerous variations of islanded flaps have been described^{10–12} but the principle is the same as that originally designed by Littler, who, in 1953, raised an island of skin from the ring finger

Figure 50.14 Sammut modification of Souquet flap. The Hueston flap has a wide arc of rotation, but the leading edge is insensate. The Souquet flap moves far less but is entirely sensate. The Sammut achieves the best qualities of both flaps by including the leading pedicle (retaining sensibility) and mobilizing it so that it permits flap advancement. Source: Donald Sammut. Reproduced with permission.

on its neurovascular bundle and transferred this to the ulnar aspect of a reconstructed thumb to confer sensation¹³ (Figures 50.15 and 50.16).

These are among the most versatile flaps for reconstruction, since the pedicle permits so much movement. They are technically challenging but provided important points of technique are observed, they have a safe ratio of blood supply to volume of flap. In most cases they are raised on a digital artery which could have supplied the entire digit and, in supplying an island, is now providing generous vascular input.

The homodigital flaps (Segmuller,¹⁰ Venkataswami,¹¹ Joshi,¹² Evans²⁴) vary in their design and orientation – the Segmuller flap is lateral, the Joshi design is predominantly dorsolateral and the Venkataswami modification was designed obliquely lateral (Figure 50.16) Evans designed an ingenious version, the *step advancement island flap*, which utilizes a series of triangular flaps, each of which advances distally into the next defect, such that the most proximal secondary defect is closed directly (Figure 50.17).

Figure 50.15 Design of homodigital island flap. Source: Donald Sammut. Reproduced with permission.

Many modifications of the island flap have been described, including the *exchange island flap* (Foucher) (Figure 50.2), the technique of dividing the flap nerve and anastomosing it to the nerve in the defect in order to minimize reorientation.²⁵ Glicenstein proposed a retrograde perfusion flap similar in principle to the Chinese radial forearm flap, but based in the digit and rotating on the transverse arcades at the level of the joints.²⁶

The vessel and nerve, with accompanying fat which contains essential venous drainage, are dissected free, as far proximally as is required. Additional advancement can be obtained by supplementary techniques such as ligation and section of the vessel to the adjacent digit at the Y bifurcation and by careful longitudinal separation of the relevant elements of the digital nerve from the common digital nerve. On the radial side of the index the digital bundle is tethered at the base; additional advancement can be obtained by releasing the bundle from this tethering (Figure 50.18).

Important points of technique

- The digital artery is not accompanied by an identifiable digital vein, since most venous drainage in the digit travels via the dorsum. It is important to include the fatty investiture of the neurovascular pedicle since this contains important venules which later dilate and drain the flap (Figure 50.19).
- One must produce adequate advancement and not be tempted to flex the finger to accommodate the flap. Flexion contracture inevitably follows. The finger must leave the operating room with the flap inset and without resort to flexing splintage.
- Any tunnelling must be relaxed, ample and there should be no points of kinking. The process of tunnelling must also ensure that no twisting movement of the pedicle occurs.

Free pulp transfer

First described by Buncke and Rose in 1979,²⁷ free pulp transfer gives arguably the most 'like for like' reconstruction, the subcutaneous fat, fibrous septa and glabrous skin of the toe pulp providing an excellent pad for the finger tip. In the young, where a useful return of sensation can be expected from nerve anastomosis, free transfer provides the opportunity to customize the transferred tissue for reconstruction. Options include the contiguous hemipulps of first and second toes, toenails including germinal matrix, wraparound flaps from first or second toes and partial lesser toes.²⁸

Pulp flaps can consist of simple skin islands or may extend to inclusion of the nail as a wraparound flap. In this case, it is useful to include the distal phalanx of the toe to which the nail matrix adheres, to provide stability and to prevent resorption of the otherwise 'open' end of the recipient skeleton.

Important points of technique

- Most microsurgeons will favour distal-to-proximal dissection in this situation. This ensures that the island of tissue is in continuity with the vessel to be harvested and also minimizes the incursion into the donor toe.
- The design and harvest of the flap and the preparation of the recipient should ensure that the transferred tissue is not excessively bulky to avoid the well-recognized 'cobra' appearance of the recipient digit.

The bank digit

The concept of the bank digit was introduced by Foucher.⁵ In multi-digit trauma a damaged finger might be beyond salvage but may still be capable of providing elements useful in the repair or reconstruction of other digits. These include any element ranging from split skin graft and nail plate, to arterial grafts or a complete island (or free) flap. One should not miss the opportunity to utilize such elements.

Venous flaps

The concept of establishing an arterial inflow to a venous flap ('arterialized' venous flap) was introduced in an experimental model by Nakayama *et al.* in 1981,²⁹ and then used clinically both by Yoshimura *et al.*³⁰ and by Mimoun *et al.*,³¹ the former to reconstruct a traumatic finger defect.

Thatte and Thatte³² subsequently classified venous flaps into three types:

- venous flow through (venous inflow, venous outflow),
- single venous pedicle, and
- arterialized (arterial inflow, venous outflow).

This classification is generally accepted, although it is only the arterialized venous flap that has a role in finger tip reconstruction.

Advantages

Ease of harvest and a thin versatile flap with minimal donor site morbidity are the chief advantages of the free venous flap. Several veins are usually visible through the thin skin of the volar wrist/forearm, which allows a choice of pedicle whose length can be

Figure 50.16 The homodigital island flap. The island is designed over the neurovascular bundle which is dissected to the base and advanced. The secondary defect receives a split skin graft. Source: Donald Sammut. Reproduced with permission.

tailored and the flap orientated to suit the finger tip defect. Small cutaneous nerves invariably run with the veins and these can be anastomosed to terminal branches of the digital nerves.

Disadvantages

The veins supplying these flaps are <1 mm diameter and the anastomoses are technically challenging. Venous flaps are by reputation difficult to monitor, as their initial blueish/purple hue and gradual darkening is easily mistaken for vascular congestion.

Capillary refill is always more brisk than the norm for flaps but is a reliable indicator.

Points of technique

The afferent and efferent veins of the flap should not be in direct continuity, since blood flow may choose this low resistance route and shunt from one to the other without perfusing the capillary bed. Longer pedicle length will aid the microsurgery. Some operators prefer shorter pedicles to try and limit the number of valves

Figure 50.17 The Evans step advancement island flap. (a) An island is designed with triangulated edges and the flap is advanced such that the leading portion surfaces the defect and successive triangles advance by one place. (b, c) Design of the flap. Note that the dorsal border is a straight midlateral line and that the triangles diminish in size from distal to proximal. (d) The flap is completely islanded. (e) The flap is advanced so that each triangle takes the place of the defect immediately distal. The final, proximal, defect is closed. (f, g) Result. Source: David Evans. Figure 50.18 Release of base of radial pedicle in the index. The radial neurovascular bundle in the index executes a sharp angle at the base. Useful extra advancement can be gained if these tethering bands are released, and the neurovascular bundle straightens out. Source: Donald Sammut. Reproduced with permission.

Figure 50.19 Fatty pedicle. The neurovascular bundle contains no formal vein since venous drainage is mainly on the dorsum of the digit. It is important to include generous fat with the pedicle since this contains important venules and drainage. Source: Donald Sammut. Reproduced with permission.

within the afferent veins.³³ Either way, the venous flaps should be reversed so any valves will not impede blood flow.

The nail

The nail deserves special mention since it is often neglected in crush and amputation injuries. Deformities of nail shape or growth can compromise otherwise very successful and inge-

Figure 50.20 Cross section of nail complex. The germinal matrix, the nail fold, the sterile matrix and the support provided by the phalanx are all essential elements in producing the nail complex shape and structure. Source: Donald Sammut. Reproduced with permission.

nious soft tissue reconstruction. Many such unfavourable outcomes can be avoided if basic features of nail support and growth are borne in mind (Figure 50.20).

- The germinal matrix must be unscarred. If it is involved in laceration, it should be repaired as accurately as possible, preferably with microscope assistance.
- The nail fold must be kept open – the nail plate is only plate shaped because the nail fold permits it out of the germinal

Figure 50.21 Nail support. The presence of the phalanx provides full support for the nail despite loss of all soft tissue. Source: Donald Sammut. Reproduced with permission.

Figure 50.22 Hang nail. The loss of distal phalanx length removes support for the nail. Source: Donald Sammut. Reproduced with permission.

matrix in this shape, much as the outlet of a toothpaste tube dictates the round shape of the extrusion. If the nail plate is removed, detached or lost, it should be replaced and kept in the fold while a new nail plate is advancing.

- The sterile matrix has special qualities – it allows the nail to adhere, while permitting slow progression of the plate as it grows. It is also smooth and flat, as is the plate. Any laceration of the sterile matrix must be repaired as accurately as possible, preferably with microscope assistance, in order to reduce scarring and to preserve these qualities.
- The distal phalanx is essential for support, whereas the pulp provides no structural support. A digit without pulp will support the nail (Figure 50.21) whereas one with soft tissue

but no bony support, will allow the nail to curve over the end (Figure 50.22). Even crushed elements of distal phalanx should be preserved if possible and allowed to unite – it is often surprising how well these remould or require just minor secondary surgery while the support is maintained.

- All surgery to an injured nail structure is best performed in the acute situation while these structures are relatively supple and, indeed, have some distinctive features which aid identification. Elective secondary surgery on germinal matrix or sterile matrix is especially difficult if it has been allowed to scar.

Psychological aspects of hand injuries

All injuries and surgery to the hand carry a psychological dimension. Leaving aside the special situation of the professional sportsman, the musician, the creative artist or the child, most will require their hands to earn their living and for the performance of the most elemental functions. It is part of the initial assessment of any hand injury quickly to sense these dimensions and to incorporate them into the analysis and plans.

The manual worker who suffers a major hand injury in a repetitive, uninspiring and low paid job also merits particular attention to this aspect. The initial attention by many professionals and the sudden thrust into the centre of attention is often unfamiliar and curiously welcome. Surgery and assiduous care follow, then discharge and increasingly spaced visits, until the patient comes out at the other end of the process, back in a humdrum, low-paid job (or unemployed), now with even worse

employment prospects and skills. The attention disappears and the specialized team moves on, while life is now even less inspiring and lower earning.

Conclusions

- Assessment of the defect, overall injury, psychological aspects is crucial as is the formulation of a plan based on restoration of function, not mere anatomy.
- The managing surgeon should master as many techniques as possible even those which seem unspecialized or unappealing. The larger the toolbox available the more likely is there to be found just the right tool for the task.
- The patient must be as informed as possible of the issues at stake, the plan of action, the realistic outcome and the possible complications. The need for secondary procedures should be set at the outset so that it becomes part of an anticipated plan not a remedy for initial failure.
- If tissue is to be discarded, one should always be aware of the possibility of harvest of skin, nail, bone, etc. for use in reconstruction in other digits.
- Points of technique for the various methods must be respected since there is usually little room for error or revision. It need hardly be added that a method should be used only if technical competence has been achieved and not merely because it is an enticing and attractive technique.

In the field of skin cover of the finger tips, restoration of function is the goal. Despite ingenious and constantly evolving methods of tissue movement and reconstruction, this field is dogged by perennial limitations, including: the relatively limited outcome of nerve repair; the incidence of neuroma and cold intolerance; the problem of scar contracture. Advances in the understanding of nerve regeneration and methods of influencing nerve recovery may one day transform our approach to these common and debilitating injuries.

CHAPTER 51

Flexor tendon injuries

Sarah Tucker and Georgina Williams

Department of Plastic Surgery, John Radcliffe Hospital, Oxford, UK

Anatomy

An in-depth knowledge of the anatomy and biomechanics of the flexor tendon system is essential to every stage of the management of flexor tendon injuries from diagnosis, surgery, correct assessment of complications through to secondary surgery. It must be remembered that this is a carefully balanced system with the function of any particular muscle not depending only on its origin and insertion, but the complex interplay between the system of pulleys in the hand and the balancing forces of all the muscles acting across the intervening joints. For example the effect of flexor digitorum profundus (FDP) acting alone would be to act purely at the distal interphalangeal (DIP) joint until this was fully flexed before acting at the proximal interphalangeal (PIP) joint in a similar manner, followed by the metacarpophalangeal (MCP) joint and lastly the wrist. However in normal function, such as grasping an object, the action of FDP will always be accompanied by balancing tensions in other muscles, and moderated by the pulley system to produce the desired functional outcome. For example, in grasping an object the wrist is stabilized and the joints of the finger are simultaneously flexed around the object.

Figure 51.1 shows the structure of flexor digitorum superficialis (FDS) as it divides and rejoins to become deep to FDP just before its insertion. This illustrates the complexity of just one element of the interplay between anatomy and function.

The wrist flexors and FDS are part of the superficial flexor muscle mass in the forearm arising from the common flexor origin. Both of the wrist flexors have pulley systems close to their insertions that redirect the vector of force and thereby increase the efficiency of their action. The flexor carpi radialis (FCR) is redirected by the scaphoid before being inserted into the bases of the second and third metacarpals and the flexor carpi ulnaris (FCU) is redirected by the pisiform before its insertion into the base of the fifth metacarpal. The FDS muscle also has an origin from the radius, and provides

independent control of pull for the FDS tendon to each digit, with the exception that the action on the little and ring is sometimes conjoined (see under Clinical examination below). The function of FDS is partly to assist with power grip, but more importantly provides individual finger flexion as required in manipulation of objects in the hand and in fine motor skills. As the FDS is inserted into the base of the middle phalanx, it acts mainly at the PIP joint, but also crosses the wrist and MCP joint, where the magnitude of its effect is determined by the balance of tension in the other muscles acting at these sites, such as the wrist flexors and extensors, the long finger extensors, and, importantly, the interossei and lumbricals.

The deep flexor muscle mass consists of flexor pollicis longus (FPL) arising from the palmar surface of the body of the radius, and the FDP arising from the ulna. FPL is the only flexor of the thumb and provides the strongest pull of all the flexors to the hand,¹ and therefore repair of the tendon to FPL must always be very resilient. FDP is a mass action muscle that provides a flexion force to all the digits through its insertion into the distal phalanx of each finger and its main function is in power grip. There is sometimes an individual muscle belly providing independent action of FDP to the index, but this is rarely the case for the other digits as the muscle belly is a single mass for them and the tendons are interconnected in the distal forearm and wrist.² In some patients there is a tendinous slip from FDP to the index to FPL.³

Pulley system

The pulleys acting on the wrist flexors have already been described above. The FDS and FDP enter a system of pulleys at the level of the MCP joint. These are thickenings in the flexor sheath that are recognizable and follow a set pattern of five annular pulleys and three cruciate pulleys⁴ (Figures 51.2, 51.3 and 51.4).

The most significant of them are the second and fourth annular pulleys known as A2 and A4. A2 is 20 mm long, arises from the proximal phalanx and contains both FDP and FDS. A4 is 12 mm long, arises from the middle phalanx and contains FDP alone distal to the FDS insertion.

Figure 51.1 Flexor digitorum superficialis (FDS) chiasma. In this cadaver specimen the flexor digitorum profundus (FDP) tendon has been removed and the complex structure of the FDS chiasma can be clearly seen. FDS tendon divides into two slips that spiral around the FDP tendon to meet each other again deep to FDP. Here the central half of each slip decussates to form a chiasma with the central half of the opposite slip, while the outer half of each slip continues to form the outer edge. Distal to the chiasma two slips are again formed, each of which contains the outer half of the original slip plus the central half of the contralateral slip. The FDS tendon has thereby formed a cradle around the FDP which will tighten on FDP when FDS is activated and may therefore play a part in the pulley system for FDP and the rebalance of the pull of FDP on the joints that it crosses on the way to its insertion. Source: Reproduced with permission of Donald Sammut.

Zones

The regions that the tendons pass through are divided into zones from distal to proximal. Zone 1 is beyond the insertion of FDS where only one tendon is present – FDP. Zone 2 is the rest of the flexor sheath. Zone 3 is from the mouth of A1 to the distal limit of the transverse carpal ligament. Zone 4 is the area deep to the transverse carpal ligament (i.e. the carpal tunnel). Zone 5 is from the proximal edge of the transverse carpal ligament to the musculotendinous junction.

Blood supply

The blood supply to the tendon varies along its length. At the musculotendinous origin a blood supply will be originating from the muscle itself, then as the tendon is further away from this the blood supply from the epitenon will become more important with some contribution to nutrition also coming from the synovium bathing the tendons in the various spaces of the hand, such as the carpal tunnel. For the finger flexors, within the flexor sheaths the blood supply is derived from the vincula (Figure 51.5) that enter the dorsal surface of the tendon, as well as nutrition arising from the synovial fluid produced by the inner surface lining of the flexor sheath.

Tendon healing

As with the healing of any tissue, the process of tendon healing consists of three overlapping phases starting with *inflammation*, followed by *proliferation* of cells and progressing on to *remodelling*.

(a)

(b)

Figure 51.2 (a) The pulleys exposed on a cadaver dissection. The filmy appearance of these structures belies the strength with which they are able to resist bowstringing of the tendon. The distinct distal edge of A2 is seen clearly, followed by C1, A3 and C2 overlying the proximal interphalangeal joint. (b) In this cadaver specimen of an index finger the filmy elements have been removed leaving the more clearly defined A1, A2 and A4 annular pulleys. Source: Reproduced with permission of Donald Sammut.

Figure 51.3 (a) This drawing shows the anatomical arrangement of the pulleys – from proximal to distal: A1, A2, C1, A3, C2, A4, C3 and A5. (b) On full flexion, when the force against the pulleys is at its strongest, the effect of the anatomical arrangement is such that the thickened parts of the flexor sheath lie in continuity without any bulkiness between them to impede flexion. (a)

(b)

Figure 51.4 (a) This cadaver specimen demonstrates that when tension is applied to the flexor tendons they are held close to the bony skeleton by the intact pulley system. (b) The same specimen has had the pulleys excised. Now when the tendon is pulled in the same way the tendons bowstring away from the metacarpophalangeal and proximal interphalangeal joints, reducing the mechanical advantage obtained from the same excursion. Source: Reproduced with permission of Donald Sammut.

Figure 51.5 Illustration of the vincula to flexor digitorum superficialis (FDS) and flexor digitorum profundus (FDP). Each tendon has a long vinculum proximally, where they need to accommodate more excursion, and a short vinculum more distally. Both vincula of the FDS arise along the length of the proximal phalanx. The long vinculum of the FDP also arises from the proximal phalanx, close to the short vinculum of the FDS, whereas the short vinculum of the FDP arises at the middle phalanx. Source: Reproduced with permission of Donald Sammut.

Traditionally, the modes of healing are divided into extrinsic and intrinsic. In the extrinsic pathway the tendon becomes adherent to the flexor sheath during the inflammatory phase. This occurs because the epitenon is in effect an epithelium and once breached allows the egress of tenocytes into the surrounding tissue with subsequent adhesion formation. In reality, the distinction is not so clear cut and cells have been shown to repopulate the tendon from within the tendon, the circulation and the bone marrow, whether adhesions form or not. What we do know is the tendon will heal even when the factors that are dependent on adhesion formation are prevented by early motion and in fact early loading increases the cellularity of the tendon with increased strength and a more orderly matrix being formed.⁵

Patterns of injury

The commonest cause of injury to a flexor tendon is a sharp laceration, for example from a knife or broken glass. A multitude of scenarios present themselves in this manner, but it is worth noting that a knife used in an assault may cause injury to either the victim if they grab the knife in defence or the assailant as they stab something that is more resistant than they expected such that the blade of the knife cuts the hand that was gripping it.

When describing the zone for an injury or repair it is usually referred to by the zone that it would lie in with the hand in the resting posture, as this is where the repair will lie for the majority of the time. However, repairs that are near the end of a zone will clearly move through more than one zone on activity.

Blunt injuries rarely divide the tendon, but they can cause significant crushing to the surrounding tissue and abrasions to the tendon that will cause adhesions if not managed well.

The FDP tendon is also prone to avulsing from its insertion into the distal phalanx. This is commonly known as ‘jersey injury’. The avulsion may also involve a fragment of bone, and this, along with whether the ongoing force of pull also

Table 51.1 Modified Leddy and Packer classification of flexor digitorum profundus (FDP) avulsion⁶

Type I	FDP and both vinculae rupture with no fractures Tendon retracts into palm, presenting as a tender lump <i>Early operative repair necessary</i>
Type II	FDP ruptures but long vincula remains intact Avulsed FDP held at proximal interphalangeal joint There may be a small avulsed bony fragment <i>Repair required within 3 months</i>
Type III	FDP avulsion with a large bony fragment that gets caught at A4 Both vinculae are preserved <i>No time limit for repair</i>
Type IV ^a	FDP and bony fragment avulsion, with tendon avulsion from the bony fragment
Type Va ^b	FDP and bony fragment avulsion, in association with fracture of the distal phalanx (extra-articular)
Type Vb ^c	FDP and bony fragment avulsion, in association with fracture of the distal phalanx (intra-articular)

^aSmith’s modification.⁷

^bAl-Qattan modification.⁸

ruptured the vinculae, will determine how far proximally the avulsed end of tendon retracts. This has been classified into type I–III injuries by Leddy and Packer.⁶ Type IV was added by Smith⁷ and types Va and Vb described by Al-Qattan⁸ (Table 51.1).

History and examination

Eliciting a careful history will raise the suspicion of a tendon injury. The commonest injury that is missed at this stage is the FDP avulsion, as the assessment often takes place in a setting where there is no hand surgery expertise. Here, in the absence of a laceration and significant swelling it is assumed that the tendon is unlikely to be injured and the lack of movement is due to pain. Examination is completed with assessment of the vascular supply and nerve function.

On examining a patient with a laceration, the integrity of every tendon that could have been affected must be assessed. The wrist flexors are tested by getting the patient to flex the wrist against resistance while simultaneously palpating the muscle bellies and tendons to ascertain whether there is continuity. FPL function is assessed using the ‘O’ sign where the patient is asked to make an O shape between their thumb and index finger. An O shape is only possible with active FPL function at the interphalangeal (IP) joint, and resistance is tested by asking the patient to try to prevent the examiner from breaking through the ring of the O. This test is more reliable than asking the patient to flex the IP joint as there are trick movements that can cause a flicker of movement at the IP joint, causing diagnostic confusion.

In the digits the resting cascade will often provide some information even before the patient is asked to do any

movements and then a composite fist formation will add to this before individual tendons to individual digits are assessed, for example the DIP joint of a digit with a divided FDP will fail to curl into the fist. FDP function is assessed by its action on the DIP joint of the affected digit.

In order to assess FDS function the FDP has to be blocked from acting on the PIP joint. This is done by holding the other digits out in full extension, releasing only the affected digit and asking the patient to bend it down. However, if there is no active flexion at the PIP joint of the little finger in this examination it is necessary to release the ring finger as well and retest for FDS function. This may then allow flexion of the little finger PIP joint, demonstrating that the little finger FDS is not independent of the ring finger FDS. This is usually due to an anomalous muscle or tendon slip from the FDS of the ring finger to the FDS of the little finger.⁹ FDS may also be completely absent in the little finger in up to 13.7% of the population, 64% of whom have this variation bilaterally.^{10,11} Therefore the presence or absence of FDS to the little finger on the other side adds little to the assessment.

In all of these examinations, significant pain on flexion in the presence of tendon continuity may represent a partial division of the tendon. In any case, where there is a deep laceration over a tendon the patient will require formal exploration in theatre under tourniquet.

Surgical management

The historical perspective and evolution of current concepts are outlined in Box 51.1.

Box 51.1 Historical perspective and evolution of current concepts: surgical techniques

At the turn of the century a laceration to the finger that had divided the flexor tendon(s) in zone 2 was usually allowed to heal and then reconstructed with a secondary tendon graft because the results of primary repair were considered to be too poor.¹² It was not until half a century later that publications began to emerge describing successful tendon repairs in zone 2.¹³ In the years following this there have been many new suture techniques tried with varying success.^{14–16} Despite the advances over the last century there is still no method of tendon repair that is strong enough to withstand the force across the repair site in normal use. Attention is now directed at a method of repair that will maximize the strength of the repair but also the stiffness of the repaired section, its tendency to gap and the force of work required to move the tendon, all of which will affect the glide of the tendon through the pulley system. Many surgeons now perform repairs with a four-strand core suture technique with a locking configuration which, combined with a strong peripheral suture can adequately bear the stresses of early active motion.^{17–19}

Exploration and tendon retrieval

Approaches to the tendon need to respect the usual principles for incisions in the hand (i.e. not crossing joint creases longitudinally). There are points of technique specific to each of the zones as described below.

Zone 5

In the forearm with multiple tendon injuries the function of each distal end can be assessed by simply pulling on it, but it can be difficult to match it to the correct proximal end. This is assisted by:

- working methodically (e.g. from the radial side to the ulnar side);
- having an in-depth knowledge of the anatomy at the various levels (e.g. the fact that the tendons of FDS to the middle and ring fingers lie superficial to those to the index and little fingers);
- a close inspection of the ends of the tendons to show their comparative cross-sectional shape and size as well as the configuration of the laceration.

To prevent errors it is wise to have completed the exploration and identified all the tendon ends on both sides of the wound and matching them before proceeding to repair any of them, working from deep to superficial.

Zone 4

This is unusual due to the depth at which the tendons lie in zone 4, but when there is a laceration to the distal forearm that occurred when the wrist and fingers were flexed the distal end will come to lie in the carpal tunnel. Although it can often be delivered into the forearm by reproducing this posture the repair site will then also be within the carpal tunnel. In this case, particularly if more than one tendon is affected, it is prudent to open the carpal tunnel to prevent an acute carpal tunnel syndrome, so this should be done as part of the exploration stage as it makes the repair much easier to do. In this situation the carpal tunnel should be opened with a step configuration so that if there is concern about bowstringing of the repaired tendons at the end it can be repaired with step lengthening.

Zone 3

When exploring lacerations over FPL and all lacerations in the palm of the hand, the proximal ends may have retracted back proximal into the carpal tunnel. In this case a separate incision is made in the distal forearm to retrieve the tendon, which is then fed through the carpal tunnel. This still requires a separate incision to allow direct vision of the grasping end as blind grasping for the tendon in the carpal tunnel carries a risk of damage to the median nerve. One method of retrieval is to feed an umbilical catheter or infant feeding tube retrograde through the tunnel then either suture it side to side to the tendon and pull both through together, or put the first part of the core suture into the tendon and feed this through the tube (Figure 51.6a–k). In this second technique the tube is used to deliver the suture only, then

Figure 51.6 This operative series shows the retrieval and repair of a flexor digitorum profundus (FDP) tendon using a four-strand Adelaide core suture and a Silfverskiöld epitendinous suture. (a) Overview after exploration of a laceration to the little finger – a clean transverse cut at the proximal end of the A4 pulley is seen. (b) Close up view shows that the distal end of FDP has been flipped out of the flexor sheath through a transverse incision at the distal end of A4 to allow exposure of enough tendon for a good repair. The proximal sheath is seen to be full of blood. (c) Milking the finger has brought the proximal end of FDP out through another transverse incision in the region of the C1 pulley. It has been prevented from retracting with a hypodermic needle. (d) The proximal end of the tendon is picked up and reflected back to allow easy access for the first bite of the core suture. The vincula is clearly seen on the dorsum of the tendon and sutures are not placed within this vascular complex. (e) The transverse bite of the cross locked suture is placed across the side of the tendon. (f) The subsequent longitudinal bite is placed. The forceps holding the tendon have not been moved throughout these manoeuvres, ensuring that minimal handling of the epitendon has occurred. (g) The suture cross thus formed can be seen on the side of the tendon. (h) An infant feeding tube is fed retrograde through all the pulleys that the proximal end needs to be delivered through.

tension on the suture is applied while easing the tendon into the tunnel opening until it delivers through and out the other end.

Zone 2

In zone 2 repairs it may also be necessary to retrieve the tendon from the palm up through the tendon sheath as described above. The distal end can usually be delivered into the wound by flexing all the DIP joints and the PIP joints as necessary; most lacerations occur with the finger flexed. It may be necessary to open some of the pulleys to gain enough access to retrieve the ends and carry out the repair. Although the pulley system should be respected and not incised without consideration, it is more important to have a repair that glides at the end of the operation

than to have intact pulleys, even at A2 and A4. If they have been opened it is not necessary to attempt to repair them at the end of the operation and doing so may actually increase the risk of adhesions or rupture due to the increased work required to move the tendon repair site through the constriction caused by a pulley repair.^{20–22} In most cases where the pulleys are left open no functional deficit is found, and in the minority who do find that the tendon bowstrings and reduces the power of flexion a secondary reconstruction of the pulleys is likely to be more effective.

It is not always necessary, or advisable, to repair the FDS as well as the FDP in zone 2²³ and repairing one slip and excising the other may provide the best compromise between ensuring

Figure 51.6 (continued) (i) The suture needle is fed into a side hole on the feeding tube, blunt end first. (j) The sharp end of the needle is then tucked into the blind end of the feeding tube, and the other end of the suture is also fed into the feeding tube. (k) The feeding tube is now withdrawn through the flexor sheath so that the suture and needle are delivered through without the sharp end of the needle coming into contact with the lining of the flexor sheath. (l) Tension can then be applied to the suture while feeding the tendon end into the opening in the pulleys. In this way the tendon is delivered through; the hypodermic needle is withdrawn as the tendon is pulled through and replaced to secure it in its new position. (m) The placement of the core suture then continues with a cross lock on the distal end, followed by a further cross lock on each end to give a total of four cross locks and four strands as described.¹⁹ (n) Here the third cross lock has just been placed (i.e. the second one to the proximal end), and the proximal end is held under tension to show the suture configuration. (o) The core suture has been tied and a Silfverskiöld epitendinous repair added. The hypodermic needle has then been removed and the tendon has slid back in so that the repair now sits deep to A4.

enough space for glide while preserving independent PIP joint flexion, particularly in the little finger.

Zone 1

If there is more than 5 mm of distal stump left on the FDP the tendon can be repaired as normal with equivalent strength when compared to reattachment.²⁴ However, if it has been avulsed, or if there is less than 5 mm, it will need to be reattached to the distal phalanx. If there is a sizeable bony fragment associated with an avulsion this can be fixed with a lag screw.

Methods for attachment where there is not a significant bony element include bone fixation devices commonly referred to as bone anchors, or drilling through the distal phalanx, either

through to the dorsum or transversely. In all cases any distal stump remnant should be elevated to allow the new insertion to tuck underneath, and the bone should be decorticated to encourage adherence of the tendon.

When bone anchors are used there are several important points of technique:

- There is no strong evidence that the angle of insertion of the bone anchor significantly affects breaking strength on cyclical loading²⁵ but care must be taken not to place a bone anchor so that it impinges on the germinal matrix of the thumb or the nail bed as this will cause ridging of the nail. For this reason it is preferable to use a screw-type bone anchor rather than a traditional anchor type, as removal of the latter once it has been detonated is extremely difficult. A check X-ray should

Box 51.2 Reattachment of flexor digitorum profundus (FDP) to the distal phalanx: author's preferred method

- 1 Transverse hole with Keith needle or hypodermic needle.
- 2 Two sutures of braided nylon in cross locked formation as per Adelaide repair.

be taken to ensure the bone anchor is in an acceptable position before utilizing the sutures.

- The distal phalanx can be drilled through with a green needle either volar to dorsal or transversely and the suture threaded down the needle to deliver it through the hole before pulling the needle on through and out the other side. When the distal phalanx is drilled through to allow the sutures to be passed from volar to dorsal, the suture may be tied directly over the nail, or a buttress can be used. The traditional buttress was a button, however there have been cases reported of the button causing necrosis of the nail bed,²⁶ particularly if it has a prominence on it at the circumference. A better buttress is the bung from a 2 mL or 5 mL syringe. In this case the suture used for the core stitch will be removed by cutting it and pulling it through from the nail at least six weeks after the repair. The suture therefore needs to be of a type and configuration that will allow it to come out easily, such as a 3.0 Prolene in a Kessler configuration.
- A Keith needle is specifically designed for the purpose of making a hole in a bone and passing suture through the hole. It is similar to a K-wire, but has a needle eye in it at one end without the diameter of the needle getting any wider. It can therefore be drilled through the bone with a K-wire driver with the suture threaded through it so that it is taken through the bone.

In the methods where the suture is passed through the bone, a less brittle suture such as braided nylon should be used to prevent the suture failing where it turns an acute corner on emerging from the bone. The author's preferred method for reattachment of FDP to the distal phalanx is described in Box 51.2.

Repairing the tendon

Where there is a partial division of the tendon this does not require repair if there is 50% or more of the tendon still intact. Any edge that may catch on the pulley should be excised while also trying to minimize the extent of exposed cut surface of tendon that is left.²⁷

There are many techniques available for repairing the tendon and these have been eloquently described elsewhere.²⁸ It is important that the surgeon masters one of them reliably before carrying out this surgery unsupervised. Four-strand techniques are generally recognized to be superior to two-strand techniques. The 'Adelaide repair'¹⁹ has increased in popularity and been shown to be easily mastered.²⁹ The choice of core suture can be made independent of the choice of epitendinous repair. There is little evidence to recommend one suture material over another. Steel and fibrewire have been shown to be stronger than nylon, Prolene and braided polyester, with no significant difference between the latter three.³⁰ In the author's experience the use of 3.0

Box 51.3 Repair of zone 2 flexor tendon injuries: author's preferred method (Figure 51.6a–o)

- 1 Midlateral incision with oblique extension at either end.
- 2 Flap sutured back.
- 3 If proximal end has pulled back and simple milking techniques fail to deliver it into the wound:
 - Incision over proximal end.
 - Insert one limb of an Adelaide repair.
 - Retrieve tendon ends using feeding tube to deliver suture only, then pull tendon through (Figure 51.6a–k).
- 4 Use hypodermic needle to hold tendon.
- 5 Incise pulleys if needed

Adelaide repair using 3.0 Prolene on a round-bodied needle.¹⁹

The benefits of an Adelaide repair over a Kessler-type suture:

- Transverse bites are placed further along tendon than longitudinal lengths of core stitch so less risk of damaging core stitch on passing needle through for transverse bites.
- More tendon length between damaged area and transverse bites is possible when access to tendon is limited.
- Tendon ends dock into place rather than buckling.

Silfverskiöld epitendinous using 6.0 Prolene on a round-bodied needle³¹ (Figure 51.6l–o)

- Check glide using tenodesis effect (Figure 51.7a,b).
- No repair to pulleys.
- Close skin.
- Apply minimal dressings to wound.
- Plaster of Paris splint made to provide a dorsal hood holding the wrist in neutral, the MCP joints at 80° flexion and the IP joints in full extension. If the FPL alone has been repaired, a dorsal hood to the thumb and fingers should be supplied – protecting the thumb alone may result in rupture due to the Linburg–Comstock³ anomaly.³²

Prolene in an Adelaide core suture configuration minimizes the trauma to the tendon and allows the two ends to be brought together in a very controlled 'docking' manoeuvre that minimizes the bunching up of the tendon at the repair site. This allows the repair site to still glide unimpeded through the pulleys.

The author's preferred technique for repair of zone 2 flexor tendon injuries is outlined in Box 51.3.

Occasionally there is segmental loss of the tendon. If this is less than 1 cm the two ends can be directly repaired, but any more than this and a graft is needed. Short segments that do not involve zone 2 can be treated with an interposition graft (Figure 51.8); longer segments and those involving zone 2 will require standard tendon grafting techniques as described below.

Rehabilitation following flexor tendon injury

Unfortunately a repair technique that allows the patient to immediately return to full normal activity has not yet been developed. The rehabilitation of flexor tendon repairs is

(a)

(b)

Figure 51.7 At the end of a repair the finger should be seen to flex with the tenodesis effect without resistance. As seen here the finger flexes fully (a) and extends with the normal cascade (b).

Figure 51.8 When a small section of graft is missing an interposition graft can be used for up to 2 cm outside of zone 2. This is facilitated by threading the length of tendon graft onto a hypodermic needle and then the loose end of a suture can be threaded through the needle before it is removed. If this is done twice, once in each direction with a separate suture each time, it provides a length of tendon with a needle and free end at each end of the graft ready for repair into the tendon defect.

prolonged and complex, and should always be explained to the patient before embarking on surgery. Therefore, although it is essential to have a physiotherapist providing the rehabilitation programme, the surgeon needs to be aware of the principles involved and the general timescale in order to provide the patient with the information they need in consenting to a repair.

There are many different protocols for rehabilitation of the healing flexor tendon. They can be divided into immobilization, early passive mobilization (EPM) and early active mobilization, also known as controlled active mobilization (CAM).

Immobilization

These techniques involve complete immobilization of the hand, wrist and fingers. Typically, the wrist and MCP joints are immobilized in flexion, and the PIP joint and DIP joints in extension; this takes tension off the finger flexors while preventing contractures at the PIP joints. The hand is usually immobilized

for 3–4 weeks before commencing active and passive flexion and extension at home. Often, the period of immobilization is interrupted by visits to hand therapy where protected passive motion may be undertaken to prevent stiffness. This method is seldom used, with the exception of children and patients unable to be compliant with the preferred regimen.

Early mobilization

EPM means passive flexion with either passive or active extension. Early active mobilization (EAM) involves active flexion and extension of the involved digit or digits. Place-hold flexion is another type of active mobilization, involving passive flexion of the finger. The patient then actively maintains that position.

The historical perspective and evolution of current concepts of rehabilitation regimes are outlined in Box 51.4 and the author's preferred rehabilitation regime in Box 51.5.

Box 51.4 Historical perspective and evolution of current concepts: rehabilitation regimes

In 1917, Harmer³³ described flexor tendon repairs coupled with early active mobilization. Just one year later, Bunnell¹² described grafting of zone 2 flexor tendon lacerations, followed by a period of immobilization.

Primary repair of zone II flexor tendons regained popularity in the 1960s.^{13,34} However, immobilization remained in vogue, in the belief that this predisposed to adhesions, which in turn improved tendon nutrition and healing. However, in some units early passive mobilization was being pioneered, and started to show promising results.^{35,36}

It is now known that adhesions are not required to aid healing and actually limit tendon excursion. In fact, the application of early post-repair controlled motion stress increases the rate of revascularization and healing of the laceration, in addition to improving the strength and remodelling of the repair.^{37–39} Two main systems are in use today: *early passive motion* (EPM) using elastic bands to provide a passive flexion force against which active extension is done (e.g. Duran and Houser⁴⁰), and *controlled active motion* (CAM) in which both flexion and extension are carried out actively in a strictly controlled programme.⁴¹

Box 51.5 Modified Belfast Protocol for Early Active Mobilization following flexor tendon repair (zones I–V): author's preferred rehabilitation regime, as used at Oxford University Hospital^a

Days 1–3

- 1 Manufacture a thermoplastic dorsal 'hood' splint with:
 - Wrist 0–20° of flexion
 - MCP joints 60–80° of flexion
 - IP joints full extension.
- 2 Explanation of the early active movement (EAM) protocol:
 - Passive flexion of fingers using contralateral hand to enable nail(s) to touch distal palmar crease (DPC)
 - Repeat exercise but maintain finger flexion using muscle power only
 - Active flexion, nail-to-distal palmar crease then return nails to fully touch the splint
 - Assess active range of movement using goniometry or tip-to-palm measurements

Concerning features include:

- Inability to flex more than two thirds of distance from nails to distal palmar crease
- Inability to fully extend the IP joints
- Full active range of movement at first appointment – therapy may need to be modified to a slower pace to allow adequate tendon scarring and healing to take place.

Week 2 and week 3 appointment

- 1 Check EAM exercises, assessing for differential gliding, quality of movement and tendon integrity.
- 2 Check pain, oedema and range of movement.

Week 4 appointment

- 1 Check EAM exercises, assessing for differential gliding, quality of movement and tendon integrity.
- 2 Progress to full active range of movement (FAROM) exercises. Focus on tenodesis, differential glide: flat fist and hook and full extension.
- 3 Removal of splint for hourly exercises.
- 4 Graded return to activity using chart in booklet.
- 5 Encourage full active extension.
- 6 Maintain passive IP joint range of movement while in a safe position.

The aim is to achieve full active range of movement within 1 week of this appointment (not including resistance/passive extension stretch).

Week 5 appointment (as required)

- 1 Review FAROM exercises and splint.

Week 6 appointment

- 1 Review FAROM exercises.
- 2 Removal of splint for light activities of daily living, continuing to wear it at night and other times of risk.
- 3 Consider night extension splint if there is ongoing limited passive extension.
- 4 Commence light resisted exercises.

Week 8 appointment

- 1 Discard dorsal hood splint.
- 2 Return to unrestricted normal activity, educating patient not to partake in contact sports until 12 weeks.
- 3 Commence full passive stretches as required.
- 4 Serial night extension splinting as required.
- 5 Assess patient for functional limitation and address as required (e.g. driving).

Week 12 appointment

- 1 Return to contact sport and/or manual lifting.

^aDuring each appointment, hand therapists provide patient education, wound and scar management, and assess splint suitability.

Complications of primary repair

The main complications of flexor tendon repairs are rupture, adhesions and joint contracture at the PIP joint.

Rupture

Every case of rupture should be reviewed, and trends in rupture rates need to be monitored. Risk factors can be divided into technical and patient related. Technical errors that lead to rupture are poor knot technique, insufficient size of bite leading to pull-out, damage to the core suture from the needle used for successive passes with the core suture or the epitendinous suture and bulky repair that then catches on the pulley system. When a ruptured tendon repair is re-explored it is important to carefully examine the suture to evaluate *how* the repair failed, although this does not necessarily answer the question of *why* the repair failed (Figure 51.9).

Patient factors are related to failure to follow the rehabilitation programme instructions, resulting in excessive strain at the repair

Figure 51.9 Inspection of the suture after a repair has failed should always be carried out as part of the learning process. Here the braided nylon suture appears to have been split just before the point where it gave way, and may represent a place where the suture went back through itself with damage being caused by the needle as it passed. The configuration that had been used in this case was a modified Kessler.

site and subsequent rupture. Unintentional excessive strain can also occur during sleep or on a sudden startle. Treatment of rupture is usually re-exploration and re-repair, unless there is a delay to presentation such that the repair is no longer possible or the pulleys have collapsed. In this case re-exploration is still needed but the patient should be consented for proceeding to a tendon graft or the first stage of a two-stage tendon graft.

Adhesions

Adhesions may also be due to technical factors, patient factors or a combination of the two. Technical factors include excessive handling of the tendon or instrumentation within the flexor sheath. Patient-related factors include pattern of injury and extent of crush, development of infection, delay to starting physiotherapy or failure to carry out sufficient mobilization during rehabilitation.

Treatment of adhesions is initially physiotherapy with two aims in mind: first, to ensure that full passive range of motion is restored and maintained, and second, to soften and break the adhesions that have been formed. Only when physiotherapy has been given a sufficient chance of success should surgery be considered, and in any case should not be embarked upon unless there is a full passive range of motion. Timing of surgical intervention is also important as tenolysis carried out too soon after the repair carries an increased risk of rupture.⁴² In all cases the patient should be warned of the risk of intraoperative tendon rupture and preparations made to proceed to the first stage of a two-stage tendon graft (see below) plus pulley reconstruction if the patient so wishes.

Proximal interphalangeal joint contracture

The PIP joint rapidly develops a contracture if full extension is not achieved during the rehabilitation exercises. If caught early, an adjustment to the splintage, with dorsal blocking to limit extension of the MCP joint, facilitates full PIP joint extension and may prevent the PIP joint contracture from becoming fully established.

Outcome measures

Audit and reporting of results should include rupture rates and some measure of the final motion achieved, such as the total active motion (TAM).⁴³ Added to this should be a patient-reported outcome to take account of overall satisfaction with the process as well as the final outcome.

Treatment of late presentation or failed repair

When a patient presents late with a divided or avulsed tendon, when the tendon has been damaged over a significant distance within zone 2, or when a tendon repair fails, the options to consider are as follows:

- *No treatment:* This may be appropriate for example where there is an isolated FDP injury and the DIP joint is stable.

- *Joint fusion* (e.g. in an isolated FDP rupture fusion of the DIP joint where it would otherwise hyperextend if used in pincer grip).
- *Direct repair*: This may still be possible in certain cases. However this should not be attempted without having a discussion with the patient as to which alternative will then be used if it is not possible. Direct repair should not be carried out if it would result in the finger being held too flexed, as will occur if the muscle has become fibrosed or fixed at a shorter length or more than 1 cm of tendon needs to be resected. The result of this would be a quadriga effect similar to when a tendon graft is set too tight (see below).
- *Single-stage tendon graft*: This may be possible in an early presentation of a rupture where the ends have retracted back preventing repair but the pulleys have not yet collapsed. This can only be assessed at the time of operation and every patient should therefore also be consented and prepared for the two-stage option.
- *Two-stage tendon graft*. This involves insertion of a silicone rod to reform the tendon sheath, followed at least six weeks later by removal of the rod and replacement with a tendon graft.
- In the thumb there is also the option of carrying out a *tendon transfer* using the FDS tendon of either the middle or ring fingers.

The choice between these options has to be made following an in-depth discussion with the patient about what is involved in the various surgical procedures, what rehabilitation is needed, and a realistic appraisal of the likely outcomes. Then, taking into account the patient's own priorities (e.g. self-employed versus retired) and preferences, it is possible to make an individualized decision as to what is the most appropriate course of action for them.

Tendon grafting

Principles

A graft of smaller calibre than the original tendon should always be used. The junctions at the ends of the graft must be outside the flexor sheath, and the tension needs careful adjustment to ensure that it is correct.

Prerequisites

The patient's hand must be quiescent with soft, supple and well-healed scars.

The patient needs to have a full understanding of the rehabilitation requirements and length of time needed before returning to normal activities.

Technique

In a two-stage repair the first stage can be divided into the following steps:

- 1 Exposure
- 2 Preparation of the graft bed
- 3 Insertion of the rod

- 4 Reconstruction of pulleys (if required).

The second stage can be divided into

- 1 Exposure
- 2 Harvesting the tendon graft
- 3 Passing the graft through the flexor sheath
- 4 Distal and proximal juncture repair.

A single-stage repair can be carried out if the assessment at the end of the exposure and graft bed preparation indicates that it is appropriate, and the operation then proceeds with harvesting the graft etc.

First stage

Exposure

The flexor sheath should be exposed for the entirety of its length from the start of A1 to the insertion of FDP. In addition the exposure needs to extend proximally enough to allow manipulation of the tendons for the proximal repair in the palm. The author prefers a mid-axial incision from the DIP to non-leading edge of the finger base. The neurovascular bundle is excluded from the raised skin flap. Extension across the pulp as well as into the palm is oblique.

Preparation of the graft bed

A 1 cm distal stump of FDP is left, and the section between this and a point just distal to the lumbrical origin is excised. If FDS is intact it should not be sacrificed. If it is found to be tight when inserting the graft or rod then one tail only of the FDS can be excised. If FDS has been divided as well it should be sharply transected 1–2 cm proximal to its insertion and removed, but before this is done a decision should be made as to whether the pulleys need to be reconstructed and if so whether the FDS is suitable for use for this purpose (see below).

At this point a decision will also need to be made as to whether a one-stage or two-stage approach is appropriate. If the pulleys are intact and open such that a graft will go through without the pulleys needing to be stretched or reconstructed first, then a one-stage approach is preferable. However, when there has been significant delay, or crushing element to the injury, or where infection has played a role in the rupture, this is unlikely to be the case and anything but the simplest stretching manoeuvre with the pulleys is likely to cause adhesion of any graft that is then passed through them at the same operation. Therefore in these cases a rod should be inserted plus or minus the reconstruction of any deficient pulleys as the first of two stages.

Insertion of the rod

All pulley remnants should be preserved and if necessary stretched with a haemostat. The silicone rod is passed from distal to proximal using a tendon retriever. The distal end is sutured to the FDP stump and the proximal end is left free in the palm, or in cases where there is damage and scarring in the palm such that the proximal juncture will need to be in the forearm, it is fed down through the carpal tunnel. Having placed it like this

with the distal end secure, the proximal end is pulled to test for bowstringing. If the silicone rod shows evidence of bowstringing the essential pulleys should be reconstructed.

Pulley reconstruction

The purpose of this is to recreate the essential features of the pulley system in order to prevent bowstringing of the flexor tendons, particularly in the region of the body of the proximal phalanx and middle phalanx where the original A2 and A4 pulleys would have been.

A tail of FDS can be used in the A2–3 region by leaving it attached at its insertion and suturing the other end to periosteum or pulley remnant, or using it to encircle as with a free tendon. Otherwise, there is usually enough tendon remnant available from the excision of FDP to use as a free tendon graft, or graft can be harvested from any of the usual donors. However, bearing in mind the need for further graft material for the tendon itself, fascia lata can be used for the pulley reconstruction and has the added advantage of providing a wider, flatter construct. If there is sufficient pulley remnant available, the graft can be used sutured to this and does not need to encircle the phalanx.⁴⁴ If not, the graft is used to encircle the rod and the relevant phalanx, at least twice and preferably three times in order to reconstruct a long pulley of equivalent strength to the original.⁴⁵ A minimum of 6 cm of graft is needed to encircle twice. At the level of the proximal phalanx the graft is passed deep to the extensor tendon, but at the level of the middle phalanx it should be passed superficial to the extensor tendon, or kept to a minimum bulk with only two passes.

The skin is then closed and hand splinted in the position of safe immobilization for the immediate postoperative period only. Beyond this, physiotherapy is aimed at ensuring that the full passive range of motion is maintained.

Second stage

The exposure is carried out through the same incision as for the first stage.

Harvesting the tendon graft

Potential tendon donors to be considered include the following:

- *Palmaris longus*: This is easily harvested with no donor deficit and keeps all the surgery to the one limb. However it is only sufficient for one palm-to-finger tip graft.
- *Plantaris*: This will yield enough graft for up to three forearm-to-finger tip grafts.
- *Extensor indicis proprius and/or extensor digiti minimi*: Each of these will provide one palm-to-finger tip graft.
- *Long extensors of the second, third and fourth toes*: Each of these will provide one forearm-to-finger tip graft.
- *Fascia lata*: Strips of fascia lata 1–2 cm wide can be rolled to form tendon-like structures, and sufficient is available to harvest as many forearm-to-finger tip grafts as are needed.

Passing the tendon through the flexor sheath

The tendon graft is sutured to the proximal end of the silicone rod and pulled through the newly formed flexor sheath from proximal to distal, minimizing any trauma to the flexor sheath.

Distal and proximal juncture repair

The distal juncture repair will be sited at the FDP insertion. The proximal end should be either just distal to the lumbrical origin from FDP, or in the forearm. This will have been decided at the time of silicone rod insertion and is predicated by the extent of involvement of the palm in the original injury with subsequent scarring. Several different methods for each of these have been described, and a number of different combinations can be chosen. However, it must be remembered in choosing a combination that it needs to be possible to test or adjust the tension prior to carrying out the repair of the second end so that the tension can be finely tuned at this point. This is judged by setting it so that the finger is just a fraction more flexed than it would normally sit in the normal resting cascade. This is normally done with a fixed-length technique distally, adjusting the tension proximally. Fixed-length distal juncture repair methods are the same as the repair methods used in zone 1 tendon repairs.

The commonest proximal repair in which the length can be adjusted is the Pulvertaft weave. Much interest has been shown in discussing the strength related to the number of weaves and the minimum number of weaves needed to provide sufficient strength is understood to be 3.⁴⁶ This is, however, a little misleading as the strength of the repair can only come from the sutures used between the two tendon ends as it does not matter how many weaves you provide, the tendons will come apart with minimal tension applied if there are no sutures used. The requirement for a minimum number of weaves is more likely to be related to the minimum length of overlap needed to fit in a sufficient number of sutures perpendicular to the line of force. The benefit of the Pulvertaft weave is the ease of setting the correct tension. This is done by pulling the two tendon ends to an estimated correct position, placing a single suture, then releasing the tendons to test for the resting cascade. If the tension is incorrect, the suture can be removed and the tension adjusted. Once the correct tension has been achieved the rest of the sutures are placed.

Another approach is to use a fixed-length technique proximally and adjust the tension at the finger tip. This is done by taking the graft right out through the end of the finger, laid along the full length of the distal phalanx. A clip is applied to the graft at the end of the finger and tension testing carried out, moving the clip as necessary to ensure the correct tension. Once it has been correctly tuned the two halves of the FDP stump are sutured to the graft and the end of the graft is cut flush with the skin at the finger tip.

Postoperatively a CAM regime is used similarly to that after a primary repair.

Complications following tendon graft

Possible specific complications include:

- **Rupture:** This requires exploration and re-repair if diagnosed quickly enough.
- **Adhesions:** These are managed in the same way as adhesions after primary repair.
- **Lumbrical plus finger:** If the graft was set too long the origin of the lumbrical is pulled too far proximal by the force applied through FDP. This leads to too much power being transferred through the lumbrical such that the finger becomes more resistant to flexion when the patient attempts active flexion despite being able to demonstrate a full range of flexion passively.
- **Quadriga:** This is the opposite problem and occurs when the graft is set too tight. In this case the affected digit lies too flexed in the resting cascade and flexes ahead of the other digits in attempted fist formation. When grasping an object the affected finger makes contact with the object ahead of the other digits and arrests any further pull on the FDP in this finger. Since FDP is a mass action muscle with all four tendons fixed in length in relation to one another this means that no additional power can be exerted through the other digits and grip strength is therefore weaker.⁴⁷

Summary

Tendon injuries are common. Outcomes are best when they are correctly diagnosed and treated at an early stage. Good surgical technique is essential in order to avoid rupture or adhesions, but of equal importance is the preparation of the patient so that they are expecting a long and complex rehabilitation programme. Patient compliance must be facilitated with a well-run, supervised programme that is delivered with clear instructions and goals.

Secondary reconstruction is complex and rarely results in the same level of function as a successful primary repair.

CHAPTER 52

Extensor tendon injuries

Gregory McCarten

Department of Plastic, Reconstructive and Hand Surgery, The Canberra Hospital, Canberra, Australia

Introduction

Repair of extensor tendon injuries remains a common starting point in the careers of many aspiring hand surgeons. In contrast to their flexor tendon equivalents, extensor tendon repairs often appear relatively straightforward. The surgeon is free from the constraints imposed by the fibro-osseous canals during flexor tendon repair. Furthermore, the ease of surgical exposure, likely absence of proximal stump retraction, simpler suture placement configurations and straightforward postoperative mobilization regimes frequently results in the delegation of these injuries to junior surgical trainees.

However, although many extensor tendon repairs are relatively undemanding, these injuries can be more complex than anticipated. Lacerations over the dorsum of the wrist can produce significant proximal stump retraction, particularly of extensor pollicis longus (EPL), which can be notoriously difficult to find. Delayed presentations or injuries involving actual tendon loss produce deficits in the tendon which preclude direct repair without producing unacceptable tension at the repair site and tendon shortening. Therefore, the surgeon will need to be cognizant of the surgical principles and techniques involved in tendon grafts and tendon transfers.

The cross-sectional morphology of extensor tendons varies significantly according to the site of the injury. Thin flat tendons encountered over the dorsum of the fingers require a different suture technique in comparison to the more rounded thicker counterparts encountered over the dorsal wrist joint. These injuries often have concomitant bone and joint injuries, requiring accurate reduction and internal fixation, joint irrigation and capsular repair. Associated nerve injuries may be present, usually the sensory branches of the radial nerve and occasionally the posterior interosseous nerve, requiring microsurgical repair. Appropriate peri- and postoperative splinting, mobilization and hand therapy are essential to avoid early tendon ruptures and joint contractures and to minimize adhesions to overlying skin.

Consequently, although straightforward injuries will be ideal for the surgical trainee, complex extensor tendon injuries present the hand surgeon with a challenging test of their surgical capabilities.

Anatomy

Forearm

The lateral epicondyle is the origin of the wrist extensors extensor carpi radialis longus and brevis (ECRL and ECRB), extensor carpi ulnaris (ECU), extensor digitorum communis (EDC) and extensor digiti minimi (EDM). Distally, the proximal radius, ulna and interosseous membrane give origin to extensor indicis (EI), abductor pollicis longus (APL), extensor pollicis longus (EPL) and extensor pollicis brevis (EPB).

The radial nerve provides motor branches at or above the lateral epicondyle to brachialis, brachioradialis (BR) and ECRL. The nerve then divides into a superficial sensory branch and its motor branch, the posterior interosseous nerve (PIN). The sensory branch continues distally applied to the deep surface of BR into the wrist and hand. The PIN supplies ECRB and penetrates supinator, supplying it and the remaining extensors, and continues distally to the wrist closely applied to the posterior interosseous membrane.

Wrist

The musculotendinous junction is located approximately 4–5 cm proximal to the wrist joint, whereas at the level of the wrist, a condensation of the fascia over the extensor muscles produces the extensor retinaculum, which prevents bowstringing (Figure 52.1). The retinaculum allows passage of the extrinsic extensor tendons through six separate compartments, each a discreet synovial lined fibro-osseous tunnel:

- Compartment 1 – abductor pollicis longus (APL) and extensor pollicis brevis (EPB)
- Compartment 2 – extensor carpi radialis brevis (ECRB) and extensor carpi radialis longus (ECRL)
- Compartment 3 – extensor pollicis longus (EPL)

Figure 52.1 Dorsal hand and wrist extensor tendon structures. EIP, extensor indicis proprius; EPB, extensor pollicis brevis; EPL, extensor pollicis longus; APL, abductor pollicis longus; ECRL, extensor carpi radialis longus; ECRB, extensor carpi radialis brevis; EDM, extensor digiti minimi; ECU, extensor carpi ulnaris; EDC, extensor digitorum communis.

- Compartment 4 – extensor digitorum communis (EDC) and extensor indicis proprius (EIP)
- Compartment 5 – extensor digiti minimi (EDM)
- Compartment 6 – extensor carpi ulnaris (ECU).

After emerging from the extensor retinaculum, the tendons of EDC are joined by intertendinous connections, junturae tendinum. Although their presence is reliable, the level at which they occur, proximal to the metacarpophalangeal (MCP) joint, is not. They are invariably present between the EDC tendons of middle, ring and small fingers. Less reliable, however, is a juncturum between the communis tendons of middle and index fingers. Junturae do not attach to EIP, an aid in tendon identification.¹ The architecture of these structures has clinical significance when applied to radial sagittal hood (RSH) repair, discussed later.

Anatomical variations

Variations in both the configuration and number of extensor tendons are extremely common and are well described elsewhere.² In general, the tendons of EDC to the index and middle fingers are singular, whereas the ring and small finger tendons are occasionally multiple. EIP lies ulnar to the index finger communis tendon and is smaller in diameter. Occasionally, it may be duplicate or located radially.³ Both EDM and APL have one, two or four component tendons.

Figure 52.2 Intrinsic musculature.

Finger extension

Finger extension is produced through a combination of two distinct motor units that have separate neural innervation systems. The radial nerve innervates the extrinsic extensors, producing extension of the MCP joints. The intrinsic system, composed of dorsal and palmar interossei and lumbrical muscles, is innervated by both the median and ulna nerves.⁴

Metacarpophalangeal joint

Extension at the MCP joint is produced solely by the extrinsic extensors. Central alignment of the extensor tendon as it traverses over the MCP joint is critical and is maintained by sagittal bands, both radial and ulna, which attach to the volar plate and intermetacarpal ligament.⁵

Although division of the ulna sagittal band produces no clinical sequelae, a laceration or rupture of the radial sagittal band results in extensor tendon subluxation or dislocation into the adjacent ulna gutter.⁶ Consequently, the extensor tendon loses its moment arm across the MCP joint, resulting in incomplete extension and ulna deviation.

Fingers

Beyond the MCP joint, the extensor tendon trifurcates into a central slip and two lateral slips. The central slip continues distally in the midline to insert on the dorsal base of the middle phalanx, producing proximal interphalangeal (PIP) joint extension (Figure 52.2). It remains centralized by the transverse retinacular ligament. The lateral slips course distally around

both sides of the PIP joint, where they are joined by the lateral bands of the intrinsic muscles. The conjoined lateral bands meet, combine and attach to the base of the distal phalanx, producing distal interphalangeal (DIP) joint extension.

Intrinsic muscles

The interossei and lumbricals comprise the intrinsic musculature. The interossei course dorsal to the deep transverse metacarpal ligament and join the lateral slips around the mid point of the proximal phalanx. The lumbricals arise from the flexor digitorum profundus (FDP) tendon, pass volar to the deep transverse metacarpal ligament, and attach to the radial lateral slip of each finger.

At MCP joint level, the intrinsic muscles and tendons are both volar to the axis of rotation. However, when the muscles and tendons reach PIP joint level, both become dorsal to that axis. The lumbricals act as the primary intrinsic extension mechanism.⁷ In contrast, the interossei contribute to IP joint extension only when the MCP joints are simultaneously flexed.⁸ The extensor mechanism is anchored in position across the PIP joint by the transverse retinacular ligament. Synchronous PIP and DIP joint extension is achieved by a mechanism in which the central slip extends the PIP joint and the lateral bands, circumventing the PIP joint, extend the DIP joint.

The critical element in this synchronous movement is the balance between the three components. Most importantly, the lengths of the central slip and the two lateral bands must be such that synchronous extension is produced. Thus, as the middle phalanx reaches alignment with the proximal phalanx, so too is there concomitant alignment of the distal phalanx.⁹

The transverse retinacular ligament extends from the conjoined lateral bands to the flexor sheath at PIP joint level, and acts to prevent dorsal dislocation of the lateral bands.¹⁰ The oblique retinacular ligament (ORL) connects the conjoined tendons from the dorsum of the distal phalanx to the volar checkrein ligaments at the PIP joint. The ORL thus lies volar to the PIP joint and sits dorsal to the axis of the DIP joint, allowing coordination of flexion and extension within those joints.¹¹ The triangular ligament is a fascial band connecting the conjoined lateral bands and the terminal tendon. It prevents volar subluxation of the conjoined lateral bands during PIP joint flexion.¹²

Zones of injury

Fingers

The classification of Kleinert and Verdan featuring eight zones of extensor tendon injury has endured (Figure 52.3).¹³ A ninth zone, relating to purely muscular injury in the mid to

Figure 52.3 Extensor tendon zones.

proximal forearm, was described by Doyle.¹⁴ As an aide memoire, excepting zone 9, odd numbered zones are located over joints.

- Zone 1 – DIP joint
- Zone 2 – middle phalanx
- Zone 3 – PIP joint
- Zone 4 – proximal phalanx
- Zone 5 – MCP joint
- Zone 6 – dorsum of hand
- Zone 7 – extensor retinaculum
- Zone 8 – distal forearm
- Zone 9 – muscular area, middle and proximal forearm.

Thumb

APL, EPB and EPL all play separate roles in thumb extension. APL inserts into the base of the first metacarpal, EPB attaches to the base of the proximal phalanx while EPL maintains a broad area of contact with the base of the distal phalanx.

As it traverses the dorsum of the MCP joint, EPL is anchored on the ulnar side by the aponeurosis of adductor pollicis, whereas radially, abductor pollicis brevis (APB) performs a similar role. Consequently, EPL is held securely in a centralized position as it courses over the metacarpal head. Consequently, proximal stump retraction is found only when EPL division occurs proximal to the MCP joint.

- Zone 1 T – IP joint
- Zone 2 T – proximal phalanx
- Zone 3 T – MCP joint
- Zone 4 T – metacarpal
- Zone 5 T – carpometacarpal joint.

Suture techniques

The optimal suture material will maximize the strength of repair, prevent rupture, reduce skin adhesions and minimize tendon shortening. Additionally, suture techniques are predicated on extensor tendon thickness, shown by Doyle to vary from 0.55 mm in zone 2 to 1.7 mm in zone 6.¹⁴ I prefer to use a 4.0 non-absorbable core suture, and a 5.0 monofilament nylon suture for a cross-stitch or epitendinous suture.

The suture configurations are zone dependent. In general, I prefer:

- Zone 1: DIP joint, running suture incorporating skin and tendon
- Zone 2: distal finger – simple running suture oversewn with Silfverskiöld cross-stitch
- Zone 3–5: modified Kessler in thickest portion of tendon, dorsal cross-stitch
- Zone 6–7: modified Kessler in thickest portion of tendon with circumferential epitendinous suture.

Postoperative regimes

Extensor tendon repairs in zones 1 and 2 are immobilized in full DIP joint extension for 6 weeks, employing a splint or Kirschner wire fixation. Patients with zone 3, 4 and 5 injuries are managed with splinting in 30–40° of wrist extension, 20° of MCP joint flexion and full extension across the PIP joints for between 4 and 6 weeks. Zone 6, 7 and 8 injuries are splinted in wrist extension and mild MCP joint flexion for 4 weeks. EPL repairs are splinted in 40° of wrist extension, 10° of MCP joint flexion and IP joint extension for 4–6 weeks, with the thumb held in a retroposed position to minimize tension across the site of repair.

Static splinting in extension for 3–6 weeks followed by gradual mobilization has been the traditional postoperative management of these injuries. More recently, controlled active mobilization (CAM) protocols and dynamic splinting have been employed. CAM involves active joint extension while limiting joint flexion through a palmar splint. In comparison, dynamic splinting involves passive joint extension with an outrigger, again with a palmar splint blocking flexion.

Newport published a retrospective analysis of static splinting, concluding that loss of flexion was the most significant complication while the average degree of loss of flexion was greater than the extension lag. Furthermore, they found that distal zone injuries^{1–4} produced significantly worse results than the more proximal zones, and unsurprisingly, complex injuries were associated with poorer outcomes.¹⁵

Khandwala's study in 2000 showed no difference in outcomes when comparing CAM to dynamic splinting.¹⁶ For suitably motivated and supervised patients with injuries in zones 4–7, these methods are beneficial and have a very low rupture rate. In the very young, and patients suspected of being poorly motivated and/or non-compliant, static mobilization is appropriate.

Complications

Adhesion formation at the site of repair, to overlying skin and underlying bone, is the most common complication of extensor tendon repair, producing extensor lag and loss of flexion. An extensor tenolysis should not be considered until gains have plateaued from therapy, and usually no sooner than 4–6 months after the initial repair. Ideally, a good range of passive motion should be present prior to proceeding with tenolysis. Capsulotomy, collateral ligament release and flexor tenolysis may need to be considered, either at the time of tenolysis, or following a poor outcome from tenolysis.

Zone 1: Distal interphalangeal joint level

Acute injuries

Loss of active DIP joint extension resulting from extensor tendon disruption in zone 1 produces a mallet finger deformity. It results from forces producing sudden flexion across the DIP

joint, commonly a direct blow to the fingertip. The injury is usually closed and the tendon disruption may be accompanied with a fracture of the dorsal lip of the distal phalanx, with joint subluxation in larger fractures. Crush injuries, saw and knife wounds are among the more common mechanisms resulting in open injuries to the extensor apparatus and, on occasion, the underlying DIP joint. Radiological assessment is essential in management of these injuries. The dominant hand is most frequently injured, with the small ring and middle fingers accounting for 90% of all such injuries.¹⁷

In the absence of subluxation or a fracture involving less than a third of the articular surface, continuous DIP joint immobilization in full extension for at least 6–8 weeks is appropriate. A further 2 weeks of splinting at night and during strenuous exercise is commonly recommended.² Results of this non-operative treatment regime have reliably shown 80% of patients demonstrate a persistent residual extension lag of 10°, usually not a functional concern.¹⁸

Operative treatment is indicated in open injuries, patients unable to work with a splint, and those with a large dorsal bony fragment with palmar subluxation of the distal phalanx.¹⁹ Where possible, direct repair of the extensor tendon should be performed. If divided at its insertion, many methods, including overlying skin suture with splinting, pull-out wires, and Kirschner wire fixation of the DIP joint have all been advocated.²⁰ Recently, bone anchors have become a popular method of reattaching EDC to its bony insertion.

The most contentious area of treatment remains the management of the substantial fracture fragment. Again, many methods of reduction and fixation have been reported, including

Kirschner wires, tension band wiring, screws, hook plates and mini external fixation.¹⁹

An elegant method of closed reduction of mallet fractures is DIP joint extension block pinning. This technique involves flexing the DIP joint and passage of a Kirschner wire into the head of the middle phalanx (Figure 52.4). The DIP joint is then brought back into extension, or as near as the dorsal blocking wire will allow, and a longitudinal Kirschner wire is passed across the DIP joint.²¹ The wires can be removed after radiological confirmation of bony healing, usually at 4–6 weeks.

Chronic injuries

Prior treatment, passive DIP joint motion and attitude of the PIPJ are all vital considerations in the management of chronic mallet finger. An 8-week trial of splinting is often attempted as, although benefits may be minimal, there is no significant downside. Radiological evidence of DIP joint arthritis or chronic palmar subluxation both negate the efficacy of further conservative treatment.

Tenodesis involves elliptical wedge excision of several millimetres of skin and tendon, with the DIP joint wired in full extension for 6 weeks.

A central slip tenotomy can be employed for patients in the presence or absence of an established swan-neck deformity.²² Optimal results from this procedure are seen in patients with extensor lags up to 35°.

Thompson described the technique of spiral oblique retinacular ligament reconstruction (SORL). Although bone anchors have replaced the original pull-out suture described, the technique involves securing a tendon graft to the insertion of EDC. The graft is taken proximally between the volar plate and flexor

Figure 52.4 Dorsal blocking technique, DIP joint. (a) Zone 1. Preoperative. (b) Intraoperative.

tendons across the PIP joint and anchored into the proximal phalanx.²³ This procedure is appropriate for mallet finger deformities with extensor lags of 45° or greater. DIP joint fusion remains appropriate for arthritic and painful chronic mallet finger deformities and those with chronic palmar subluxation.

Zone 2: Middle phalanx level

Acute injuries

Knives, saw blades and crushing injuries are frequently responsible for extensor tendon disruption in this region. One or both of the lateral bands may be divided, as may the triangular ligament. Sharp lacerations are repaired with 5.0 nylon in a figure of eight manner or a running configuration. A cross-stitch as described by Silfverskiöld may also be added.¹⁴ Where a segmental defect precludes primary repair due to unacceptable tension, a lateral band turndown provides an elegant solution.¹⁴ Swan-neck deformities resulting from a chronic zone 2 injury are approached using the SORL reconstruction, described previously.

Zone 3: Proximal interphalangeal joint level

Acute injuries

Loss of PIP joint extension follows disruption of the extensor mechanism at, or just proximal to, the PIP joint. Lacerations and blunt trauma can produce injuries including any or all of

complete or partial divisions of the central slip and lateral bands, breaches of the joint capsule and fractures of the dorsal lip of the base of the middle phalanx. Palmar dislocation of the PIP joint results in central slip injuries ranging from attenuation to complete disruption.

Central slip injury results in the loss of PIP joint extension, allowing that joint to assume a flexed attitude. Should the injury result in volar migration of the lateral bands, the DIP joint subsequently goes into hyperextension, resulting in a boutonniere deformity, which may manifest within 10–14 days post injury.

Closed injuries

Treatment of an acute closed central slip rupture consists of splinting or Kirschner wire fixation of the PIP joint in full extension for 6 weeks, while encouraging active DIP joint flexion exercises to promote dorsal migration of the lateral bands.

Rarely, the central slip is avulsed with a fracture fragment from the dorsal lip of the middle phalanx. Small undisplaced fragments can be ignored, and managed by splinting or Kirschner wire fixation as described. The treatment of choice for larger displaced fragments is more controversial. Kirschner wire fixation and screw fixation have been advocated, as has excision of the fracture fragments and tendon repair to bone with pull-out wire or suture anchor.²⁰

Where possible, I prefer to reduce the fragment by placing a dorsal blocking technique as described previously (Figure 52.5). The wires are removed at 6 weeks.

Figure 52.5 Dorsal blocking technique, PIP joint. (a) Preoperative. (b) Intraoperative. (c) Postoperative.

Open injuries

Wounds over the dorsum of the PIP joint raise two major questions. Has the central slip been breached, and if so, has the joint been entered? Transection of the central slip may be partial or complete, and may also involve one or both lateral bands (Figure 52.6). Primary repair with a core suture such as a modified Kessler with a braided synthetic suture on a taper needle, oversewn with a cross-stitch is used.

When the division is at, or near, the bony insertion of the central slip, reattachment to bone using a bone anchor provides a simple and secure option. Postoperative management requires splinting of the PIP joint in full extension for 5–6 weeks. Any concerns regarding the patient's postoperative compliance are best addressed by placing a Kirschner wire across the joint. Where a deficit exists in the central slip precluding primary repair, the distally based flap of extensor tendon as described by Snow is an elegant technique.²⁴

Aiche recommended central slip defects be repaired with midline advancement of both lateral bands, which are sutured together once dissected free of ORLs.²⁵ When the central slip is detached to a displaced intra-articular fracture of the dorsal lip of the middle phalanx, I employ a technique using dorsal blocking wires identical to that for treating a similar injury in a mallet finger.

Chronic injuries

Chronic boutonnière deformities result from traumatic central slip disruption or elongation secondary to inflammation. Volar migration of the lateral bands increases PIP joint flexion and DIP joint extension, eventually producing fixed contractures of both joints. Dynamic splinting and serial casting are indicated when passive DIP joint flexion is possible when the PIP joint is held in extension, and should also be considered preoperatively to optimize the passive range of motion within the joints.

In the absence of passive DIP joint flexion with the PIP joint held in extension, Fowler's central tenotomy corrects DIP joint hyperextension, and reduces PIP joint flexion. A mallet finger does not result, perhaps due to fibrosis and shortening of joint capsule and ligaments. Patients with fixed contractures require physiotherapy and splintage prior to any surgical procedure. Furthermore, the surgeon must be cognizant not to sacrifice preoperative PIP joint flexion for a postoperative stiff extended PIP joint.

If electing to proceed, various tendon relocation procedures have been described. Matev advocated division of the lateral bands, using one for central slip reconstruction, the other for DIP joint extension.²⁶ Littler and Eaton described division of both lateral bands distal to the PIP joint, conserving the lumbrical tendon for DIP joint extension, and translocating the lateral bands to the midline, fixing them to the base of the middle phalanx.²⁷ PIP joint fusion or arthroplasty are appropriate procedures for patients with arthritic PIP joints.

Zone 4: Proximal phalanx level

Acute injuries

When caused by sharp instruments, these extensor tendon injuries are usually straightforward. Regardless of whether the tendon wound is complete or incomplete, the anchoring roles of the sagittal bands prevent any proximal stump retraction. Repair is managed with a modified Kessler suture of non-absorbable (polyester) material and an epitendinous cross-stitch.

Major crush injuries, circular saws, chain saws and similar produce far more complex problems in this region. In these circumstances, defects of 10 mm or more may be produced not only in the extensor mechanism, but also in the dorsal cortex of the proximal phalanx as well as the overlying skin. Options for

(a)

(b)

Figure 52.6 Boutonnière deformity. (a) Zone 3. Boutonnière deformity 10 days post dorsal PIP joint laceration. (b) Zone 3. Central slip division with breach of dorsal capsule exposing PIP joint.

extensor tendon reconstruction include tendon grafting, tendon transfer or a reverse plasty of EDC as described by Foucher *et al.*²⁸

After initial wound debridement and underlying fracture stabilization, local flaps may be needed to provide stable skin cover. Since complex injuries in this region are frequently associated with adhesions, early mobilization is desirable.

Zone 5: Metacarpophalangeal joint level

Acute injuries

Septic arthritis

Open wounds located over the dorsum of the MCP joint are common and frequently result from a punch to a human mouth – the ‘fight bite’ injury. Apart from the contaminated skin wound, penetration of human teeth can cause partial or complete division of the extensor tendon and contaminate the underlying joint with oral flora. Due to the seemingly innocuous appearance of the initial wound, presentation is often delayed for several days, during which time contamination proceeds to florid infection.

Pain, swelling, erythema and discharge from the wound, usually the middle finger of the dominant hand, complete the common clinical picture. X-Rays can appear normal, display a foreign body (tooth), or show evidence of septic arthritis or osteomyelitis.²⁹

Cultures from affected joints commonly reveal infection with streptococcal and staphylococcal organisms.³⁰ Prompt wound exploration, preferably within 24 h, is required. The MCP joint must be entered, cultured and copiously irrigated. Depending on the operative findings, repeat irrigation may be required after a further 48 h. Repair of the tendon is best deferred until completely satisfied the underlying joint is free of infection. Since the tendon injury is frequently partial, early active mobilization can be commenced within one week after conversion to a clean wound.

Sagittal band injuries

Blunt MCP joint trauma, forced MCP joint flexion and, in a position of resisted extension, even seemingly insignificant injuries are all capable of sagittal band injury. The radial sagittal band, usually in the ring or middle finger, is the most commonly affected.⁵

Clinically, the patient may describe a snapping or clicking during MCP joint flexion, occasionally leading to confusion with a trigger finger. These patients demonstrate a subluxation of the extensor tendon on finger flexion (Figure 52.7).

More severely affected patients will display a complete dislocation of the affected extensor tendon into the ulna gutter. With the extensor tendon no longer centralized over the metacarpal head, the moment arm is lost, and MCP joint extension will produce both extensor lag and ulna deviation. Four weeks of buddy taping is appropriate for symptomatic patients, and those with subluxation, if commenced within 2–3 weeks of injury.

Figure 52.7 Subluxation of EDC middle and ring fingers.

Good results have been obtained from wearing an MCP flexion-blocking splint while allowing PIP joint flexion, for a period of 6–8 weeks.³¹

The most difficult group to treat are those who fail conservative management, and those presenting more than a month post injury. Kettelkamp *et al.* recommended direct repair of the RSH, aiming to restore centralization of the extensor tendon as it traverses the metacarpal head. When necessary, they advocated concomitant release of the ulna sagittal band.⁵

In long-standing cases, direct repair of the RSH may not be possible. A plethora of ingenious methods have been described to reconstruct the extensor hood.⁴ Personally, I find the most effective method to achieve centralization and prevent dislocation into the ulna gutter is Wheeldon's technique, involving use of an adjacent junctura tendinum between the middle and ring fingers (Figure 52.8).³²

At operation, a junctura tendinum connecting the affected digit and the adjacent ulna digit is identified. It is detached from the adjacent tendon, and draped over the affected extensor tendon, and imbricated into the palmar radial sagittal band, thus acting as a sling preventing ulna dislocation.

Although the anatomy of the distribution of the junctura tendinum is variable, it is rare not to find one available for this purpose. Should no tendinum be readily available, McCoy described a proximally based sling of the mid third of the extensor tendon looped around the lumbrical and sutured to itself, again acting as a sling to prevent ulna subluxation. The MCP joint is splinted in extension for 6 weeks, and PIP joint flexion is commenced after 2 weeks.³³

Open injuries

While lacerations to the sagittal bands are uncommon, they can produce loss of MCP joint extension as well as extensor tendon subluxation to the opposite side of the MCP joint.¹⁴ Most

Figure 52.8 Wheeldon's technique for correction of extensor tendon subluxation in zone 5.

commonly affected are the radial sagittal bands to either the ring or middle fingers, and repair can be performed using a simple suture of braided polyester.

Zone 6: Metacarpal level

Acute injuries

In comparison to more distal zones, zone 6 repairs achieve more favourable outcomes as they are not complicated by underlying joint injury or damage to intricate flexor and extensor tendon systems.

Additionally, extensor tendons at this level have a smaller surface area, and are generally covered by substantially thicker subcutaneous tissue. All these factors combine to reduce the potential for adhesion formation after tendon repair. A braided polyester core suture in a modified Kessler or modified Bunnell configuration is appropriate, whereas use of a cross-stitch is at the surgeon's discretion. In a static splint the wrist is placed in 30° of extension, with the MCP joints in neutral. Dynamic mobilization is appropriate in compliant patients.

In late presentations, direct repair may not be possible, in which case end to end or end to side transfer to an adjacent tendon is appropriate. In more severe defects, tendon transfers may be required, with EIP providing an excellent transfer. Where the overlying soft tissue is satisfactory, a two-stage tendon graft utilizing silicone rods is another reconstructive option.

Zone 7: Dorsal wrist level

Acute injuries

Penetrating trauma at this level usually injures both the extensor retinaculum and the underlying extensor tendons. When the cross-sectional diameter of the tendon permits, a core suture repair using a 4.0 non-absorbable suture is performed. Frequently, the proximal tendon ends are markedly retracted, requiring

extensive exposure. Severe wounds, such as those from a chain saw, cause problems not only with tendon identification, but also with ragged tendon ends and significant segmental loss of tendon. Tendon grafting or tendon transfer may be necessary under these circumstances. Where possible, I prefer to repair at least some part of the extensor retinaculum to prevent subluxation or bowstringing of the tendons.

The surgeon should be aware of anatomical variations within APL, frequently in one, two or four slips, creating the potential for confusion when attempting to repair proximal and distal stumps. Repairs of APL and EPB are commonly associated with repair of sensory branches of the radial nerve.

At their osseous insertions, the tendons ECRL and ECRB are relatively flat and broad. The insertion of, now commonly available, anchoring devices has proved to be a more effective, simple and elegant technique to reattach these tendons than the pull-out wire techniques used previously.

Chronic injuries

Septic arthritis of the wrist, Colles fractures and aggressive bouts of dorsal wrist synovitis all predispose EDC and EPL to attrition ruptures. EPL rupture is best managed with an EIP tendon transfer whereas ruptures of EDC are treated with suture of the distal stump to adjacent extensor tendons. Alternatively, FCU can be used as a new motor.

Zone 8: Proximal and distal forearm

Open distal forearm injuries produce disruption at the musculotendinous junction. Achieving adequate strength of repair is difficult due to the diaphanous nature of the overlying fascia. Occasionally, a side-to-side tendon transfer may be required.

Penetrating injuries to the proximal half of the forearm, usually the result of glass, chain saws or knives, result in partial or total muscle belly divisions. Intramuscular fibrous septa may

help with orientation of muscle bellies, and also provide the most robust structures for suture placement. Concomitant nerve injury to both the superficial sensory branch and the PIN at this level are frequent and can be challenging to identify.

Injuries to extensor tendons of the thumb

Zone 1

Open injuries

Direct repair of tendon ends is usually possible as proximal retraction is minimal. Of greater concern is damage to the underlying capsule with exposure of the DIP joint. Vigorous lavage of the joint is required prior to capsular and tendon repair, and a single K wire is used to hold the joint in extension. Bone-anchoring devices are appropriate for reattaching EPL when division has occurred at its insertion.

Closed injuries

In the absence of a significant fracture or subluxation, acute closed injuries resulting in EPL disruption, 'mallet thumb', are treated with 8 weeks of splintage.³⁴ Indications for operative intervention extend to those cases with a large bone fragment or volar subluxation. These cases are managed using the dorsal blocking wire technique.

Zones 2 and 3

MP joint lacerations in the dorsum of the thumb can result in division in any or all of EPL, EPB and the joint capsule. Choice of suture, suture configuration and postoperative splinting are as previously described for zone 2 in the finger.

Zones 4 and 5

Injuries sustained over the first metacarpal may incur injury to EPL, APL and EPB. The cross-sectional morphology of APL and EPL allows for a core suture in a modified Kessler configuration. EPB is repaired by simple suture. Sensory branches of the radial nerve are numerous and require preservation or repair as appropriate.

Open injuries

Retraction of the proximal stump of EPL in these zones is likely. If found to be excessively damaged or delayed presentation does not allow it be pulled out to length, an extensor indicis (EIP) transfer is indicated. I prefer to use a Pulvertaft weave using a braided non-absorbable suture.

Closed injuries

Attrition ruptures of EPL are well described in patients with rheumatoid arthritis or previous plating of lower radial fractures. Inability to retropose the thumb while held in abduction is the diagnostic sign of EPL rupture. Minimal DIP joint extension may still be present, despite EPL rupture. Although a palmaris longus tendon graft can be used, an EIP tendon transfer remains my preferred solution.

CHAPTER 53

Tendon transfers

Adam C. Gascoigne¹ and Stephen Flood²

¹Department of Anatomy and Neuroscience, University of Melbourne, Australia

²Department of Plastic and Reconstructive Surgery, Austin Health, Heidelberg, Australia

Introduction

Tendon transfer is the surgical transplantation of a normal muscle–tendon unit (MTU) into a new location to restore a non-functioning MTU. In 1770 a French surgeon named Missa repaired a middle finger extensor tendon injury by grafting the index and ring finger extensors, thus performing the first recorded tendon transfer.¹ However, the modern conception of tendon transfer as expressed above was formulated by Carl Nicoladoni in 1881,^{2,3} and further developed by Tomasz Drobnik with particular reference to radial nerve palsy in 1894.^{4,5} There was subsequently a dramatic expansion in the number and use of tendon transfer techniques by surgeons faced with the polio epidemics and war injuries of the early twentieth century. In this chapter we present the senior author's (SF) approach to tendon transfers for peripheral nerve injuries and tetraplegia (Figure 53.1). Some definitions are given in Box 53.1.

Indications

The essential indication for tendon transfer is the functional impairment of an MTU, either through interruption of its nerve supply, direct injury to or abnormal development of muscle. Indications for tendon transfer include:

- irreversible peripheral nerve injury,
- failed nerve transfer,
- adjunct to nerve transfer,
- traumatic loss of muscle or tendon,
- brachial plexus injury,
- spinal cord injury,
- central neurological injury including stroke, and
- congenital or developmental disorders.

In general, tendon transfers are only considered where such impairment is irreparable, as in nerve root avulsions, nerve injuries not amenable to repair, failed nerve transfers, and late

presentation of nerve injury with motor endplate fibrosis.⁶ Burkhalter has also advocated the use of early tendon transfer as an adjunct to nerve repair to retain function and reduce development of contractures during nerve recovery.^{7,8} Such a transfer serves to improve function during nerve regeneration, eliminating the need for external splinting, supplements the power of the muscles being reinnervated, and may serve as a definitive procedure where nerve regeneration is limited. However, such transfers should not be themselves associated with significant loss of function, or result in deformity following recovery of function in the affected nerve. For the majority of other cases, the senior author prefers to see neurological function plateau prior to considering tendon transfers. Based on the seminal works of Sunderland and Seddon, nerve regeneration progresses at approximately 1 mm a day.^{9,10} Depending on the location of injury, this may mean delaying surgery for up to 12–18 months.

Biomechanics

The majority of standard tendon transfer techniques are based on sound biomechanical principles. An understanding of basic biomechanics is helpful for the surgeon, particularly when faced with a difficult case where the standard approach may not be feasible. The ultimate aim of a tendon transfer is the creation of a new MTU capable of generating torque sufficient to move a target joint through a useful range of motion.¹¹ Torque is determined by the power (force-generating ability) of the muscle, and its leverage (mechanical advantage).¹² Other relevant biomechanical characteristics are the degree of tendon excursion, and the tensioning of the muscle during transfer.

Power and leverage

The power of a muscle is proportional to its physiologic cross-sectional area (PCSA).¹³ Leverage is determined by the moment arm, which is the perpendicular distance from the

Figure 53.1 Flexor digitorum superficialis (Royle, Thompson, Bunnell) opponensplasty. Source: Reproduced with permission of Donald Sammut.

Box 53.1 Definitions

- Tendon transfer: surgical transplantation of normal muscle–tendon unit (MTU) into a new location to restore function of a non-functioning MTU
- Arthrodesis: surgical immobilization of a joint by fusion of adjacent bones
- Tenodesis: surgical anchoring of a tendon to bone
- Tenodesis grip: passive grip due to finger flexor shortening with wrist extension

target joints axis of rotation to the line of pull of the muscle (Figure 53.2). It should be noted that the moment arm may vary depending on joint position, and any measurements should be taken with the joint in a useful position. Muscles whose line of pull pass further from the axis of a joint have relatively more leverage, and hence exert greater torque.¹⁴ Thus, for an MTU to be useful for a transfer, it must have sufficient power and leverage to move the target joint.

Tendon excursion

An additional consideration is the excursion of the MTU being considered for transfer. This is the distance a tendon can move from when it is relaxed to its fully contracted position. Tendon excursion and contraction velocity are proportional to muscle fibre length.¹³ In order to be a candidate for a transfer, an MTU must have sufficient excursion to move the target joint through a useful range of motion. The moment arm is

again relevant here (see above). As the moment arm increases, the amount of joint movement produced by a given amount of tendon excursion decreases. Hence, adjusting the moment arm of a transferred MTU is a tradeoff between range of movement and leverage.

Tensioning

Normal contraction of an MTU requires overlap of actin and myosin filaments in the sarcomeres of the muscle fibres. An excessively tight or loose muscle will not contract effectively, as is expressed by the Blix curve.¹⁵ Hence, it is critical for the surgeon to put the transferred MTU under appropriate tension. Previously it has been suggested that it may be preferable to place the transferred MTU under excess tension, relying on postoperative relaxation and lengthening to correct any errors.⁶ However, studies have demonstrated that this may overestimate the degree to which the muscle may remodel to accommodate its new length and result in a significant loss of muscle power.¹⁶ Ultimately, the surgeon should aim to neither over- nor under-tension the transferred MTU by setting it as close to its optimal length as possible. However, this is not easy to establish intraoperatively, as the muscle's slack length once it has been released from its insertion is not reliably related to its optimal length.¹¹ Nevertheless, an on-table estimate of the tension on a transferred tendon remains the usual method of determining the amount of tension to put on the transferred MTU. The senior author uses a comparison of distance from MTU origin to previous and new insertion as a guide.

Figure 53.2 Moment arm. (a) The moment arm of a muscle whose line of pull passes distant from the axis of the joint has great mechanical advantage but acts through a relatively small range of motion. (b) By comparison, a muscle with a line of pull that passes close to the axis of the joint acts through a large range of motion but has little leverage. Source: Brand, 1974.¹⁴ Reproduced with permission of Elsevier.

Principles

General principles guiding tendon transfer have been developed and refined since the early twentieth century. They include the following:^{6,17–23}

- **Appropriate strength:** The donor MTU should be of comparable strength to the recipient, in order to provide useful movement at the target joint.
- **Adequate power:** The donor MTU should be capable of contraction against resistance, which corresponds to a grading of 4 or better on the Medical Research Council (MRC) scale.
- **Amplitude of excursion:** To be useful for tendon transfer, an MTU must have sufficient amplitude of excursion to be effective at moving the target joint.
- **Anatomic location:** The donor MTU should contract in parallel with the recipient, and be located such that its transfer results in a functionally useful line of pull. This may be optimized during the procedure by redirecting the tendon using pulleys.
- **Control:** The donor MTU must be effectively under voluntary control. Transferring a spastic muscle will result in a negative outcome.
- **Supple joints:** Preoperatively, maximum range of motion must be achieved for the joints to be moved by the transferred MTU. If possible, any existing soft tissue contractures should be dealt with during the procedure.
- **Expendability:** The benefit gained from the tendon transfer must be greater than the loss of the donor MTU in its original location.
- **Single function per transfer:** Each tendon transfer should be used to restore a single function to avoid compromising on strength and movement.

- **Suitable soft tissue bed:** The transferred MTU should not pass through scarred, inflamed or oedematous tissues that may inhibit its free movement by development of adhesions.
- **Synergism:** The patient will find it easier to learn to use an MTU whose original function is synergistic with the function it is replacing. If this is not practical, muscles that are usually activated together are also suitable for transfer, for example wrist flexors and finger extensors.

It should be borne in mind that these are not hard and fast rules that need to be followed in all cases. For example, Steindler proposed that the 'gliding apparatus' of the tendon should be preserved or reconstructed as much as possible, to minimize the risk of adhesions developing.¹⁷ Obviously, this is not possible for every patient, though if its course is through scarred, inflamed, or oedema tissues, then it may be desirable to revise the soft tissue bed using flaps or grafts. Nevertheless, these principles are useful guidelines for both assessing a patient's suitability for tendon transfer and also in selecting the best procedure.

Approach

Patients presenting with peripheral nerve palsies should have a comprehensive history taken, recording the symptoms, aetiology, time course and any investigations or procedures performed. A complete neurological examination should document the motor and sensory deficit and the limb should be further assessed for soft tissue injuries, especially for any areas of scarring, oedema or inflammation along the path of any tendon transfers. Measurements of the passive and active ranges of motion of all affected joints should be taken. Further imaging

and investigation by means of nerve conduction studies and electromyography may be performed where the diagnosis is not clear. Once the problem has been clearly defined, the reconstruction may be planned.

Surgical technique

A number of different techniques have been developed for the repair and transfer of tendons. An interlacing suture, described by Guy Pulvertaft in 1956 and henceforth known eponymously as the Pulvertaft weave,²⁴ has been proven to be superior to other techniques used historically, including the Kessler grasping suture and side-to-side repairs described by Mason and Nicoladoni.²⁵ Recently, alternatives to the Pulvertaft weave have been developed, such as the lasso²⁶ and spiral linking²⁷ repairs, which demonstrate comparable strength and may be easier and quicker to perform. The senior author's preference is to use the Pulvertaft weave (Figure 53.3).

Radial nerve palsy

Anatomy^{6,8,28-30}

The posterior cord of the brachial plexus continues as the radial nerve after having given off its terminal branches in the axilla. It comprises motor and sensory fibres from the ventral rami of C5–T1. While in the axilla it gives off its first two branches to triceps, to the long and medial heads. It crosses the lower border of teres major to enter the anterior compartment of the arm and immediately dives into the posterior compartment via the triangular interval. It then runs in the spiral groove (aka radial groove) of the humerus. While in the posterior compartment it gives its last two branches to triceps, one to the lateral head and a second to the medial head, as well as two sensory branches: the lower lateral and posterior cutaneous nerves of arm. Approximately halfway down the arm the radial nerve pierces the lateral intermuscular septum to re-enter the anterior compartment. Here it gives off a medial branch to brachialis and lateral branches to brachioradialis and extensor carpi radialis longus (ECRL). It then enters the cubital fossa under cover of brachioradialis, before dividing into deep and superficial branches. The deep branch

passes between the two heads of supinator to become the posterior interosseous nerve, while the superficial branch continues down the anterior compartment of the forearm under cover of brachioradialis. The posterior interosseous nerve immediately divides into branches to the extensor musculature of the forearm. The superficial branch of the radial nerve emerges on the radial side of brachioradialis at the wrist to cross the anatomical snuffbox and provide the sensory supply to the dorsum of the hand and the radial three and a half digits.

Clinical findings^{6,8,23}

The characteristic sign of radial nerve palsy is wrist drop. Due to the loss of the extensor musculature of the forearm, the patient is unable to extend the wrist or digits. In addition, grip strength is lost due to the weakness of finger flexion with the wrist in a flexed position. Low radial nerve lesions are defined as those below the elbow, thus sparing supply to brachioradialis and ECRL. In these cases, wrist extension is relatively preserved, though with radial deviation. Due to the proximal origin of the majority of the branches of the radial nerve, triceps function is only affected in very high lesions. The sensory deficit of radial nerve injury is less significant, only affecting the less sensitive dorsum of the hand and digits.

Approach^{6,8,23,31}

As discussed above (see Indications), some authors advocate using an early tendon transfer procedure to preserve function and prevent contractures in cases of radial nerve injury. Where this is not done, the use of a dynamic outrigger splint (Figure 53.4) results in greatly improved grip strength by fixing the wrist in extension.³² The key reconstructive aims are: wrist extension, metacarpophalangeal (MCP) joint extension, and thumb extension and abduction. These are generally performed in set combinations for ease of access and operative technique, with the main difference being the choice of MTU to be used for restoration of MCP joint extension.⁸

Wrist extension

For reconstruction of wrist extension, the pronator teres to extensor carpi radialis brevis (ECRB) transfer is ideal (Figure 53.5), and other options are rarely considered. If radial

nerve recovery is not anticipated, this should be performed end to end to achieve a more direct line of pull. Otherwise, the transfer should be performed by an end-to-side technique, to allow ECRB to resume wrist extension once it regains function.⁶ Pronator teres should be released from its insertion with a strip of periosteum to provide a robust attachment.³³ It is tunnelled subcutaneously superficial to brachioradialis and ECRL, and inserted into the tendon of ECRB.⁸ If desired, ECRL may be synchronized to ECRB, with pronator teres redirected to the new extensor complex.

Metacarpophalangeal joint extension

To restore MCP joint extension, a tendon transfer to extensor digitorum communis (EDC) is required. The surgeon is presented with a number of alternatives for this purpose (Table 53.1). Of these, the flexor carpi radialis (FCR) transfer^{34–36} is generally preferred in low radial nerve palsy, as its loss is balanced on the radial side of the wrist by the preserved function of ECRL.⁶ By comparison, use of the flexor carpi ulnaris (FCU)²¹ transfer sacrifices the only remaining muscle acting on the ulnar side of the wrist, resulting in radial deviation. However, both of these transfers suffer from the major drawback of having relatively low excursion for their intended function. For this reason, the flexor digitorum superficialis (FDS) transfer^{37,38} is sometimes preferred, as it has significantly greater excursion, allowing full extension of the digits without requiring wrist flexion. Whichever donor is used, they may be attached to EDC either by leaving it in continuity, or by dividing the tendons of EDC to allow end-to-end attachment of the transferred tendon (Figure 53.6). If the tendons are divided, they may be passed superficial the extensor retinaculum to optimize the line of pull.

Thumb extension

Extensor pollicis longus (EPL) is the common target for tendon transfers to restore thumb extension. It is divided at its musculotendinous junction and transposed to the radial aspect of Lister's tubercle. Palmaris longus is divided at the wrist and

freed up proximally, passed over the radial side of the wrist, then inserted into the distal stump of EPL. The line of pull of the transferred tendon should cross the anatomical snuffbox, resulting in combined extension and abduction with muscle contraction (Figure 53.7). An alternative is to use the ring finger FDS tendon to power palmaris longus. This is usually done during a Boyes transfer, when part of FDS is also being used for MCP joint extension.

Median nerve palsy

Anatomy^{30,39–42}

The median nerve is formed by a root from each of the medial and lateral cords of the brachial plexus. The larger lateral root carries the contribution from C5, C6 and C7, and the smaller medial root carries the contribution from the C8 and T1. It thus receives motor and sensory fibres from the ventral rami of all the segments contributing to the brachial plexus. It initially lies anterolateral to the third part of the axillary artery, but after crossing the lower border of teres major to enter the anterior compartment of the arm it crosses in front of the artery to lie on its medial side. The median nerve lies medially in the cubital fossa, entering the forearm by passing between the two heads of pronator teres. The nerve then runs under the fibrous arch of the origin of FDS, continuing down the forearm bound to the deep surface of FDS by areolar tissue. Within the forearm it gives off the anterior interosseous nerve, which supplies the deep layer of forearm flexor musculature. Injuries above where the anterior interosseous nerve is given off are usually defined as high median nerve lesions. Proximal to the wrist the median nerve gives off its palmar cutaneous branch, and then enters the carpal tunnel on the radial side of the tendons of FDS. The recurrent motor branch supplies the thenar muscles, and the remainder of the nerve provides the palmar digital nerves for the radial three and a half digits, and also supplies the radial two lumbricals. Note that there is some variation in the supply of the thenar muscles (see below, under Ulnar nerve palsy). There is also frequently variation in the pattern of innervation due to median to ulnar connections in the forearm, such as the Martin–Gruber anastomosis.⁴³ A median to ulnar connection, or Marinacci anastomosis,⁴⁴ is less common. It is important for the surgeon to recognize that the presence of these connections may result in unusual presentations of peripheral nerve injury.⁴⁵

Clinical findings^{23,41,42}

Injury to the median nerve below where the anterior interosseous nerve is given off results in loss of thumb flexion and opposition, with preserved forearm flexor function. In high median nerve palsy this is also lost, with the exception of some wrist and finger flexion provided by FCU and the bellies of flexor digitorum profundus (FDP) supplied by the ulnar nerve. Sensation is lost over the palmar surface of

Table 53.1 Approach to radial nerve palsy

Reconstructive aim	Preferred options	Alternatives
Wrist extension	Pronator teres to ECRB	Rarely consider brachioradialis (if function preserved) or FCR

the hand and radial three and a half digits. This is has great functional significance, as sensation in this distribution is essential for precision movement. Palmar sensation is preserved in compression or injury of the median nerve in the carpal tunnel.

Approach^{23,31,41,42}

The key reconstructive aims are: thumb opposition, thumb interphalangeal (IP) joint flexion, and index distal interphalangeal (DIP) joint flexion (Table 53.2). However, it should be noted that even with restoration of thumb opposition, many patients’ hand function remains poor due to the debilitating sensory deficit.⁴² For this reason, opponensplasty may not be appropriate for every patient.

Thumb opposition (opponensplasty)

The usual target of opponensplasty procedures is the tendinous insertion of abductor pollicis brevis (APB) at the proximal phalanx of the thumb. Bunnell stated that any tendon transfer intended to restore thumb opposition should be passed ‘through a tendon pulley constructed at the pisiform bone or by passing it around the tendon of the flexor carpi ulnaris’, and be ‘inserted into the ‘dorso-ulnar aspect of the base of the proximal phalanx of the thumb to give pronation.’⁴⁶ Any donor MTU that satisfies these requirements may be used for opponensplasty. The extensor indicis proprius (EIP)⁴⁷ opponensplasty (Figure 53.8) provides effective thumb opposition with the minimal functional sacrifice. It is also effective even in high median nerve lesions where other candidates for transfer are paralysed. The EIP tendon is identified on the ulnar aspect of the index finger EDC tendon and is divided immediately proximal to the extensor expansion. Alternatively, if further length is desired it may be harvested with a length of extensor expansion (see Figure 53.12), though this is usually unnecessary for opponensplasty. The tendon should be freed from its attachments in the distal forearm and passed around the ulnar aspect of the forearm to the tendinous insertion of APB at the proximal phalanx of the thumb.

Alternatives to the EIP opponensplasty include the palmaris longus,⁴⁸ superficialis^{46,49,50} and abductor digiti minimi

Table 53.2 Approach to median nerve palsy

Reconstructive aim	Preferred options	Alternatives
Thumb opposition	EIP opponensplasty ⁴⁷ ADM opponensplasty ⁵¹	FDS opponensplasty ⁴⁶ Palmaris longus opponensplasty ⁴⁸
Thumb IP joint flexion	Brachioradialis to FPL	ECRL to FPL ECU to FPL
Index DIP joint flexion	FDP side to side (lose independent flexion of fingers)	ECRL to FDP

(ADM)⁵¹ opponensplasties. The palmaris longus opponensplasty may incorporate palmar fascia in continuity with the tendon or the contralateral palmaris longus as a free tendon graft in order to gain sufficient length to reach the APB insertion. It is tunnelled subcutaneously from distal forearm to the thumb. This method is best for a low median nerve lesion with an intact palmaris longus. One drawback is its line of pull, which results in less effective opposition than that offered by other options.⁴² This may be partially overcome by passing the tendon via a pulley created at the pisiform as suggested by Bunnell.⁵²

The FDS opponensplasty utilizes the tendon to the ring finger (Figure 53.9). The line of pull may be optimized by bringing the tendon through a window in the flexor retinaculum as described by Snow.⁵³ This is also more secure than simply diverting the tendon at the distal end of the carpal tunnel. The tendon is divided via a distal incision in the finger or palm, and transferred across the palm to the tendinous insertion of APB. One shortcoming of this method is the significant rate of complications including deformity and extensor lag of the donor digit.⁴² Harvesting the FDS via a palmar rather than digital incision may reduce this risk.⁵⁴

The ADM opponensplasty (Figure 53.10) offers the further benefit of restoring the appearance of bulk to the thenar

Figure 53.8 Extensor indicis proprius (EIP) (Burkhalter) opponensplasty. (a) EIP identified on the ulnar aspect of the index finger extensor digitorum communis (EDC) tendon. (b) EIP divided immediately proximal to the extensor expansion and freed from attachments in distal forearm. (c) EIP passed around ulnar aspect of wrist to the tendinous insertion of abductor pollicis brevis at the proximal phalanx of the thumb. Source: Reproduced with permission of Donald Sammut.

eminence. It is released from its insertion and transferred across the palm to APB. This may be complicated by compression of the ulnar nerve by oedema or scar where it is crossed by the transferred tendon. To overcome this, Littler and Cooley,⁵⁵ Ogino *et al.*⁵⁶ and more recently Cawrse and Sammut⁵⁷ have suggested modifications that may reduce this risk, either by partial or complete detachment of ADM from its proximal origin.

Thumb IP and index DIP joint flexion

In high median nerve injury, thumb IP and index DIP joint flexion may require restoration. For thumb IP joint flexion, ECRL or extensor carpi ulnaris (ECU) may be transferred to (flexor pollicis longus (FPL). For index finger DIP joint flexion, ECRL may be transferred to FDP, or a side-to-side synchronization of FDP may be performed, relying on the ulnar-innervated component of the muscle.

Ulnar nerve palsy

Anatomy^{30,41,42,58,59}

The ulnar nerve commences as the continuation of the medial cord of the brachial plexus in the axilla, comprising fibres from the ventral rami of spinal segments C8 and T1. It also usually receives a contribution composed of C7 fibres from either the lateral cord of the brachial plexus or the median nerve in the axilla; these are destined for FCU in the forearm. The nerve lies on the medial side of the axillary artery, and enters the posterior compartment of the arm by piercing the medial intermuscular septum. It then passes between the medial epicondyle and the olecranon, through the cubital tunnel, and enters the anterior compartment of the forearm by passing between the two heads of FCU. It passes down the forearm beneath FCU and superficial to FDP, giving branches to those muscles, and accompanied by the ulnar artery. High ulnar nerve injuries are those that occur above where these branches originate. Just proximal to the wrist, the nerve emerges and gives off volar and dorsal sensory branches. At the wrist, they pass through the ulnar (Guyon's) canal, superficial to the flexor retinaculum, to enter the hand. It then divides into superficial and deep branches. The superficial branch provides the palmar digital nerves for the little finger and the ulnar aspect of the ring finger, and supplies the palmaris brevis muscle when present. The deep branch innervates the the intrinsic muscles of the hand with the exception of the thenar muscles and two of the lumbricals. This pattern is variable, however, with the supply to the lumbricals shared unevenly between median and ulnar nerves in some cases. Frequently opponens pollicis and FPB may also receive a branch, receiving either a sole supply from the ulnar or dual innervation from both ulnar and median nerves.

Clinical findings^{23,41,42}

The claw or intrinsic minus hand is virtually pathognomonic of ulnar nerve injury. The loss of the intrinsic muscles of the hand

and unopposed pull of the long extrinsic tendons result in hyperextension of the MCP joints and flexion at PIP and DIP joints. Specific testing may elicit Froment's sign: flexion of the thumb IP joint when holding a piece of paper between thumb and index finger, indicating weakness of adductor pollicis and the first dorsal interosseous. High ulnar nerve lesions are above the origin of the branches to FCU and FDP, resulting in reduced grip strength and radial deviation of the hand. An ulnar nerve palsy also results in loss of sensation over the ulnar one and a half digits.

Approach^{23,31,41,42}

The key reconstructive aims are: restoration of key grip by thumb adduction and correction of clawing. It is usually not necessary to reconstruct index finger abduction to achieve a useful key grip, as the patient is able to stabilize the index finger against adjacent digits (Table 53.3).

Thumb adduction (adductorplasty)

The common target for restoration of thumb adduction is, unsurprisingly, adductor pollicis. Again, a variety of donor MTUs may be used. Common choices include the ring or middle finger FDS,⁶⁰ the ECRB,^{61,62} or EIP.⁶³ In the case of ECRB and EIP, additional length may be required in order to reach adductor pollicis. For EIP this may be achieved by harvesting a length of the central tendon of the extensor expansion in continuity with the tendon (Figure 53.11), but ECRB requires a free tendon graft. Whichever donor is used, in order to recreate the line of pull of adductor pollicis, a pulley is required. This may most easily be achieved by passing the tendon around the second or third metacarpal (Figure 53.12).

Correction of clawing

The essential problem in the intrinsic minus digit is the hyperextension instability of the MCP joint, with flexion of the PIP and DIP joints (Figure 53.13). Procedures for correction of clawing thus focus on correction of this deformity.

Stiles and Forrester-Brown⁶⁴ first described transferring a single slip of each FDS tendon to EDC to correct clawing. Their technique was modified by Bunnell,⁶⁵ who transferred each slip onto the lateral bands of the extensor expansion.

However, this frequently resulted in complications due to adhesion formation and overcorrection.⁴² Bunnell's procedure was further modified by Littler,⁶⁶ whose technique is now widely known as the modified Stiles–Bunnell procedure. The FDS tendon of the middle or ring finger is divided over the PIP joint and split into four slips. Each slip is then passed through the lumbrical canals and inserted into the radial lateral band only. There have subsequently been many further modifications to the technique, though the essential elements – the division of a single FDS tendon into four and the attachment of the resulting slips into the individual digits – remain the same. The senior author's preferred method is that described by Riordan⁶⁷ and Zancolli,⁶⁸ in which the A1 pulley is used as the insertion of the slips of FDS (Figure 53.14). Alternatives to FDS include wrist flexors and extensors as described by Brand,⁶⁹ though these require free tendon grafts of sufficient length to reach their targets.

Combined palsy

Patients presenting with combined peripheral nerve palsies should have their individual problems and severity carefully characterized. This requires a detailed examination and further investigation with electromyography and nerve conduction studies with an aim to establishing both remaining function as well as deficiencies. Once this is done, a tailored approach to the individual patient may be planned. Innervated free muscle transfer may be considered for difficult situations where there are no suitable donor tendons, or where a standard transfer would result in unacceptable loss of function.

Tetraplegia

Restoration of upper limb function is a priority for tetraplegic patients, comparable to or of higher significance than bladder, bowel, sexual and lower extremity function.^{70–72} It allows the tetraplegic patient some autonomy, permitting completion of some personal activities of daily living (ADLs) independently or with the aid of appliances. Surgical restoration of upper limb function by means of tendon transfers originated with the work of Bunnell in the mid-twentieth century.⁷³ Significant advances in the techniques used were made by Moberg, who abandoned the prior focus on providing the patient with a tip-to-tip tripod pinch grip in favour of a lateral pinch or key grip between the thumb and index finger.⁷⁴ This gave the patient a functional grip without the stiff hand resulting from the multiple tenodeses required to achieve a thumb fixed in opposition.⁷⁵ Even more recently, single-stage reconstructions aimed at reducing hospital stay and improving patient outcomes have been described. The approach to the surgical reconstruction of upper limb function in tetraplegia used at a major spinal unit in Australia is described in this section (Box 53.2).

Assessment

Careful assessment is of key importance. Neurological stability should be ascertained, and the functional level clearly established. Current functional capabilities should also be reviewed, including bed mobility and transfers, and use of occupational aids or appliances including wheelchairs. Any psychological issues should be addressed, and the patient's motivation and expectations assessed. Patient must be highly motivated and involved in their treatment and postoperative rehabilitation to allow recruitment of transferred muscles and any previous issues with compliance should be examined in detail. Unrealistically high expectations regarding the level of function attainable post procedure should be gently corrected. A general medical history should be taken, as significant ongoing medical problems are a relative contraindication.

Contraindications to surgical reconstruction of upper limb function in tetraplegia include:

- unavailability of suitable muscles for transfer;
- severe pressure sores/generally unwell;
- severe muscle spasticity or joint contractures; and
- inadequate patient preparation or motivation.

Examination

Careful examination and recording of upper limb function are important in the preoperative period, both for patient selection purposes and to compare pre- and postoperative function. Residual muscle function is assessed and the patient given a categorization for each upper limb according to the international classification (see below). Potential donor muscle groups should be assessed for spasticity and range of motion of elbow, wrist, and hand joints measured.⁷⁶ Standard preoperative examination should be undertaken to screen for any medical issues which may be problematic in the perioperative period.

Classification

Moberg recognized that using a patient's spinal level of injury may not accurately reflect the degree of motor impairment and residual function. He devised a classification system for use in planning surgical restoration of upper limb function based on which muscles remained with strength of grade 4 or greater according to the familiar Medical Research Council scale, that is a muscle of either full strength or whose strength is reduced but may still move the joint against resistance.⁷⁴ This classification system was adopted and improved at the first International Conference on Tetraplegia in Edinburgh in 1978, the result of which is International Classification for Surgery of the Hand in Tetraplegia (Table 53.4), the Giens revision of which is still in widespread use. The patient receives a separate classification for each arm, and sensory function is recorded together with the sensitivity group as either O (ocular input only), or Cu (intact tactile function, defined as 10 mm or better two-point discrimination at the thumb). This system is useful to provide a quick summary of a patient's residual function in order to help plan surgery. In general, relatively high lesions that result in absent triceps and intact biceps and brachioradialis with one or both of ECRL and ECRB fit into groups 1 to 3. These patients will require reconstruction of elbow extension in addition to forearm reconstruction. Mid-level lesions with intact triceps function with or without pronator teres and FCR occupy groups 3–5, and these groups generally have a good outcome from tendon transfers. Elbow extension is preserved, and the surgeon may proceed directly to forearm reconstruction. Pronator teres function also allows supination/pronation, which is otherwise difficult to restore. The remaining groups (6–9) are only lacking function in the intrinsic muscles of the hand, with or without the long extensors of the fingers and thumb. There are many surgical options for these patients, who may even be treated as for an ulnar nerve palsy.

Preoperative

Preparing the tetraplegic patient for tendon transfers to restore upper limb function should begin as early as possible. Splinting of joints in a useful position to prevent problematic contractures should commence at an early stage. The patient and members of their social support network, including spouse, family and carers, should be educated regarding the operation and rehabilitation. Allied health reviews regarding these topics should be performed, and any appliances required for the postoperative period ordered, including electric wheelchairs. If there are any outstanding medical issues these should be addressed and optimized in the preoperative period. The procedures for a given patient should be individualized according to their residual function and goals. Use of a 'one size fits all' approach to tendon transfers in tetraplegics is a recipe for disaster. As a general rule the less functional upper limb is operated on first.

Box 53.2 Further principles of tendon transfer in tetraplegic patients**Level of injury**

The commonest levels of cervical spinal cord injury are between the C4 and C7 vertebral levels.⁷⁵ In general, injuries above the fifth cervical cord segment are not amenable to surgical restoration of upper limb function by means of tendon transfers due to lack of transferable muscles with useful function. Assessment of residual neurological function forms a crucial part of the workup and is considered in greater detail in *Assessment*, below.

Timing of surgery

Patients must be neurologically stable in order to determine their level of impairment. Furthermore, the postinjury period is fraught for patients managing difficult psychological and social changes, and significant motivation required to achieve a good outcome from tendon transfers. However, the appropriate amount of time to wait post injury before embarking on surgical restoration of upper limb function will differ considerably between patients. As such, firm cut-offs are misleading, and may under- or overestimate the amount of time required for an individual. In general, however, a minimum of 6–12 months is required for the patient to reach neurological stability following injury as prior to this significant gains may still be made with rehabilitation alone.

Multidisciplinary team

High-quality nursing care and input from allied health staff in preparation for surgical reconstruction of upper limb function and during the postoperative phase are crucial for a good outcome. This helps prevent postoperative complications and streamlines rehabilitation and retraining of muscle groups in their new function. As such, the ideal environment for patients undergoing this complex procedure is within an established programme with a multidisciplinary team, comprising reconstructive surgeons experienced in tendon transfers, rehabilitation medicine physicians, hand therapists, physiotherapists and specially trained nurses.

Goals

The goal of surgical restoration of upper limb function in tetraplegia is the improvement in quality of life and enabling independent completion of ADLs. The means by which this is achieved is by restoration of elbow and wrist extension by means of tendon transfers and augmentation of the passive tenodesis effect to enable hand grip by means of tenodeses and arthrodeses.^{74,79}

Elbow extension

Restoration of triceps function allows improvements in bed mobility, transfers and stability, wheelchair skills, operating reach, ability to push off bedclothes, social contact, and enables further tendon transfers for reconstruction of forearm function. There are two established options for donor muscles: posterior deltoid and biceps.

The posterior deltoid to triceps transfer for restoration of elbow extension in the tetraplegic patient is a procedure pioneered by Moberg in the 1970s.⁷⁴ This takes advantage of the mechanically advantageous position of the deltoid muscle and its separate innervation by the axillary nerve (Figure 53.15). Initially tendons harvested from the toe extensors were used to extend the donor muscle to the triceps insertion, but more recently the Y-shaped Dacron graft designed by Jacques Tessier has proven an effective

Table 53.4 International Classification for Surgery of the Hand in Tetraplegia (Giens classification 1984, adapted from Edinburgh classification 1978)

Sensitivity group	Motor characteristics	Description of function
0	No muscle below elbow suitable for transfer	Flexion and supination of elbow
1	Brachioradialis	
2	Extensor carpi radialis longus	Extension of wrist (weak or strong)
3	Extensor carpi radialis brevis	Extension of wrist
4	Pronator teres	Extension of wrist and pronation of forearm
5	Flexor carpi radialis	Flexion of wrist
6	Finger extensors	Extrinsic extension of fingers (partial or complete)
7	Thumb extensors	Extrinsic extension of thumb
8	Partial digital flexors	Extrinsic flexion of fingers (weak)
9	Lacks only intrinsics	Extrinsic flexion of fingers
X	Exceptions

alternative.⁷⁷ The skin incision is made over the midaxial line of the arm, with care taken not to injure the upper lateral cutaneous nerve of arm. In a plane superficial to the deep fascia over deltoid, the muscle is dissected out and the posterior third mobilized. The Tessier graft is secured to posterior deltoid proximally and to the tritendinous triceps insertion distally.

Biceps brachii to triceps transfer has been used to restore elbow extension in tetraplegia since the 1950s.⁷⁸ It is generally less preferred than posterior deltoid transfer due to the greater loss of elbow flexion power, increased difficulty in rehabilitation and retraining, and the risk of radial nerve injury during biceps transfer.^{77,79} However, some research has suggested that biceps transfer allows stronger elbow extension, resulting in antigravity movement in a greater proportion than in posterior deltoid transfers.⁸⁰ It should be noted that an intact and functional brachialis is required for a biceps transfer to be considered as an option. The approach is made through a transverse incision in the cubital fossa. The biceps tendon is released from its insertion into the radial tuberosity, with care taken not to injure the lateral or medial cutaneous nerves of forearm. A second incision is made on the medial side of the arm and the medial intermuscular septum divided to allow the biceps tendon to be passed posteriorly. A further incision is made over the olecranon, through which the biceps tendon is fixed to the tendinous insertion of triceps and the olecranon using sutures with or without a tenodesis screw.

Forearm reconstruction

With intact elbow extension, forearm reconstruction may be attempted. Through a combination of tendon transfers and tenodeses it is possible to achieve wrist extension, finger grasp

(a)

(b)

and lateral key pinch between thumb and index finger. Finger grasp is achieved by augmenting the tenodesis grip associated with wrist extension. The Alphabet procedure was devised by Fridén *et al.* as a combination of procedures consisting of seven individual operations done as a single-stage reconstruction for hand function tetraplegics. It has been shown to be effective in providing hand function in patients with C6 tetraplegia.⁸¹ It comprises a number of procedures which may be performed together or separately (Box 53.3). The split FPL to EPL tenodesis (also known as New Zealand tenodesis⁸²) is designed to stabilize the IP joint of the thumb. Free grafting of the ring finger FDS tendon to the extensor hood by looping it under the EDC tendons results in the fingers assuming an intrinsic plus position. Thumb CMC joint arthrodesis fixes the thumb in a position useful for a lateral key grip. One alternative used by the authors is that of a silicone interpositional spacer (Swanson implant) in the first webspace between the first and second metacarpals (Figure 53.16). Brachioradialis to FPL and ECRL to FDP tendon transfers are to restore thumb and finger flexion

Box 53.3 Alphabet procedure (Advanced Balanced Combined Digital Extensor Flexor Grip reconstruction)

- 1 Split FPL to EPL tenodesis
 - 2 Free tendon graft (FDS 4) to extensor hood digits 2–3 and 4–5

respectively. EPL is rerouted to the dorsal forearm fascia to passively extend the thumb during wrist flexion, and finally ECU is shortened and attached to the ulnar head to stabilize the wrist.

Postoperative care

Patients who have undergone tendon transfer procedures, particularly those who are tetraplegic or immobilized, require high-quality postoperative care to prevent complications, and allow commencement of rehabilitation and retraining. In the absence of significant contraindications it is important for all these patients to be on prophylactic anticoagulation due to the high risk of venous thromboembolism in the postoperative period. Traditional teaching dictates that a 3–4 week period of static immobilization must follow any tendon transfer procedure, to allow tendon healing and reduce risk of early rupture.^{21,41,79} However, in recognition that early active mobilization has become widespread practice following tendon repair procedures,^{83–86} there is mounting evidence that such rehabilitation protocols may improve outcomes following tendon transfer procedures as well,^{87,88} an approach particularly advocated by Brandsma.⁸⁹ Such protocols may reduce oedema and development of adhesions, and allow earlier commencement of rehabilitation and retraining.⁸¹

According to a systematic review performed by Sultana *et al.*, benefits of such protocols include reduced cost of rehabilitation, improved function in the short term, similar long-term outcomes, and no increase in risk of complications such as tendon pull-out.⁸⁸ It is important to emphasize that careful patient selection is essential when deciding on a rehabilitation programme. For success with early active mobilization patients must be particularly motivated, compliant and able to follow complex instructions from hand therapists. In both early or delayed mobilization protocols, mobilization should be introduced in a gradual fashion by hand therapists experienced in managing patients following tendon transfer or repair procedures, followed by progressive strengthening exercises and finally, full activity.^{41,90} Devices such as electrical stimulators and biofeedback may be used for muscle reeducation, though studies of their effectiveness have been disappointing.^{91,92}

The senior author's preference is to reserve early active mobilization for selected patients. Otherwise, the protocol requires immobilization for two weeks followed by passive range of motion exercises, and then a gradual return to normal activity after 6–8 weeks. Following restoration of elbow extension with either deltoid to triceps or biceps to triceps transfer it is our routine to immobilize the elbow in a Bedsloe caliper splint for 12 weeks. Initially the caliper should be set to allow a range of motion of 0 to 15°, to be gradually increased each fortnight if the previous increase is tolerated.

Conclusion

Tendon transfers have been used since the late nineteenth century to restore function for patients with irreversible neurological or musculoskeletal injury. Recently, with the development of microsurgical techniques and improvement in our understanding of neuroanatomy, nerve repair and transfer and innervated free muscle transfer have become the usual treatments of choice for many of these problems. However, there remains a role for tendon transfer, either for early function during nerve recovery, or for those whose pathology are not amenable to nerve repair or transfer. This chapter should equip the surgeon with the essential knowledge of tendon transfer: the principles, approach and techniques required to perform these procedures.

CHAPTER 54

Amputations, replantation and thumb reconstruction

Gráinne Bourke

Department of Plastic and Reconstructive Surgery, Leeds Teaching Hospitals, Leeds, UK

Complete and partial digit loss in the hand has serious sequelae: physically, psychologically and financially. Surgical intervention is not always indicated. However, when used appropriately, replantation and reconstruction can make a real difference to long-term function. The key is matching the reconstruction to the patient and choosing the right time.

Although surgical and rehabilitation techniques have evolved, there are still aspects of repair and reconstruction that we need to improve. For example, we still have limited outcomes in sensory recovery after nerve repair. In complex digit reconstruction and replantation we use autologous donor sites, leaving defects and scars.

Occupational injury accounts for a significant number of amputations, including agricultural and industrial accidents.¹⁻³ These are complex crush and avulsion injuries, and digit salvage and achieving functional outcomes can be challenging, even to the most skilled and experienced hand surgeon.⁴

Aetiologies

Digit loss can result from either systemic or local factors. Systemic illness such as diabetes, vasculitis and arterial insufficiency all present extremely challenging clinical scenarios. These cases should be managed in a multidisciplinary setting and systemic therapies such as prostacyclin, steroids and immunosuppressants will play a significant role in achieving successful outcomes.

In the treatment of malignant disease of the soft tissue or bone wide local excision or amputation may be the only option for local tumour control. This may need to be followed by adjuvant chemotherapy or radiotherapy and again multidisciplinary management is obligatory. Planning and timing of reconstruction is critical. It can be useful to confirm clear tumour margins before embarking on complex reconstruction.

The commonest cause of digit loss at any level is trauma. Avulsion, crush and thermal injuries are the more difficult to treat, largely as the zone and extent of injury are often underestimated at the time of presentation.

Clinical history and assessment

The potential options for replantation or reconstruction following amputation are based on assessment of the patient and the amputated part.

The patient's age, occupation and pastimes along with their previous medical history will aid the decision-making process. It is important to consider the psychological implications of injury and reconstruction. The patient's future plans and how they perceive themselves and the injury will all affect the outcome.

In assessing the amputated part again there are three elements to consider: the condition of the part, the functional importance of the part and the ischaemic time if the injury is proximal.

Management principles and amputation options

Non-operative management

Success in elective amputation or terminalization of an amputated digit is reliant on achieving a pain-free, padded, sensate, mobile finger tip. If the residual finger end is neither padded nor sensate then it is unlikely that it will be involved in useful function. In cases of ischaemic loss in diabetics this can be a real challenge as the remaining soft tissues are poorly vascularized, often insensate and the risk of infection is higher. Here it is best to ensure all necrotic tissue, including bone, is excised and to leave the finger end to close by secondary intention. This will take considerable time but long term the results are good.

Distal finger tip injuries in healthy patients, where the distal phalanx remains covered with soft tissue, can be managed non-operatively. This results in a sensate tip with reasonable padding and there is no other donor site. Treatment in this fashion can take several weeks and the patient needs to be informed so they can adjust their lifestyle accordingly.

Operative principles

In distal finger tip injuries where the injury, the patient or the surgical expertise preclude replantation then homodigital, cross fingers flaps and terminalization of the finger tip are all viable options.

It is important to remember that terminalization will almost always result in further shortening of the skeleton to achieve soft tissue cover. The digital nerves should always be isolated and trimmed so that they are lying in a well-padded proximal location and are not likely to cause painful neuromata over time. In distal injuries the residual nail bed should be excised to avoid a hook nail deformity. The flexor and extensor insertions should be preserved where possible.

In more proximal loss at the level of either the proximal or distal interphalangeal joints, the condyles should be shaved to improve the appearance, the tendons on the extensor and flexor surface should be allowed to retract so as to avoid a quadregi effect and sufficient volar skin is left to cover the finger end.

Ray amputation is often reserved for the index finger and second metacarpal ray. It is rarely performed as a primary amputation unless for soft tissue tumour excision. As it is often performed to improve cosmesis following proximal digit loss then a volar approach is superior to avoid a visible scar. It also provides better visualization of neurovascular structures. In the central rays transposition of the adjacent ray to close gapping between fingers and avoid grip incontinence is a reasonable option. Balancing the loss of grip strength and the improvement in cosmetic appearance are the key factors in deciding whether to transpose an adjacent ray. If grip strength is important then transposition should be avoided.^{5,6} Careful dissection of digital neurovascular structures is important to avoid hypersensitivity and neuroma formation in the palm of the hand.

Replantation

Indications

The traditional indications for digit replantation include multiple digits, thumb, single digit loss distal to the flexor digitorum superficialis (FDS) insertion and all amputations in children. However, with the advent of improved microsurgical techniques and better outcomes of survival and function, other indications that previously we would have deemed unlikely to yield long-term success are now only relative contraindications.^{7,8}

We know now that digital replantation is possible up to 24h after the injury,⁹ in children under 1 year¹⁰ and after other organ transplantation.¹¹ We can also store amputated digits temporarily elsewhere on the body (contralateral forearm, groin, axilla) while the zone of more proximal damage is reconstructed and made suitable for replantation.^{12–14}

It is also possible to get good functional recovery from isolated index finger amputations proximal to the FDS insertion. Buntic *et al.* have demonstrated total active motion of 170° in zone 1 injuries and 133° of total active motion in zone 2 injuries.¹⁵

However, it is also worth remembering that a poorly sensate, stiff index finger will be bypassed for functional purposes.

Assessment and preoperative preparations

The initial clinical assessment of parts and patient should include analysis of the type of injury – crush, avulsion, thermal injury, guillotine and compression. In transportation of parts they should be kept moist and cool. It is imperative that the amputated part is not frozen or directly in contact with water or ice. Preoperative photographs and X-rays are always worthwhile to document the soft tissue and bony injury level.

Operative principles

Preparation of patient and part can occur simultaneously. The time spent discussing operative planning with the anaesthetic and theatre teams is invaluable. Communication about types of fixation, timing, operative sequencing is essential for ensuring optimal surgical time management. This is very important, in particular where ischaemic time is already extensive and critical, such as macro limb or multiple digit replantation.

A hyperdynamic circulation with peripheral vasodilatation is desirable during the operative procedure. This can be combined with close monitoring of core and peripheral temperatures and aiming for a difference of less than 1° while ensuring the patient is warm and comfortable. Local anaesthetic regional blockade will also help with ensuring a pain-free setting for the patient both during and after surgery and can be substituted for general anaesthesia in situations where the patient is not suitable.¹⁶

During the induction of anaesthesia the amputated parts can be assessed, prepared and marked. In general the injury will dictate the access incisions but where there is choice Brunner incisions yield good access on volar surfaces and are amenable to cover vessels and nerves after revascularization and the ensuing swelling.⁸ It is worth marking vessels and nerves; even though they may appear obvious now, they may not be later once osteosynthesis is completed, and it is frustrating and time wasting to relocate structures a second time. It can be difficult to identify veins dorsally but either they can be marked at the time of initial assessment, if easily seen, or you can wait until the arterial repair is flowing and see where they are located then. The former is easier for repair as the tourniquet is still inflated and visibility is far superior.

Operative sequencing is important but we think the most important part is that the operator is at ease with the routine chosen, whether it is the work from volar to dorsal or in more traditional method of achieving bone fixation first followed by tendon repair. It can be advantageous to repair the flexor tendons first prior to bony fixation as this gives very clear visibility of the flexors for repair and aids in stabilizing the parts so that bony fixation is easier too, but clearly if the option of a volar fixation plate is used then this is not compatible.

In replantation of digits, including the thumb, achieving osteosynthesis and repairing tendons prior to microvascular or nerve repairs is important as otherwise there is a risk

of disruption of your microscopic-assisted repairs and/or problems with vessel length.

In choosing the method of fixation, the level of the injury, bone comminution, distance from joint surfaces and soft tissue access will dictate the possibilities.⁸ Internal fixation can be a very successful option as you already have good visualization of proximal and distal components and so greater anatomical precision is possible. Also early postoperative mobilization and rehabilitation will be possible with greater potential for long-term functional success.

Skeletal shortening is beneficial, in particular if there is comminution of parts. It aids in achieving direct repair of neurovascular and tendinous structures. It will also aid the soft tissue cover, which often is not fully considered until the end of the case and closure over vessel or nerves can be problematic. Bone shortening will save time and improve long-term functional outcomes, in particular for macro or multiple replantations where nerve repairs are mixed and more distant from motor and sensory end organs.

It is easier and quicker to achieve plate fixation/retrograde Kirschner wiring to the mobile amputated part first once the level of bone synthesis is decided. A plate can be placed dorsal or volar depending on the level of injury and the bone cortices available.

Standard tendon repair techniques using epitendinous and multistrand core sutures are well documented and these should be employed to achieve the optimal tendon repair.^{17–21}

Correct evaluation of level and extent of arterial vessel injury in the hand and amputated part is crucial. In avulsion injuries the level of intimal damage exceeds far beyond the level of tendon and bone injury. In order for the revascularization to work successfully, inflow perfusion pressure is very critical. It is worth assessing and ensuring good inflow before proceeding to vessel repair. It is easier to decide to vein graft at this early stage than have a tight repair or no inflow and have to repeat and revise anastomoses later. If there is any doubt or concern about the inflow it is always worth checking with the anaesthetist that the patient is haemodynamically stable, warm and well perfused, so that you can then focus on more specific local factors to ensure adequate inflow.

Sensory outcomes are critical in ensuring long-term functional use so nerve coaptation should be performed with good visualization of nerve ends and ensuring proximal and distal nerve ends are of good quality.²² This can be achieved with ease after arterial anastomoses and while the tourniquet is still inflated.

The alignment for venous repair is dictated by the bone fixation and if anatomical alignment has been achieved then co-located proximal and distal vein ends will be visible.⁸ Venous drainage can be achieved through direct repair, vein grafting or vein transfer from an adjacent digit.^{23,24} The latter is a very worthwhile option, excluding the need for vein grafting and ensuring the recipient vein is out of the zone of injury as it is from an adjacent unaffected digit.

Having achieved success in the osteosyntheses, tendon repairs and revascularization it can be distressing to find that there is inadequate skin cover at the end of the procedure, so time spent planning skin incisions and flaps early on is invaluable. Skin closure should be loose and sutures infrequent to allow for tissue swelling and any blood that will seep from wound edges in the early postoperative time.

Ring avulsions

Ring avulsions have been classified by Urbaniak and subsequently Kay and Adani. These classification systems are based on the severity of vascular, bone and joint injury, correlating these with the predicted functional outcome.^{23,25–28} In the Kay classification system, which is probably the most widely used today, type I describes an injury where the digit vascularity is adequate with or without a bony injury. In type II and III injuries the digit vascularity is compromised and in the latter there is also a bony injury. The presence of a bony injury and vascular compromise, either arterial or venous, predicts a more sinister outcome for the digit, with a higher risk of early or late failure. The poorest prognosis is for those classified as type III injuries where a bony injury is combined with both arterial and venous insufficiency.²⁵ Most recently, Chung and Sears concluded that outcomes from ring avulsion of fingers (78%) was comparable to that for replants in general (80%). This was a systemic review article and they have recommended replanting complete finger avulsions where the proximal interphalangeal joint and the FDS tendon are preserved.²⁹

Distal digital replantation

Distal digital replantation has regained popularity over the last two decades. In the early era of microsurgery, distal replantation was deemed to be more technically demanding. This, combined with doubts about functional outcomes and increased costs, led to a drift away from very distal replants. However, there are several published series of outcomes from distal replantation showing good functional outcomes and a high success rate in specialized centres.^{30–32}

Finger tip injuries and amputation levels have been classified by Allen, Foucher and Tamai.^{7,33,34} In distal replantation, Sebastian and Chung have proposed a new system based on the difficulty of the microvascular and neural repairs. We have found this paper to be both practical and very useful in balancing and explaining the potential for success/failure in the various amputation groups³⁰ (Figure 54.1).

Success rates for replantation of distal finger tips rely on the experience and microsurgical expertise of the operator. Although the vessel diameters of both the distal arteries, and in particular distal veins, are very small it is still possible to achieve and maintain patency of vessel anastomoses.

Assessment of the amputated part is essential to decide if there are suitable patent vessels with the potential for revascularization. It is the paucity and size of available veins for drainage that is the limiting factor for successful outcome and survival.^{32,35}

Zone 1 Amputations (distal to FDS insertion)	Zone 1 Distal amputations (finger tip amputations) (distal to FDP insertion, at the root of nail bed)	Zone 1A (distal to lunula through sterile matrix)			Artery: Very difficult Vein: ≈Impossible Nerve: ≈Impossible
		Zone 1B (between lunula and root of nail bed, through germinal matrix)			Artery: Difficult Vein: Very difficult Nerve: Very difficult
		Zone 1C (between FDP insertion and neck of middle phalanx, periarticular)			Artery: Easy Vein: Difficult Nerve: Easy
	Zone 1 Proximal amputations (between FDP and FDS insertions)	Zone 1D (between neck of middle phalanx and FDS insertion)			Artery: Easy Vein: Easy Nerve: Easy

The fingertip is defined as the portion of the finger distal to the flexor and extensor tendon insertions

Thumb amputations are classified using the same descriptors. Zone 1 thumb amputation refers to amputations distal to the mid-proximal phalanx of the thumb (distal to first web)

Figure 54.1 Sebastin and Chung classification system for distal digital amputations, outlining the difficulties in microsurgical vessel and nerve repairs at each level. The finger tip is defined as the portion of the finger distal to the flexor and extensor tendon insertions. Thumb amputations are classified using the same descriptors. Zone 1 thumb amputation refers to amputations distal to mid-proximal phalanx of the thumb (distal to first web). FDP, flexor digitorum profundus; FDS, flexor digitorum superficialis. Source: Sebastin & Chung, 2011.³⁰ Reproduced with permission of Lippincott Williams & Wilkins.

The operative method is similar to more proximal replantation procedures. It is important to tag the vessels, and nerves if available, to aid ease and speed for future repair. The distal phalanx can be secured with a small Kirschner wire where appropriate. It is worthwhile repairing the nail bed early in zone 1 and 2 amputations as this aids in stabilizing the finger tip while performing the vascular anastomoses. The location of nerves and vessels varies slightly, depending on the amputation level (Figure 54.1). In zone 1 and 2 injuries it is not always possible to locate a dorsal or even a volar vein in the amputated part until after the artery is flowing. Even if veins are visible, the anastomoses are challenging due to vessel size and visibility. However, success rates are higher when venous drainage has been achieved.³⁰ Alternative method for temporary venous drainage, such as external bleeding or venocutaneous fistulas, can be used successfully but these need to be explained to the patient along with the risk of transfusion.³⁶ Clearly there is a definite risk–benefit ratio that needs to be discussed and agreed with the patient in relation to achieving successful finger tip replantation versus terminalization of the affected finger^{30,32} (Figure 54.2).

The benefits of distal replantation include preservation of finger length, better range of motion of the distal interphalangeal joint and less risk of finger tip hypersensitivity. These have to be offset against a longer hospital stay and operative time with ensuing greater costs. There are cultural and social factors

which influence the expectations and aspirations of this group of patients which are clear in the published literature. The majority of distal finger replantations are undertaken in Asia.^{30,37}

As the incidences of more proximal and multiple digit amputation are declining secondary to health and safety education and awareness it may be these cases of very distal replantation will need to be performed in specialized microsurgery centres.³¹

Postoperative care

After surgery, a splint is applied. In the early postoperative time this does not need to be rigid but needs to protect the replanted digit(s) from injury and also to promote a comfortable position for the patient and limb. It is important to ensure that any dressing is not constrictive or tight circumferentially and that the dressing used will not dry out into tight constricting bands over time. Patients should be cared for in warmed environment with expert nurses. Maintaining a good perfusion pressure, along with adequate analgesia, is critical to outcome success as with all microvascular procedures.

Regular monitoring of any revascularized parts is essential but it is also important to try to maintain a stress-free environment, especially in children where the risk of vasospasm is higher. Thus haemodynamic monitoring should be minimal in children unless there is a clinical reason to justify provoking a stressed or agitated young child.

Figure 54.2 (a) Amputated distal tip of middle finger. (b) Proximal finger with amputated tip. (c) Finger X-ray demonstrating amputation level. (d) X-Ray of amputate. (e, f) Replanted finger at two weeks.

If there is any suggestion of arterial or venous compromise then immediate re-exploration should be performed. It is better to release sutures, and check vascular status early if there is doubt, as the longer the interval between low/no flow in the vessels and re-exploration the less likely that salvage will be possible.

Complications

The complications of digit replantation can be classified in a timeline of occurrence.

Failure to achieve or maintain flow is particularly disheartening, but can usually be avoided by careful patient and part selection. This is usually due to a combination of factors, including the type of injury, for example a crush injury that has not been clarified or appreciated in the preoperative assessment. There can be errors in transportation of the amputated part, which on occasion is left in direct contact with ice and is frozen, causing cellular damage that is irreversible.

If there is failure of the arterial flow then it is always worthwhile returning to Virchow's triad and assessing the blood flow, vessel wall and the circulating blood.

The blood flow can be compromised locally from tight dressings or skin flaps that have become restrictive following local swelling, or it may be compromised systemically if there is a poor circulating volume or the perfusion pressure is low.

There may be residual vessel damage from the injury which necessitates a vein graft for reconstruction of the vessel wall. There may be procoagulant factors in the circulating blood related to smoking, inflammation or systemic disease. Each should be addressed in a systematic and timely fashion.

Compromise of venous drainage can present in two ways: early, with excessive bleeding or later, with blue discoloration and swelling of the digit. Assessment is similar to that for arterial occlusion and on occasion simply releasing dressing and sutures will allow return of flow if the constriction is realized in a timely fashion. Late venous compromise is often related to infection and the chance of regaining flow is low. It is important to pick up problems with venous outflow early, as once it is prolonged the arterial flow will cease as well.

Infection is really only a problem if it interferes with vessel flow and usually presents as this, but other soft tissue or bony infection does not present that often.⁸

Cold intolerance can cause significant disability postoperatively, but is related to the injury process rather than replantation.³⁸

Complications of bony union and position can ultimately cause concern long term, in particular when combined with stiffness or tendon adhesions. So it is always worth taking the time to achieve good bone apposition and correct alignment at the time of replantation rather than have to address problems at a later stage.

Outcomes

In children, survival following replantation is lower than in adults. This is usually attributed to the mechanism of injury in children being more likely to be a crush/avulsion injury.^{8,39} Saies

et al. demonstrated an overall survival for digital replantation in children of 63%. The salvage rate was 72% when there was laceration, versus 53% when there was crush or avulsion injury.⁴⁰

In adults, the outcomes in patients with diabetes and smokers are statistically worse.⁴¹ Rates of survival of replanted finger in adults range from 60% to 94%,^{42,43} again depending on systemic factors and the type of amputation mechanism.

The recovery of useful digit (54%) and thumb (61%) sensation was analysed by Glickman and MacKinnon in 1990. The mechanism of injury, age of the patient, cold intolerance, digital blood flow and sensory re-education all influenced the recovery level.²²

The rate of secondary surgery is high, with published rates of up to 93% in proximal replants.⁴⁴ Tenolysis, skin grafting, bone grafting, joint fusion and osteotomy are all common in injuries proximal to the FDS insertion and in more severe degloving injuries.^{42,45}

Thumb

Anatomy and biomechanics of movement

The thumb has two phalanges and one short metacarpal articulating with the trapezium. It is this latter articulation that makes the thumb unique and sets it apart functionally from the other digits of the hand. The carpometacarpal joint is both concave and convex on each articular surface, a saddle joint. On an anteroposterior X-ray view the trapezium is concave and the metacarpal base is convex but in the lateral view the opposite is true. It is this unique geometry of the basal joint that allows multiplanar motion, and in particular opposition.⁴⁶

There are four extrinsic tendons to the thumb – one flexor, two extensors and one abductor – and four intrinsic muscles – abductor, adductor, flexor and opponens pollicis. Each functional movement of the thumb is achieved through a complex sequence of contracting and relaxing of these musculotendinous units. It is this fine balance of flexibility and stability which makes our thumb useful.

The sensitivity of the thumb tip enables fine touch and precision pressure grips. The radial and median nerve supply the thumb on the volar and dorsal surfaces with two central volar digital nerves and multiple small dorsal nerves supplying the thumb and webspace.

The thumb is supplied by an arcade of arteries on the flexor and extensor surfaces.^{47–49} The princeps pollicis is often the named dominant blood supply and supplies the radial and ulnar digital vessel in 73% of cases.⁴⁸ Ames *et al.* demonstrated a superficial and deep vessel to the first webspace in 54% of 40 hands dissected.⁴⁷ Parks *et al.* demonstrated a single end artery to the thumb in 75% of 50 cadavers they studied, correlating with the risk of ischaemia from injection, thrombosis and injury.⁴⁹

There are both dorsal and volar venous networks of the thumb. The dorsal system commences with a venous arcade at

the level of the nail bed. The venous diameter gradually increases where the veins converge and travel proximally to drain into the metacarpal arcade and eventually the cephalic vein.⁵⁰

Thumb reconstruction

Thumb replantation and reconstruction has evolved over the last 30 years and we are now more demanding of the outcomes of reconstruction functionally and cosmetically. This is largely related to improved microsurgical techniques and facilities and more refined rehabilitation programmes. Through the new access to internet and social media, patients are also more aware of outcomes and we are better at sharing ideas and competing for the best outcomes.

However, there are limits to our success, including incomplete nerve regeneration and recovery, a donor site defect due to use of autologous reconstruction and limited resources for the psychological aspects of loss and reconstruction.

The frequency and method of thumb amputation has also changed over time, with health and safety at work and changes in population education and awareness.

Clinical history and assessment

The aetiology of thumb loss and information about associated medical conditions are important in deciding the reconstruction options available for each case. The type of injury (i.e. avulsion, guillotine, crush) defines the level of bone and soft tissue injury, including the possibility of extension of the vascular injury, in particular in cases of avulsion.

The survival of thumb replantations are poorer in smokers and this should be considered when discussing outcomes preoperatively.^{51,52}

During examination, an assessment of remaining soft tissue cover, defects in sensation and associated joint stiffness or injury should be considered.

Management principles and options

Acute management of thumb injury and loss is similar to that for other digits. As the functional implications of thumb loss are so great, preservation of length, mobility and sensibility is critical.

Methods for thumb reconstruction have been classified into three groups – distal third, middle third and proximal third. An extensive description of this classification system and proposed reconstructive methods was published by Muzaffer *et al.* in 2005.⁵³

Loss through the distal third of the thumb

Injuries that are distal to the interphalangeal joint of the thumb are classified as distal third injuries. Although there may be some loss to the thumb length with these injuries, the effect on functional use is not significant.⁵⁴ However, ensuring adequate soft tissue cover and sensation is critical to outcome. As with any pulp injury, if the area is small and suitable for non-operative treatment then this is optimal. Sensation is then preserved, there is no donor site and in general mobility is also maintained.

Operative options

In defects where there is exposed distal phalanx or there is significant pulp loss, then adjacent flaps can be considered. These include homodigital flaps, such as Moberg's homodigital advancement flap, which enables closure of volar soft tissue defects. This is a bipedicle volar flap incorporating the digital nerves and arteries with overlying skin. In cases where this is causing significant flexion at the interphalangeal joint then a proximal releasing incision on to the base of the thumb will give better advancement. It is important, as with all islanded volar flaps, not to dissect the arterial pedicle too extensively to avoid damage to the arteries or accompanying draining venae comitantes.

Adjacent digits can also be used for soft tissue cover. In order to avoid the possibility of a webspace contracture, cross-finger flaps from the index finger are generally avoided. Foucher designed an islanded flap based on the first dorsal metacarpal artery. This is a reliable flap with a skin paddle over the extensor surface of the proximal phalanx of the index finger. The pedicle is located over the first dorsal interosseous and it can be raised as a sensate flap.

As with all islanded digital flaps, the pedicle must not be dissected extensively as this will disrupt the venous drainage. The arc of transposition is at the base of the webspace and the flap can be tunnelled subcutaneously to reach the thumb tip. This is an excellent local flap for covering the tip of the thumb, preserving length and providing adequate soft tissue cover where patient or surrounding s preclude any more advanced techniques.

We have used this for a polytrauma case where the patient had an extensive list of other significant injuries, including an intracranial bleed, spinal and pelvic fractures and the thumb tip arrived to the hospital frozen. It is worth noting that in cases such as this, visual dissection of the pedicle is not possible as there is extensive subcutaneous haematoma and swelling. However, it allows immediate and efficient closure of the thumb without shortening. The full-thickness graft to the dorsum of the index finger heals remarkably well. This leaves all options for further reconstruction available for the future once the patient has recovered mentally and physically (Figure 54.3).

There are other less commonly used flaps, such as islanded pulp flap from the ulnar border of the middle finger or free toe pulp from the great toe, both of which are reliable and are worth considering where local options are limited.

Loss through the middle and proximal thirds of the thumb – toe transfers

The vascularized transfer of a toe for thumb reconstruction is a well-established technique. In 1966 Buncke described his experience with hallux to hand transplant in a Rhesus monkey.⁵⁵ Subsequently, Cobbett went on to report a case of transfer of the great toe to replace an amputated thumb.⁵⁶ The suitability of either a big toe, a modification of this transfer, or a second toe for reconstruction is dependent on the operating surgeon, the

Figure 54.3 (a) Multiple trauma case with thumb amputation (see text for details). (b) Postoperative X-ray demonstrating preservation of bony length. (c) Four weeks postoperative Foucher flap to preserve length and provide soft tissue cover.

injury and the patient. There are pros and cons to each in relation to the appearance of the reconstruction and the donor site.

The principles of toe transfer harvest are similar to those for other microvascular flap harvest. A knowledge of the arterial and venous anatomy of the foot, in particular of the first web is critical.^{57,58} The timing of reconstruction is usually delayed in order to ensure psychological and physical preparation, but immediate reconstruction has been reported without increased morbidity.^{59,60} The advantages of immediate reconstruction are apparent in that digit reconstruction is immediate, including the nerve regeneration and mobility. However, as these are highly specialized transfers, the chance for revision and reconstruction if there is microvascular failure is slim. In cases where there are other associated injuries, immediate reconstruction is precluded.⁶¹

In planning a thumb reconstruction using a toe transfer there are several elements to consider. These include the level of bony injury, the quality of the remaining bone and joints, the motor units remaining for flexion and extension and the potential for regaining useful sensation.

It is not advisable to transfer the metatarsophalangeal joint of the great toe as this is important both functionally and aesthetically for the foot. The metatarsophalangeal joint of the second toe rests in extension and the arc of motion of this joint lies in extension rather than flexion. Thus where there is very proximal thumb loss, pollicization of the index finger should be considered even if it too is injured.⁶²⁻⁶⁴

As with all free tissue transfers there are global factors that are key. These include ensuring microsurgical skill of the operating team and an anaesthetist familiar with the principles of microvascular transfers. The general operative principles are similar to those outlined for replantation but the advantage in late reconstruction is that the whole team and patient have more time to prepare. The key elements acutely relate to maintaining flow and avoiding vasoconstriction once the toe has been transplanted. Long-term functional outcomes will reflect tendon and nerve recovery and use.

The procedure can be performed by one or two teams depending on what is the tradition in your unit. We have traditionally had a single team with a lead surgeon and the benefits of this are that the knowledge of vessels and soft tissue dissection does not need to be transferred. We have found this to be an efficient and safe method for microvascular transfers and the operative times are comparable to a two-team approach.⁶⁵

In preparing the hand, the level of future osteosynthesis is central and all other soft tissue structures can be measured from this site. Adequate exposure of the digital nerves, blood vessels and tendons for repair is essential. It is worth remembering that sufficient access and visibility is needed for repair of longitudinal structures, and time spent dissecting and preparing at this initial phase is always worthwhile. Once the toe has been transferred, the ischaemic clock is ticking and the transfer itself can obscure the proposed site of repair of tendons and nerves in particular.

The choice of exposure for tendons and nerves will depend on the previous injury and it is unusual to have to excise any skin, unless it is scarred and restrictive. The choice of vessels for inflow and outflow will vary, but where possible remaining out of the zone of injury is optimal as here you avoid scars and vessel dissection is quicker and easier. In thumb reconstruction there are several options but the radial artery and cephalic vein at the anatomical snuffbox are almost always available, and the vessel size is ideal for revascularization of a toe transfer.

There are several excellent articles on toe-to-hand transfers which detail techniques for flap dissection.⁶⁵⁻⁷¹ In harvesting a second toe it is usual to harvest an extension of skin overlying the metatarsophalangeal joint onto the dorsum of the foot and leave the plantar surface free from scar. There are various methods of flap dissection but probably the most common nowadays is early retrograde dissection of the vascular pedicle.^{65,71}

This means identifying the dorsal veins first and then proceeding to the first webspace and identifying a suitable arterial system linked with the tibial vessel of the second toe. In about 80% of cases a reliable dorsal system is present and the artery can be dissected proximally to join the dorsalis pedis with relative ease after dividing the intermetacarpal ligament.^{57,58} In the other 20% of cases the plantar system is dominant and retrograde dissection of the arterial pedicle is more time consuming as the vessel courses beneath the interosseous muscle to the great toe, with various muscular branches that need to be ligated or coagulated.

Once the arterial and venous pedicles have been identified and dissected then the extensor tendons, dorsal nerves, plantar digital nerves and flexor tendons can be dissected methodically. Finally, the soft tissues are freed from the metatarsal along the level of the metatarsophalangeal joint from the fibular side first, while visualizing the flap pedicle so as to avoid damage to important structures.

At this stage the tourniquet can be deflated and the flap pedicle can be checked. On occasion it may take a few minutes for the toe to regain the pink blush of well-vascularized tissue and it is worth covering it with a warm damp swab and taking a break rather than increasing the risk of further vasospasm by interfering with the pedicle.

Prior to dividing the vascular pedicle it is worth rechecking the measurements of the longitudinal structures from the point of bony fixation.

After removing the toe from the foot, attention is then focused on preparation of the toe for bony fixation and tendon repair. The most common sites for bony fixation are at the base of the proximal or middle phalanges of the second toe or, in a great toe, transfer through the proximal phalanx or at the base of the distal phalanx. This is because the metatarsophalangeal joint of the great toe is functional and every effort should be made to preserve it where possible. In cases of second toe transfer it is actually better aesthetically to remove the whole ray and leave the patient with a linear scar between the great and third toes.

The type of fixation used can vary, depending on the access, level of bone visible and the technical skill and preference of the operator. In adults, where possible internal plate fixation is preferable and assists in postoperative early mobilization. However this is not always an option and simple fixation with longitudinal Kirschner wires is adequate. The wire or plate can be fixed to the transfer first after the cartilage has been removed from the joint surface. It is important to remember not to damage the growth plate in children.

In acute reconstruction after tumour resection the flexor pollicis longus tendon can be repaired distally and this is easily achieved before the bone is fixed as visibility of the tendon ends is excellent.

Attention can then be turned to the extensor tendon and flexor tendon if not already repaired. The dominant extensor tendon for the distal joint of the second toe in particular can vary, as this can be assessed easily prior to tendon repair. Finally, all microvascular structures are repaired while the tourniquet is inflated. It is worth repairing the nerves at this stage as visibility and access are optimal. In long-term outcome, recovery of sensation is critical to enable functional use (Figure 54.4).

Once all structures have been repaired, the tourniquet can be deflated, the vascular clamps are removed and vessel flow can be assessed. A topical vasodilator is often applied across the anastomotic site at this stage; the hand is covered with a warm damp swab and left to perfuse.

The foot closure after second toe harvest requires removal of the metatarsal and repair of the intermetatarsal ligament, followed by direct skin closure. This yields an acceptable donor site.

Closure of the foot after harvest of the great toe can be more problematic, as local flaps and skin grafts are required to maintain length. The donor site is cosmetically poor. Hence the use of modified great toe transfers, which yield much more acceptable donor sites.

Figure 54.4 Free toe transfer for thumb reconstruction in a child after traumatic loss.

Modifications of great toe transfer

The free neurotized wraparound flap from the big toe was described by Morrison *et al.* in 1980.⁷² This incorporates part of the distal phalanx of the great toe with the nail bed, neurovascular pedicle and soft tissue cover, so that the donor site of the great toe is much improved and preserved. The thumb is reconstructed either by this alone or with an interim iliac crest bone graft to increase the length of the construct. The transferred toe is narrower and more 'thumb like' than the traditional great toe transfer, but still has the aesthetic and functional elements to provide a valuable and useful thumb reconstruction. Further modifications of this method using pre-operative distraction lengthening, extended length and combined with a second toe proximal interphalangeal joint have all been described.^{73–75}

Distraction lengthening

Continual distraction lengthening of the thumb was first described by Matev in 1973.^{76,77} This is a useful technique for lengthening the thumb metacarpal and preserves the inherent sensation of the thumb soft tissue envelope. This is a very reliable technique and the bony defect can be left to ossify spontaneously or it can be bone grafted to achieve bony union and stability.^{78,79} The length of bone distracted can be up to 3 cm while still maintaining adequate soft tissue cover and sensation.⁷⁹ This technique can also be used in conjunction with vascular toe transfers to improve the donor defect of the foot.⁷⁵

However it is worth remembering that the distracted thumb is stiff and this, combined with often inadequate soft tissue cover, means that the reconstruction may not be as useful as expected. However, distraction definitely has a role in thumb and digit reconstruction and is a valuable skill for the reconstructive surgeon. A simple linear distractor is adequate for thumb lengthening as rotation is not usually a problem.

Pollicization

In proximal loss of the thumb, apart from microvascular toe transfers the only other current option for reconstruction is pollicization of another digit on the hand. In 1984 Michon *et al.* compared the functional and cosmetic results for reconstruction of the traumatically lost thumb using toe transfers and pollicization of the index finger. They concluded that toe transfers offer better overall functional outcomes where available, but in isolated proximal thumb loss pollicization can yield very functional and cosmetically acceptable results.⁶³

Pollicization of the index finger was first described by Gosset in 1949.⁸⁰ Since then, modification of surgical technique, indications and outcomes have all been published extensively.^{53,80–84} In proximal thumb loss, pollicization offers the ability to recreate a sensate stable thumb of adequate length to oppose to the other remaining digits of the hand. The index finger is most commonly transposed and injury to this digit does not preclude transposition. Injured index fingers can be transferred in isolation or in combination with a great toe wraparound flap.^{64,85}

The principles for recreating a functional thumb are similar for traumatic and congenital absence but in traumatic loss there is more flexibility in recreating intrinsic and extrinsic motion. The proposed digit for pollicization should offer the potential for recreating a thumb of adequate length, alignment, stability, sensibility and mobility that would render it functional and cosmetically acceptable.^{80,84,86–90}

This procedure involves careful planning of skin flaps to recreate a webspace and provide cover for the new thumb. The dorsal veins and nerves are dissected and preserved where possible to ensure adequate venous drainage and preservation of sensation. The extensors to the digit are then identified and can be used for recreation of extension and abduction of the thumb where appropriate. The distal extensor expansion can be divided longitudinally to recreate distal attachments for the intrinsic thumb abductor and adductor, where preserved, as well as a central element to recreate long extensor.

In order for the digit to move untethered to the position of the thumb, the vascular arterial pedicle must be dissected sufficiently proximally and the radial digital artery of the middle finger will need to be divided from the common artery. In the trauma setting, adequate arterial supply to this adjacent digit should be confirmed before dividing its radial digital artery. The digital nerves must be dissected to allow adequate transposition and movement and this requires the intraneural dissection of the common digital nerve between the index and middle rays.

The pulley system of the proximal portion of the flexor tendons is released and the intrinsics are dissected from the metacarpal to enable shortening and adjustment of the bone.

The second metacarpal must be shortened, rotated and transposed to yield, where possible, a thumb of matching length to that on the contralateral hand. Once the digit is free then it can be repositioned in the place of the absent thumb, followed by tension-free realignment of the longitudinal structures. In traumatic reconstruction the length of the second metacarpal resection, the adjustment of the tendon alignment, the reconstruction of the short muscles of the thumb and the positioning of the skin flaps are dependent on the level and extent of bone and soft tissue loss.

Webspace

The first webspace between the thumb and index finger allows the thumb a unique range of functional rotational motion. The skin envelope is soft, thin and pliable to allow for a wide range of motion between the thumb palm and digits, including adduction, abduction and opposition. This specialized area is often involved either primarily or secondarily in injuries to the thumb and first ray.

A contracture of this webspace will involve not only the skin but also the fascia and muscles it clothes. It is important in releasing the webspace that all tight and restricting structures are freed, sparing the neurovascular bundles and motor branches from median and ulnar nerves. This usually requires releasing the palmar and dorsal fascial layers overlying and

encasing the adductor pollicis and the first dorsal interosseous. The origin of the transverse component of the adductor from the third metacarpal may need to be divided. The ensuing soft tissue defect will almost always be greater than anticipated.⁹¹

The reconstruction options vary depending on the degree of contracture, residual soft tissues and available local and remote donors. It is usual to have to use at least local flaps for web expansion, including single or multiple Z-plasties and transposition flaps from nearby digits. However, in choosing any of these local options it is important to remember that they are probably also within the zone of injury, and preoperative markings and flap options should incorporate previous scars.⁹²

In injuries where the webspace has been obliterated by tissue loss or ischaemia, the reconstructive options should include pedicled or free tissue transfers from distant sites. There are several routine flaps available for transfer available, including groin, lateral arm, posterior interosseus, first webspace of the foot, or really any area where expendable pliable thin soft tissue is available⁹³ (Figure 54.5). We routinely use free groin flaps for web reconstruction where the defect requires imported soft tissue. The donor site is hidden and the flap size can vary considerably, with the advantage of being able to thin the flap bulk at the time of transfer^{94,95} (Figure 54.6).

Postoperative care

The immediate postoperative care requires attention to the hand and patient. The thumb should be protected by either a bulky dressing or a splint. It is the application of the dressing which is most crucial. The dressing should be non-constricting at the time of application and also have the potential to remain so after any postoperative swelling or bleeding. In the free tissue transfers the patient should be kept warm and comfortable with a well-filled circulating blood volume to promote distal perfusion. These microvascular transfers should be monitored by experienced nursing staff and any concern about flap vascularity should be escalated. This allows for early exploration and flap salvage.⁹⁶

Rehabilitation and outcomes

Rehabilitation and hand therapy are the cornerstones for good outcome, as with all hand surgery. In adults hand therapy can commence early once the viability of the flap or transfer is confirmed and the operating surgeon is comfortable.

Good functional outcomes after thumb reconstruction are recorded in the literature.⁹⁷ Parvizi *et al.* have shown the functional benefit of thumb reconstruction. They have concluded that occupation and the patient's relative focus on appearance must be considered when evaluating the best options for reconstruction and the overall benefit to each individual.⁹⁸ Functional evaluation of thumb replantation or reconstruction with a great toe transfer are comparable, with Buncke *et al.* actually demonstrating better inter phalangeal joint motion in great toe transfers than in amputated thumbs that had been crushed or avulsed.⁹⁹

Figure 54.5 (a) Burn contracture of the first web space, thumb and index finger. (b, c, d) Lateral arm free flap to reconstruct the web space, release the thumb and index fingers.

Metacarpal hands

Mutilating hand injuries are rare but devastating. They are often associated with multidigit loss and destruction of the sensory tactile glabrous skin of the digits and palm. Michon first ascribed the term *metacarpal hand* to these injuries in 1974. He divided it into two broad groups:

- the complete loss of all digits,
- 'thumb without fingers'.

The outcome then, as now, is dependent on the sensory capacity of the remaining or reconstructed hand, as without reliable sensation it is unlikely that the hand will be used functionally or reliably.¹⁰⁰

Subsequent classifications by Wei *et al.* and Kotkansalo *et al.* have focused on more specific classification in relation to amputation level and reconstructive options for thumb and fingers.^{101,102} In the Wei classification, type I describes those hands where all the fingers have been amputated at the level of the middle of the proximal phalanx or more proximally, while the thumb is uninjured or amputated distal to the interphalangeal joint. In type II injuries the thumb is also amputated proximal to the level of the interphalangeal joint.¹⁰¹ The other salient feature in these injuries and with reconstruction is the state of the skin or soft tissue covering the remaining hand and wrist as this will also play a critical role in the level of functional recovery and use of the hand.

Management principles and options

These cases should be treated, as with all major traumas, in a systematic fashion with primary exclusion or treatment of all life-threatening associated injuries. This is pertinent, in

Figure 54.6 Free groin flap for dorsum hand and web space reconstruction.

particular with blast injuries, where trunk and other limbs are likely to be involved as well.

Specific treatment of the hand requires attention to preservation of skeletal structures, including joints, and the preservation neurovascular structures where possible to allow future reconstruction. It is important not to shorten or remove specialized tissue to enable closure. It is far better to preserve all viable tissue and digit length and cover with pedicled or free groin flap or other fasciocutaneous flap where possible. Soft tissue cover should be expedited and, if possible, should be achieved immediately. In cases where there is significant contamination or doubt exists about the viability of parts then it is acceptable to delay cover. Ideally, however, soft tissue cover should be achieved within 48 h to prevent further tissue loss from desiccation. It is important when achieving cover at this early stage to use pliable and padded soft tissue flaps rather than skin grafts. The latter will contract over time and will limit movement and constrict any remaining webspaces, thus compromising residual function further.

Once soft tissue cover has been achieved, there is then time to focus on reconstructive options available for thumb and digit reconstruction. It is also important to consider the webspace and pliability of the skin of the hand to ensure that thumb and digit motion is enabled as much as possible.

The psychological effects of these severe hand injuries should also be managed in parallel. Several studies have indicated the high incidence of posttraumatic stress disorder and the link between physical and psychological outcomes in this patient

population. It is important to address these psychosocial elements early to promote psychological wellbeing and this will aid physical recovery.^{103–105}

In type I injuries (Table 54.1), where the thumb is adequate then one can focus on reconstruction of the webspace and digits. In cases where the skin is preserved then the focus can remain entirely on establishing a competent sensate prehensile hand. This can be achieved using toe transfers to the 2–5 metacarpal rays. The location of the transfers should depend on the flexibility of the thumb and the competency of the webspace. Where the thumb is intact but is stiff or the soft tissues are not pliable, then it is best to transfer onto the radial digits so as to promote useful grip.

Where the thumb and soft tissues are pliable and the basal joint is competent then transferring the toes to the more ulnar rays can achieve both narrow pulp-to-pulp grip, along with large object grasp. Finger reconstruction can be achieved with second toe transfers or *en bloc* transfers of second and third toes. The options for reconstruction will be limited by the donor site that is acceptable to the patient and surgeon.

In type II injuries (Table 54.2), the thumb is also compromised and here the challenge is producing a hand that yields the most functional grips using the repertoire of toe transfers and lengthening procedures available. Reconstruction of the thumb takes priority over the other digits, and trying to achieve symmetry of thumb appearance to the contralateral side, if present, combined with the need to reconstruct multiple digits means the possibility of using the great toe as donor

Table 54.1 Classification of metacarpal hand type I

Subtype	Level of finger amputation	Recommendations
IA	Distal to the MCP joint	1. Bilateral 2nd toes for amputations distal to the webspace 2. Combined 2nd and 3rd toes for amputation proximal to the webspace (transproximal phalanx transfer)
IB	Through the MCP joint with intact metacarpal articular surface	Combined 2nd and 3rd toes (composite joint transfer)
IC	Through the MCP joint with damaged metacarpal articular surface or transmetacarpal amputation	Combined 2nd and 3rd toes (transmetatarsal transfer)

MCP, metacarpophalangeal.

Table 54.2 Classification of metacarpal hand type II

Subtype	Level of thumb amputation	Recommendations
IIA	Distal to the metacarpal neck	Whole or trimmed great toe transfer (transproximal phalanx transfer)
IIB	Proximal to the metacarpal neck with adequate thenar muscle function	1. Preliminary distraction lengthening or interpositional bone graft followed by whole or trimmed great toe transfer, or 2. Transmetatarsal 2nd toe transfer
IIC	Any level with inadequate thenar musculature	1. Thumb reconstruction in a second stage following finger reconstruction, and 2. Tendon transfer to restore opposition
IID	Any level with damaged carpometacarpal joint	Same as in IIA and IIB, but aiming at reconstructing immobile thumb post

Source: Wei *et al.*, 1997.⁷⁰ Reproduced with permission of Lippincott Williams & Wilkins.

Figure 54.7 (a) Metacarpal hand following burn injury – preoperative. (b) Postoperative view showing hand span after a free groin flap to create the webspace, a free toe transfer for thumb reconstruction and skin graft to release the remaining digits.

for the thumb with use of the second and/or third toes for reconstruction of the other digits. Contralateral ring finger transfers offer the advantage of length and mobility over multidigit transfers.¹⁰⁶

If the soft tissues have also been compromised or lost then these will need to be reconstructed as a first stage (Figure 54.7). It is important at this stage to adequately release any contractures of the webspace and to resurface any areas of contracted skin where vascular or neural pedicles will cross. This can be challenging, in particular if there have been burns or avulsions. Although a small amount of skin and soft tissue can be harvested with the toe transfer it is really important that any skin closures at the time of digit transfer are not tight or under tension to prevent compression and pedicle compromise.

At the time of toe transfer, in particular, in these cases of severe hand injury attention paid to pedicle length and pathway is critical. It is always worth documenting by illustration or photos the location of vascular and neural pedicles so that at times of secondary surgery a clear picture of these vital structures is available. The site of osteosynthesis should be measured before harvesting the toe to ensure appropriate length of tendons, nerves and the vascular pedicle. It is important to remember that in these multidigit reconstructions the overall hand length is shortened and thus anticipating the site of the reconstructed thumb pulp and pulp of the reconstructed digits is worthwhile.

Postoperative care

A multidisciplinary programme of postoperative care should commence immediately. This includes physiotherapy, occupational therapy, psychology and nursing care. In the

immediate postoperative time it is important to ensure a system of monitoring transfers in a regular and robust fashion and we have routinely used clinical observation.⁹⁶

Further surgery to adjust tendons, scars, soft tissue bulk and revise osteosyntheses is common in this complex patient group.^{102,107}

CHAPTER 55

Compartment syndrome in the extremities

Steven E.R. Hovius and Tim H.J. Nijhuis

Department of Plastic and Reconstructive Surgery, Erasmus MC University Medical Center, Rotterdam, The Netherlands

Introduction

Compartment syndrome in either upper or lower extremity is often underestimated and may have detrimental consequences for functioning of the involved extremity. Muscle groups in the extremities are separated by fascial sheaths to ensure that muscles move in the right vector and achieve maximal efficiency during contraction. Fascial sheaths also provide additional surface area for muscle origins because bone alone does not offer enough surface area. Fascial sheaths protect neurovascular bundles.

Groups of muscles in the arms and legs, together with blood vessels and nerves, are contained in compartments surrounded by non-elastic fascia and/or bone; therefore, whenever bleeding and/or oedema occur, increased pressure is inevitable. This increased pressure can harm the intracompartmental soft tissues, leading to detrimental consequences. Focusing on the different compartments in both the upper and lower extremities a distinct architecture can be recognized.

In this chapter we address the anatomy of both upper and lower extremities to illustrate the rationale for the occurrence of compartment syndrome, its consequences and management strategies.

Anatomy

Fascia

The thickness of the fascia is determined by the amount and direction of the applied force. Comparing the fascia of the lower leg (i.e. fascia cruris) to the fascia of the forearm (i.e. fascia anti-brachii), not only can a significant difference in thickness be noted, favouring the fascia cruris, but also a difference in the direction of the fascia fibres. The fascia cruris fibres run in a circular direction, whereas the fibres of the fascia anti-brachii do not have a uniform shape or direction. This difference can be explained by the constant contraction and relaxation of the calf muscles, which is of much higher amplitude than that of their forearm counterparts.

Upper extremity

Forearm

The forearm contains three compartments: dorsal, volar and mobile wad compartments. The *dorsal compartment* contains the abductor pollicis, extensor pollicis longus, extensor carpi ulnaris, extensor digiti minimi and extensor digiti communis muscles. Inferior to the muscles, the radius and ulna can be found, separated by the interosseous membrane. The *volar compartment* is separated into superficial and deep muscles. The deep muscles include the flexor pollicis longus, flexor digitorum profundus and pronator quadratus. The superficial muscles are the palmaris longus, pronator teres, flexor digitorum superficialis, flexor carpi ulnaris and radialis. The ulnar and radial bone and the interosseous membrane border the compartment dorsally. Volar borders are the subcutaneous antebrachial fascia. This fascia also separates the volar compartment from the *lateral compartment* (i.e. the *mobile wad*), which holds the brachioradialis, extensor carpi radialis brevis and longus muscles.

Hand

Looking at the different osteofascial compartments of the hand, 10 separate compartments can be distinguished: four dorsal interossei compartments, three palmar interossei compartments, the adductor pollicis compartment, and the thenar as well as hypothenar compartments.

Lower extremity

Lower leg

Anatomically, the lower leg can be divided in four compartments: the deep and superficial posterior compartments and the lateral and anterior compartments.

The fascia cruris, tibia, fibula and interosseous membrane surround the anterior compartment. The anterior tibial muscle, extensor hallucis longus and extensor digitorum longus are the muscles in this compartment. The anterior tibial artery and veins run along these muscles distally and the deep peroneal nerve innervates them.

The lateral compartment comprises the long peroneal and brevis muscles and the common peroneal nerve proximally. The crural fascia, intermuscular septum fascia and fibula compartmentalize these structures.

The superficial posterior compartment is separated from the deep compartment by the transverse intermuscular septum and is ensheathed by the fascia cruris. This compartment holds space for the plantar, soleus and gastrocnemius muscles.

The deep posterior compartment is encircled by the already mentioned transverse septum, the tibial and fibular bones and the interosseus membrane; it also contains the tibial nerve and posterior tibial and peroneal arteries and veins. Muscles that are located in this compartment are the posterior tibial, flexor hallucis longus and flexor digitorum longus muscles.

Foot

Three compartments cover the full length of the foot: medial, lateral and superficial compartments. In addition, five intrinsic compartments are described (i.e. four interossei compartments and an adductor compartment) and a calcaneal compartment.

The medial compartment holds the flexor hallucis brevis and the abductor hallucis muscle. The lateral compartment contains the abductor digiti quinti and the flexor digiti minimi muscles. In the superficial compartment the flexor digitorum brevis, the flexor digitorum longus tendons and the lumbrical muscles are located. Also, the medial plantar nerve is running through this compartment. The interossei and adductor compartments hold the interossei muscles and the adductor muscle, respectively. The calcaneal compartment not only comprises the quadratus plantae muscle, but also the posterior tibial, medial and lateral plantar nerves. All vessels of the foot run through this compartment: the posterior tibial, medial and lateral plantar arteries and veins.

Pathophysiology

Each compartment has an ideal pressure for optimal tissue perfusion, based on the balance between the hydrostatic and osmotic pressure. The intracapillary hydrostatic pressure normally varies between 20 and 30 mmHg and relates to the difference between venous and arterial pressures.¹ The osmotic pressure or interstitial fluid pressure ensures prevention of outflow and ranges between -5 and +5 mmHg.²

Disturbance of this pressure balance can occur as a result of an increase of intracompartmental pressure (ICP) or a decrease of compartmental volume caused by bleeding or swelling of the tissue or a reduction of external volume due to high-pressure compression or casting. It is generally accepted that an increase of the interstitial fluid pressure above the intraluminal pressure of the capillary will prohibit adequate perfusion of the intracompartmental structures.³

As soon as the perfusion is jeopardized, hypoxia will lead to oedema and the initiation of anaerobic metabolism. This

cascade leads to a further increase of ICP and thus an even greater decrease of capillary flow. Subsequently, only an intervention can halt this process. If intervention is not performed within 3 h after the onset of ischaemia, an impaired muscle response will occur. Six to eight hours after ischaemia the muscle and soft tissue will have suffered irreversible damage.⁴

Diagnosis

Subjective

Compartment syndrome is a clinical challenge where the clinical history foretells the physician the problem. Classically pain, pallor, pulselessness, paraesthesias and paralysis (also called 'the five P's') are described as the clinical symptoms related to compartment syndrome. Although pain and loss of sensibility are not universal findings,⁴ in our survey only one of our patients was asymptomatic (see below ischaemic contracture). In all other patients symptoms were present but unfortunately not adequately recognized or treated.

The review by Wall *et al.* confirmed 'the five P's', except their observation that pulses may be present. Moreover, the pain may be out of proportion to the injury and there is a palpable painful tenseness or swelling of the compartment.⁵ Also important is pain on passive stretch of wrist and fingers in the developing compartment syndrome of the upper extremity. Progressively, the increased pressure will lead to ischaemia of the nerves, resulting in late-onset clinical signs as sensory and motor deficits.

In the upper extremity a supracondylar fracture of the humerus is the most frequent cause for the development of an ischaemic contracture, followed by a fracture of the forearm. These fractures should be monitored carefully with regard to compartment syndrome, especially in children.⁶

It is important to note that compartment syndrome is often missed or discovered later because of modern early treatment with drugs to diminish pain. In most modern hospitals it is supposed to be a medical mistake if patients have pain. At our unit and in our hospital compartment syndromes have been missed for this reason.

Objective

Intracompartmental pressure

An objective measurement for the diagnosis of compartment syndrome is evaluation of ICP. Aside from the decision of evaluating pressure, one should perform a fasciotomy immediately if there is any doubt about compartment syndrome. In our medical practice, working in a trauma referral centre dealing with substantial injuries to the extremities, it is common practice to perform preventive open fasciotomies, especially if vascularization is compromised more proximally.

Many authors have described the assessment of pressure monitoring for the diagnosis of compartment syndrome. Some

of the techniques described are the side-portal needle, the slit catheter,⁷ the Whitesides' infusion technique⁸ and a regular 18-gauge needle.

All techniques are based on the same concept, which is in fact an intracompartmental placement of a specific measuring device (i.e. the subtle difference between the different techniques), a fluid column and a transducer for measurement of ICP. As such, either a continuous or a repeated ICP measurement can be established. Ideally, the same clinician monitors the ICP with an interval range ranging from 30 min to 12 times a day.⁶

A recent experimental study by Hammerberg *et al.* compared the reliability of different devices, both digital and analogue, using three different terminal devices.⁹ The devices investigated were the 18-gauge bevel-tipped needles, the side-ported bevel-tipped needles and the slit catheters. They concluded that the differences between these three terminal devices are small and unlikely to have an impact on clinical decision making for fasciotomy. However, when the electronic measurement approach is compared with the analogue Whitesides' technique, the electronic technique is favoured because it does not require prior preparation. Nevertheless, Hammerberg *et al.* recommended using the slit catheter for continuous monitoring of one compartment. In the event, multiple compartments are at risk or multiple measurements in the same compartment are required. The clinician should use either a standard 18-gauge or side-port bevel-tipped 18-gauge needle.⁹

Near-infrared spectroscopy

Near-infrared spectroscopy uses a differential light absorption to measure the level of haemoglobin, thus providing a measure of oxygenation. Recognizing decreased muscle oxygenation is correlated to the intracompartmental tissue perfusion gradient and thus could be helpful in the diagnosis of acute compartment syndrome.¹⁰ Furthermore, Reisman *et al.* showed an inverse correlation between tissue perfusion and ICP. They noticed an 8% difference, with the perfusion dropping below 10 mmHg.¹¹ As near-infrared spectroscopy can scan at different depths intracompartmentally, it seems to be useful for monitoring patients at risk of compartment syndrome.

Treatment

If a compartment syndrome is not adequately released, necrosis with all its consequences will be unavoidable. In the presence of the aforementioned symptoms our advice is to act with aggressive decompression of compartments without delay. Surgery is the only treatment that can prevent the disastrous consequences of compartment syndrome by restoring the microcirculation and preventing further damage to the muscles and nerves. Measures such as opening of the plaster cast and elevation of the extremity are not sufficient in these cases. Sheridan and Matsen found that the frequency and severity of complications of decompression were directly related to the promptness with

which it was performed.¹² In cases of a suspected vascular injury, decompression has to be combined with vascular exploration and restoration of blood flow. At our unit most decompressions are performed preventively. This is especially the case in crush injuries of the extremities, and particularly if vascularization of the involved extremity is at risk. We do not have a wait-and-see policy and thus do not use this objective evaluation on a regular basis. Table 55.1 provides an overview of fasciotomies carried out in our unit between 2002 and 2012 in order to prevent compartment syndrome or further damage due to ischaemia in cases of compartment syndrome. This table illustrates our policy not to wait and see.

Upper extremity

Forearm

When addressing compartment syndrome, the superficial and deep flexor compartments, the dorsal compartment and mobile wad in the forearm, the carpal tunnel and the intrinsic compartments should be released. The most affected muscles in compartment syndrome of the forearm are the deep muscles in the volar compartment. Different approaches have been reported to release the compartments. They all share, however, the same principle of placing a long longitudinal incision over the forearm. Ronel *et al.* investigated the best approach for releasing the compartments of the forearm.¹³

To open the volar compartment, a radial approach was described. An incision is made radial to the volar midline, starting at the proximal wrist crease and extended to the antecubital fossa. In this way the superficial fascia can be seen and opened to enter the deep muscles radial to the flexor carpi radialis.

Central and ulnar approaches were also investigated. For the central approach the volar incision is planned in the midline, the fascia is opened and, approaching either ulnar or radial to the palmaris longus, the deep muscles can be inspected. The ulnar approach requires an incision radial to the flexor carpi ulnaris. The dorsal compartment is opened through a midline incision in the dorsum of the arm. After opening the superficial fascia the compartment should be adequately decompressed.

Gelberman *et al.* described incisions that were prolonged over the carpal tunnel and introduced a curved incision for easy access to the muscles without harming the brachial artery or major nerves.¹⁴ The senior author uses a similar approach as described by Gelberman.

Hand and wrist

A well-executed study by DiFelice *et al.* illustrated the compartments of the hand and proposed a protocol for releasing them.¹⁵ Placing two incisions on the dorsum of the hand – one on the thenar region and one on the hypothenar region – allows access to all compartments. Another incision over the carpal tunnel allows release of the carpal tunnel as well as Guyon's canal.

Regarding the dorsal incisions, the incisions should be made over the second and fourth metacarpals. The incision over the

Table 55.1 Overview of fasciotomies in upper and lower extremities in the preventive (i.e. primary) trauma setting and with evident symptoms of compartment syndrome to prevent permanent damage due to ischaemia (secondary), Department of Plastic & Reconstructive Surgery and Hand Surgery, Erasmus MC, University Medical Center, October 2002–October 2012

Data extracted from the surgery records from the Department of Plastic & Reconstructive Surgery and Hand Surgery of the Erasmus MC, University Medical Center, October 2002–October 2012.

second metacarpal creates access to the first dorsal interosseous muscle, the adductor pollicis, the second dorsal interosseous and the second palmar interosseous. In contrast to our experience, DiFelice advises release of the interossei from its origin (i.e. the connection to the second metacarpal bone) as well. The adductor pollicis fascia can be found radial and inferior to the first dorsal interosseous. The incision over the fourth metacarpal logically gives access to the fourth and third interosseous compartments using a similar approach to that described over the second metacarpal.

To release the hypothenar fascia a longitudinal incision should be placed just ulnar to the fifth finger. This will prevent harming the motor nerve bundles. The thenar incision should be parallel to the first metacarpal bone. Be careful not to lacerate the motor bundles innervating the thenar muscle.

To open the carpal tunnel, the well-accepted longitudinal incision is placed at the centre of the tip of the fourth metacarpal in full flexion, running distal towards the flexing point of the wrist. The flexor retinaculum is the roof of the carpal tunnel and the floor of Guyon's channel. After opening the skin, the retinaculum is followed ulnar to the point where the ulnar nerve is

visualized. Subsequently, the tendon sheath between the os pisiforme and os hamatum can be opened to release Guyon's channel. To release the carpal tunnel the flexor retinaculum can be opened.

The senior author opens the thenar and hypothenar sheaths via the carpal tunnel incision and not via separate incisions, therefore using only three incisions – two dorsal for the interosseous muscles and one volar in the hand – to adequately release the compartments.

Lower extremity

Lower leg

Exposure of all four compartments is required to prevent (further) necrosis in the acute compartment syndrome, including the tarsal tunnel and compartments in the foot.

In the literature, two techniques used to release the compartments in the crural area are frequently described.¹⁶ Either a single lateral incision can be made or a two-step anterolateral and posteromedial approach can be used. The first author favours the two-step approach and therefore we choose to discuss this technique in detail.

Two-step anterolateral and posteromedial approach

The first incision is anterolateral, which allows exposure of the anterior and lateral compartments. The incision should be placed over the anterior intermuscular septum. The fascia is then opened and, moving laterally, the lateral compartment can be decompressed. Be aware of the superficial peroneal nerve, which exits the lateral compartment 10 cm cephalad from the lateral malleolus. Decompressing the anterior compartment the fascia should be opened medial from the intermuscular septum. The anterior tibial and extensor hallucis longus muscles protect the deep peroneal nerve and peroneal artery. This paradigm, as described by Kashuk *et al.*, allows an easy and safe dissection.¹⁷

The posteromedial incision is placed medial from the tibia and over a length of 15 cm sufficient exposure is created for a safe decompression. Some promote extending the incision with a medial retromalleolar incision, which evidently will release the tarsal tunnel.¹⁸ After placement of the first incision, the fascia can be opened and anterior retraction will prevent laceration of the saphenous vein and both the saphenous nerve and vein. After the superficial compartment is decompressed, approaching the insertion of the soleus muscle can expose the deep compartment. Retraction of this muscle exposes the fascia of the long flexor digitorum, which can then be opened. It is important to identify the neurovascular bundle (i.e. posterior tibial nerve and artery), which is located between the soleus and anterior tibial muscle.

Recommendation

The posteromedial incision is designed to create a safer decompression of the deep and superficial posterior compartments. In our practice, the two-step incision technique is mostly used to prevent inadequate deep flexor compartment release and unnecessary damage, as this technique opens the compartments under direct vision. This is especially important in a training institution.

Foot

For the foot, various techniques have been described and a nice overview is given by Frink *et al.* in which the dorsal fasciotomy is promoted.^{16,19} This approach uses two incisions medial to the second metatarsal bone and lateral to the fourth metatarsal bone. Taking care of the superficial veins and nerves, the fascia can be located and should be opened longitudinally over each interosseous compartment. Subsequently, the medial compartment is decompressed with an incision parallel to the plantar surface, starting just caudal to the insertion of the Achilles tendon (i.e. tarsal tunnel). The incision exposes the medial and abductor compartment. Lifting the abductor compartment opens the calcaneal compartment. The superficial and lateral compartments can be opened, consequently, through the calcaneal compartment. The superficial compartment is found just lateral to the medial compartment and after opening the medial fascia longitudinally, the flexor digitorum brevis can be retracted inferior and the medial fascia of the lateral compartment exposed.

Our approach to foot compartmental release is to use two dorsal incisions for the dorsal compartments. The incision over the tarsal tunnel is further lengthened distally on the medial side parallel to the plantar fascia to open the abductor, calcaneal, superficial and lateral compartments of the foot.

Late sequelae

Volkmann's contracture of the upper extremity

The classic case of a patient with an ischaemic Volkmann's contracture is a child sustaining a supracondylar humeral fracture treated with a cast. The following days the child is in considerable pain and although the cast is changed the pain is not relieved. Subsequently the fingers start clawing gradually and the wrist is no longer able to extend. Passively the fingers can only be stretched when the wrist is flexed completely. Furthermore the sensibility of the hand is severely impaired.

In 1881, Richard von Volkmann described a condition of muscle ischaemia, necrosis and subsequent contracture of the forearm. This condition was the result of diminished arterial blood supply due to the application of tight, constricting bandages to the injured arm.²⁰ In 1908, J.J. Thomas collected 107 cases with ischaemic contracture from the literature. He reported that contractures were also possible in patients without treatment with splints or bandages; extrinsic pressure could therefore not be the only cause of Volkmann's contracture.²¹ The current understanding is that various injuries can cause swelling of the soft tissues in relatively tight osseofascial compartments.²² The deep flexor compartment of the forearm is the first to be damaged as it closest to the bone, with a tight surrounding fascia.²³ Also the flexor digitorum profundus is most distant from the arterial anastomotic pathways available to re-establish circulation. The centre of the muscle, providing tendons to the middle and ring fingers, is particularly vulnerable.²⁴

In more severe cases or when the trauma is more in the vicinity of other compartments, the infarction can also encompass the superficial flexor muscles, the extensor muscles and the intrinsic hand musculature. When ischaemia is prolonged, the muscles become necrotic and are eventually replaced by fibrous tissue and fat. In addition, the initial ischaemia can cause nerve damage, which becomes worse when the surrounding muscle becomes fibrotic.

If compartment syndrome is not treated adequately, Volkmann's ischaemic contracture will occur (Figure 55.1). As our understanding of the pathogenesis of compartment syndrome has improved over the years, more specific diagnostic and therapeutic measures have been introduced, reducing the incidence of Volkmann's ischaemic contracture.^{26–30}

Unfortunately ischaemic contracture still occurs as a result of an underestimation of the symptoms, with serious consequences for the function of the involved extremity. Not only is a fully developed contracture of the flexor muscles with impaired sensibility in the forearm extremely incapacitating, it can also cause

Figure 55.1 This 4-year-old girl sustained a supracondylar fracture (six months earlier) resulting in a severe Volkmann's ischaemic contracture with proximal interphalangeal contractures and loss of motion in fingers and wrist as well as sensibility loss in both ulnar and median nerve distribution. Source: Hovius & Ultee, 2000.²⁵ Reproduced with permission of Elsevier.

psychological trauma. In the United States, failure to diagnose an acute compartment syndrome is a well-known cause of litigation against the medical profession.³¹

An established contracture varies from a few affected deep flexor muscles with no nerve damage to a complete infarction of one or more muscle compartments with extensive nerve damage. Treatment should therefore be custom-made and directed to improve overall function. Although several methods of treatment have been reported, long-term results in different treatment regimens are rarely described.^{28,32–34}

In our study we analysed our cases (25 patients) and reported on the long-term results of the different treatment methods for Volkmann's contractures.³⁵ Patients filled in questionnaires concerning their disability, together with their satisfaction with the treatment. They were examined physically, including arm length, and tests were performed to measure

strength and sensibility. In addition, motor function was classified based on Buck Gramcko's classification. Most patients sustained supracondylar fractures and the mean age was 13 (range 2–60) years. Follow-up had a mean of 7 (range 3–29) years. Post-trauma severe pain was encountered in 88%, loss of sensation 80%, blue fingers 60% and skin necrosis in 28%. In the majority, sensibility, motion and strength improved in the first months. In five patients sensibility did not improve.

Treatment varied, ranging from conservative splinting through excision of fibrous tissue, neurolysis, tenolysis, proximal 'muscle slide', tendon lengthening, tendon transfers and nerve grafting to free vascularized, innervated musculocutaneous flaps.

The treatment of an established contracture depends strongly on the severity of the infarction and the affected muscle and nerve tissue. Decisions about when and how to operate are not easy and are often discussed in literature.

Based on our study, we operate on patients with poor or insufficient hand function, with severe muscle necrosis diagnosed by MRI and with neurological signs in an earlier stage to prevent further joint stiffness and nerve damage by fibrosis.^{23,33,35,36} Severe muscle necrosis is easily differentiated from viable muscle tissue at an early stage, and can subsequently be removed. In patients with a so-called 'prolonged pain syndrome' we strongly advise early neurolysis and excision of fibrotic tissue, as in our experience it will immediately resolve the pain.³⁵

In patients with good to reasonable hand function we suggest initial conservative treatment with hand therapy and splinting while waiting for spontaneous improvement of sensibility and motor function. If after three months hand function does not improve or diminishes, surgical intervention has to be considered.

In patients with insufficient hand function with infarction of a considerable part of the deep and superficial flexors and neurological signs, excision of fibrotic muscle tissue, neurolysis and tenolysis is advised.³⁵ Good results can be obtained if excision and neurolysis are combined with tendon transfer, specifically in the early cases. We do not recommend tendon lengthening only, due to the high recurrence rate of the contractures and possible loss of power grip strength.

In patients with poor hand function with extensive infarction diagnosed by MRI, we advise a free vascularized innervated muscle transfer. We prefer a two-stage procedure with early excision in the first stage followed by the flap and if necessary a nerve graft in the second stage a few months later. If in the first stage the nerve is in continuity without deformity, a neurolysis is performed. In our experience quite often a substantial recovery of sensory function will occur in these cases. If in the first stage the nerve is deformed, a nerve graft is planned in the second stage, combined with the free muscle transfer (Figure 55.2). The nerve is mostly deformed when a substantial number of the forearm flexor muscles are fibrotic. In the majority of our patients both hand mobility and sensory function improved

Figure 55.2 Second phase: median and ulnar nerve reconstruction with sural cable grafts and a free vascularized innervated gracilis flap for flexor function (same patient as Figure 55.1). In the first phase scar tissue excision, neurolysis and flexor tenotomy was performed. Source: Hovius & Ultee, 2000.²⁵ Reproduced with permission of Elsevier.

tremendously after free muscle transfer (Figure 55.3). Although the contractile force of the gracilis muscle will stay limited for grip strength, a considerable increase of power grip strength was noticed in our cases.

We have described the considerable difference in length of the forearm and hand on the affected side in relation to the healthy side in our patients who still had open growth plates.³⁵ Reasons for this length difference might be impaired oxygenation of growth plates and impaired muscle function and damaged nerve tissue. We therefore recommend informing children and/or parents or caregivers about the possibility of a length difference of the forearm developing when they have an ischaemic contracture of the forearm.

Volkmann's contracture of the lower leg

Zwipp discussed the late sequelae after compartment syndrome in the lower leg and foot.³⁷ The contractures can be subdivided into five groups. Group I consists of small toe contractures, including hammertoes (i.e. intrinsic muscle necrosis and contractures of the m. flexor brevis) and claw toes (ischaemic damage of the m. flexor brevis and flexor digitorum longus). Group II comprises the pathology of the hallux, which can be either isolated muscle necrosis of the flexor hallucis longus (resulting in a claw deformity during knee bending) or a contracture of the flexor hallucis longus. Group III is the combination deformity of groups I and II. Group IV is the pes equinus deformity based on the contractures of the superficial dorsal compartment (without nerve dysfunction) or based on dysfunction of the anterior compartment (either muscle necrosis or nerve paralysis). Group V is the pes equinovarus deformity, which is caused by the tibial, peroneal or combined ischaemic nerve injury.

There is little information about the surgical options in the literature. The group of Hansen proposed scarred muscle

excision (including the respective tendon),³⁸ but the recent work of Zwipp *et al.* promotes a percutaneous release of tendons by Z-plasties, which can adequately correct the contracted toes and/or foot. In the experience of the first author most cases have sustained an ischaemic event of the anterior compartment with or without the lateral compartment. The lack of extension of the forefoot and toes is corrected by tendon transfers if possible, such as the transfer of the viable posterior tibial tendon to create either extension of the forefoot or extension of the toes. Other examples we have encountered include contracture of the toes following extension at the ankle joint. Release of fibrosis and tendon transfers is mostly performed in these cases.

CHAPTER 56

Nerve injury, repair and reconstruction

Renata V. Weber, Andrew Yee, Michael M. Bottros and Susan E. Mackinnon

Department of Surgery, Division of Plastic and Reconstructive Surgery, Washington University School of Medicine, St Louis, MO, USA

Introduction

The future of peripheral nerve surgery holds exciting possibilities. The advancements in the last 25 years have included an understanding of the internal neural topography facilitating the development of nerve transfers and neural substitutes for short-gap/small-diameter injuries. Despite these innovations, the major limitation to peripheral nerve recovery is still the time it takes for the nerve to regenerate. This remains true regardless of the technique used for the repair. Without prompt motor nerve input, denervated muscle after a prolonged period of time becomes resistant to nerve regeneration. Although avoidance of tension at the neurorrhaphy site and improvements in suturing techniques have improved the process to some extent, the ultimate success is dependent on innervation time, number of neurorrhaphy sites, supply and type of donor nerves, and the condition of the surrounding tissue. At every coaptation site, a percentage of nerve fibres are lost.

Tension is harmful to a repair site and, in the case of a large gap, a nerve graft is often used to fill in the deficit. Autologous nerve grafts are limited and the sural nerve remains one of the most common sources. Alternatives to standard treatment for short, small-diameter nerve gaps include commercially available nerve conduits and acellular human processed nerve allografts. Schwann cell-lined nerve conduits and tissue-engineered substitutions are still experimental, but may offer the solution for enhanced nerve regeneration in the future. It is important, however, to remember that even the 'gold standard' nerve autograft gives functional results typically deserving of a 'bronze' award, and no nerve substitute to date equals the results of an autograft. Nerve transfer techniques have largely replaced nerve grafts for many proximal level nerve injuries in our practice.

Types of nerve injury

Nerve injury

Peripheral nerve injuries can be classified in several ways. Sir Herbert Seddon's classification system was the first and was based on gross and histologic anatomical changes rather than the mechanism of injury.¹ He described three types of nerve injuries: (a) *Neurapraxia* involves a local conduction block at a discrete area along the course of the nerve. Wallerian degeneration does not occur and the recovery is excellent within a 'short' time period. (b) *Axonotmesis* implies axonal damage, while (c) *neurotmesis* is the equivalent of a peripheral nerve transection. In both axonotmesis and neurotmesis, Wallerian degeneration occurs distal to the site of injury. Although the former will recover, the latter cannot.

Within axonotmesis, Seddon described a degree of injury associated with scarring and less complete recovery. Within neurotmesis, he described an 'in continuity' total scar and a non-recovery injury. However it was Sunderland who emphasized Seddon's expanded description of axonotmesis and neurotmesis, with a classification that emphasized five degrees of nerve injury.² Mackinnon later emphasized a sixth-degree injury that could include normal fascicles with various degrees of injury to other fascicles (Table 56.1 and Figure 56.1).^{3,4} First-degree (neurapraxia) and second-degree (axonotmesis) injuries recover spontaneously, the latter at the classic rate of 1–1.5 mm/day or 1 inch/month (2.5 cm/month).⁵ Fourth- and fifth-degree injuries do not recover, while third- and sixth-degree injuries have partial recovery for different reasons. The difficulty associated with surgical correction of a fourth-degree injury is limiting the repair to the fascicles affected by fourth- and fifth-degree damage and not damaging fascicles normal fascicles with the potential for spontaneous recovery. The sixth-degree injury is the surgeons most technically challenging injury. We also use the simpler classification of 'favourable' and

Table 56.1 Classification of nerve injury

Mackinnon	Sunderland	Seddon	Injury	Recovery	
				Outcome	Rate
Degree I	Degree I	Neurapraxia	Conduction block resolves spontaneously	Favourable	Fast/excellent
Degree II	Degree II	Axonotmesis	Axonal rupture without interruption of the basal lamina tubes	Favorable	Slow/excellent
Degree III	Degree III		Rupture of both axons and basal lamina tubes, some scar	Favourable	slow/incomplete
Degree IV	Degree IV		Complete scar block	Unfavourable	None
Degree V	Degree V	Neurotmesis	Complete transection	Unfavourable	None
Degree VI			Combination of I–V ± normal fascicles	Mixed	Mixed

Figure 56.1 Schematic representation of the cross-section of a normal peripheral nerve showing the connective tissue and nerve tissue components. The cross-section of the peripheral nerve on the right demonstrates a mixed, or sixth-degree, injury pattern. The fascicle at the top left is normal. Moving in a counter-clockwise direction, fascicle I is a first-degree injury (neurapraxia) with segmental demyelination. Fascicle II is a second-degree injury (axonotmesis). The second degree involves both the axon and the myelin. The endoneurial tissue is not damaged. Fascicle III demonstrates a third-degree injury, with injury to the axon, myelin and endoneurium. The perineurium is intact and normal. Fascicle IV demonstrates a fourth-degree injury, with injury to the axon, myelin, endoneurium and perineurium. The fascicle is marked by scarring across the nerve, with only the epineurium being intact. Fascicle V is a fifth-degree injury in which the nerve is not in continuity and is transected. The surgeon will separate the fourth- and fifth-degree injury patterns, which will require reconstruction from the normal fascicles and the fascicles demonstrating first-, second- and third-degree injury patterns. These latter patterns of injury require, at most, neurolysis. Source: *Nerve surgery*, Susan Mackinnon (ed.), Thieme 2015. Reproduced with permission.

‘unfavourable’ injuries. Favourable injuries recover fully and quickly (neurapraxia, first degree) or slowly (axonotmesis, second degree) and injuries that partially recover slowly (axonotmesis, third degree). ‘Unfavourable’ injuries will not recover (neurotmesis, fourth and fifth degree).

Nerve injuries may alternatively be classified by mechanism of injury and by open versus closed injury. This clinical

classification is useful in determining the likelihood for spontaneous recovery, and provides an algorithm for managing these injuries. Table 56.2 lists the typical nerve injury patterns and their significance with respect to assessment and treatment. For simplicity, nerve injuries can be grouped as: (a) stretch and avulsion injuries; (b) crush and compression injuries; and (c) penetrating injuries. Although generally, avulsion and crush

Table 56.2 Classification of nerve injury by mechanism

Type	May be injured	Significance
Stretch/avulsion injury		
Avulsion	Nerve roots Nerves exiting Foramen, bony fracture	Unable to be repaired primarily Indication for nerve transfer
Stretch	Any nerve	Mixed nerve injury (degree VI)
Crush and compression injury		
Complex crush	Skin, subcutaneous tissue, muscle, nerve $\pm$ bone	Varying degree of depth, loss of function is related to amount of tissue destruction
Chronic compression	Nerve	Slow onset, reversible
Acute compression	Nerve $\pm$ muscle	Quick onset, reversible muscle ischaemia, variable recovery of both muscle and nerve
Compartment syndrome	Nerve + muscle	Quick onset, reversible muscle ischaemia if ischaemia less than 6 h; no or variable recovery of muscle if released after 6 h
Penetrating injury		
Sharp	Skin, subcutaneous tissue, muscle, nerve $\pm$ bone. All levels	Needs surgical exploration because of high probability for nerve disruption
Blunt	Variable	Injury may extend further than expected
Blast	Variable	Injury pattern depends on ballistic makeup and velocity
Electrical	Variable	Neuropathy is from damage to myelin sheath and ranges from neuropathy to causalgia

Source: Weber et al. Mackinnon Repair and grafting of peripheral nerve. In Gurtner & Neligan (eds), Plastic Surgery Volume 1: Principles; Elsevier, 2013. Reproduced with permission of Elsevier.

injuries tend to be closed injuries, they may be open. When the skin is violated, a significant force was exerted to the body and thus it is not unusual to have associated soft tissue, vascular and orthopaedic injuries. The extent of soft tissue loss, especially muscle and skin, will ultimately influence the outcome of the nerve repair. More extensive soft tissue damage, with or without concomitant bony injuries, raises the complexity and the likelihood for a staged reconstruction. Often, the nerve reconstruction is and should be delayed in light of more acute vascular and orthopaedic injuries.

Traction and avulsion injuries

Stretch or traction injuries to a nerve occur when the strain exerted on a particular nerve exceeds the maximum limit that nerve diameter can accept. The internal structure of the nerve becomes injured, usually without any appreciable external evidence of injury. High-velocity or high-impact injury can often lead to an avulsion of the nerve or nerve root. Soft-tissue attachments around joint or bony foramina act as tethering points along the nerve's path. If arteries and veins run in parallel to the nerves, which is often the case, a severe injury can compromise the circulation. Unless the surgeon involved is skilled at vascular as well as nerve and tendon repair, the nerve injuries are often ignored while the trauma team deals with the limb-threatening injury. Even at major medical centres with unlimited resources and personnel it is rare to see a multi-specialty surgery occur in the emergency setting. The nerve injury is usually addressed at a later date.

Nerve injuries in which the proximal nerve is accessible are repaired directly or with a graft. When warranted, nerve transfer

and possible tendon transfers can be performed to complement and augment the nerve reconstruction.⁶

Nerves avulsed distally at the neuromuscular junction present a different problem, as there is no distal end unavailable for repair. For motor nerves, the proximal nerve can be directly implanted into the muscle belly. Some studies show as good as M4 motor recovery 1–2 years after direct nerve-to-muscle neurotization;⁷ however, experimental studies do not support these findings; rather, recovery is much less than a nerve coaptation would produce⁸ and we rarely use this technique in preference to tendons or muscle transfers.

Crush injuries

The most common peripheral nerve injury in the extremities is from external forces crushing the tissue. In the case of light compressive forces, a self-limiting neurapraxia occurs, but with increased force, the higher the probability of irreparable damage. In addition to external force, increased internal pressure from a haematoma, fracture and local tissue oedema may complicate matters. Compartment syndrome is the ultimate extreme of the spectrum and constitutes a surgical emergency. An early sign of impending compartment syndrome is a decrease in vibration sensibility.⁹ The complications of a missed compartment syndrome is so devastating that the standard of care is to err on the side of caution and release the muscle compartment if clinical index of suspicion is high.

Although nerves are fairly resistant to injury, especially when the surrounding tissue is not significantly damaged, a mixed nerve injury can often occur. The connective tissue surrounding the

larger nerves can contract as it heals, causing an additional compression of the nerve as well as a tethering effect to the surrounding tissue. In addition, local soft-tissue damage, especially to muscle, which is much less resilient to pressure than skin, nerve and tendon, can lead to fibrosis. Thus a relatively minor nerve injury may none the less have enough muscle swelling to cause irreparable damage without clinical evidence of a compartment syndrome leading to a more extensive permanent damage than one would anticipate.

This mechanism of nerve injury is usually treated conservatively and exploration is warranted if the nerve recovery does not follow an expected pattern. Along with traction injuries, crush injuries are treated conservatively with serial exams and electromyograms (EMGs) at three months if no clinical evidence of neurological recovery is noted.

Penetrating injuries

Penetrating trauma can be a result of sharp or blunt penetration, and will often have concomitant vascular structures and tendons injured in addition to the nerve injury. A sharp laceration, such as a hand laceration from a knife or piece of glass, necessitates exploration if a nerve deficit is present. The likelihood that the nerve is partially or completely transected is high. It is recommended to explore these injuries semi-electively within the first week. The more time that passes from the injury date, the less likely the two ends of the nerve can be mobilized to perform a primary repair. More than likely a gap will result after the traumatized nerve is trimmed to healthy nerve and a graft will be needed. In our practice, however, acute nerve grafting is performed if there is concern about a degree of injury that would make it difficult to reoperate in the future.

In the event of a penetrating trauma with an associated vascular injury, immediate exploration is warranted. Occasionally in proximal injuries with large arterial injuries with or without underlying fractures, the nerve injury is overlooked in the face of more urgent vascular and orthopaedic injuries. Rather, the deficit is noticed postoperatively, when it is unclear if the nerve injury is from the inciting event, iatrogenic during the repair of the vascular injury, or secondary to oedema or haematoma. Although a CT scan or MRI may be helpful to evaluate for the latter, internal scarring of the nerve may not always be clearly determined.

Blunt penetrating and blast injuries are usually treated conservatively, similar to closed crush and stretch injuries, because they may recover spontaneously. The local tissue trauma often causes a neurapraxia that resolves; however, electrodiagnostic studies and the algorithm for traction or crush injury followed should evaluate those that do not recover after three months.

Evaluation of nerve injuries

One must first start with a complete history and thorough physical exam. Sensation may be tested using the two-point static and moving discrimination, the Semmes-Weinstein filament test, or the '10 test'. This quick and easy test uses the

patient's own subjective perception to moving light touch to elicit differences in sensation between the right and left sides of the mirror digit.¹⁰

Both index fingers are stroked at the same time and patients are asked if the sensation is the same or different between the two digits. We find this technique to be particularly useful in young children and in patients who have some underlying neuropathy.

Determining spontaneous motor or sensory nerve recovery in closed injuries may be difficult, but the mechanism of injury can offer insight into the likelihood for early surgical management. For sensory recovery, serial physical exam is done looking for an advancing Tinel. In motor nerve injuries, the serial physical exam is accompanied by electrodiagnostic testing, as EMG changes precede clinical recovery. If by 3 months there is no evidence of reinnervation by way of motor unit potentials, surgical exploration and reconstruction is recommended. By evaluating and following the patient soon after the injury, we are in control of ordering any electrodiagnostic testing needed and thus avoid delay in recognizing a nerve deficit that will not resolve spontaneously.

There are clinical investigations using newer ultrasound machines that can detect nerve pathology; however these studies are still investigational and are highly operator-dependent.¹¹

An open injury is easier to assess, as surgical exploration is most often justified except in the case of a blast injury. Typically, we recommend that a sharp injury with associated motor or sensory deficits be explored within 7 days if possible. Conventionally, it is accepted that primary neurorrhaphy should be possible up to 2 weeks after an injury. With injuries that present later than 3 weeks, the surgeon should be prepared to do a graft repair.

Nerve repair

Timing of repair

In the case of a nerve transection, patients who are clinically stable should be taken to the operating room for exploration and repair of the nerve within the first 7–10 days. Nerves repaired acutely within the first 2 days are considered repaired primarily. A delayed primary repair occurs between 2 and 7 days. In either case, the proximal and distal ends of the nerve are freshened and an end-to-end coaptation performed. Nerves repaired after the first week are considered repaired secondarily. The cut-off days of 2 and 7 are arbitrary because even at 2–3 weeks from injury, the nerve can occasionally be coapted without need for a graft; however, the longer the time from injury, the less likely it is that a primary neurorrhaphy can be achieved, even with significant mobilization of the proximal and distal nerve ends.

Tension and nerve repair

Impaired regeneration as a result from scarring at the neurorrhaphy occurs when there is excessive tension at the repair site. Studies on an uninjured nerve show that a 15% stretch of

Figure 56.2 Tension-free nerve repair. A nerve repair without tension is important for optimal recovery, as tension on the nerve repair will significantly downgrade the functional results. In addition, it is important to have redundancy at the coaptation sites. Tension is checked by performing range-of-movement on the extremity. (a) Nerve repair without tension at single coaptation site. (b) Nerve grafting without tension at two coaptation sites. (c) This patient had a radial sensory neuroma that was grafted with a lateral antebrachial cutaneous nerve graft in the hand. The tension-free repair sites with redundancy occurred at both ends of the nerve graft. Source: *Nerve surgery*, Susan Mackinnon (ed.), Thieme 2015. Reproduced with permission.

the nerve causes a reduction in microvascular flow. For the hour after relaxation the peak velocity is decreased to 66% of its normal velocity.¹²

In clinical practice we do not formally measure the tension across a neurorrhaphy; however we prefer to have a completely tension-free repair (Figure 56.2). Each nerve end is mobilized in order to re-approximate the two ends in a reasonable manner. A single 8–0 or 9–0 nylon suture is used to bring the newly fresh nerve ends together. If the nerve remains together after the limb is manipulated in its normal range of motion, the tension is deemed to be appropriate and the remainder of the repair completed with 9–0 nylon.

Strain on the nerve decreases the microcirculation and excessive tension will cause the repair to break down. Additional tricks such as positioning the arm in adduction or placing the wrist and fingers in flexion will significantly decrease the tension across the repair site. Depending on the location of the injury, this may increase the total length of available nerve; however, we do not recommend using postural manipulation in order to force primary repair. Not only can dehiscence occur when the joint near the repair is moved too early, but it may create significant stiffness from prolonged immobilization.¹³ An immobilized nerve also results in scarring at the repair site. If the nerve ends cannot be brought into reasonable proximity, it is recommended that the resulting gap is reconstructed with a nerve graft technique.

Type of repair: epineural versus fascicular

Any repair that withstands gentle range of motion is considered a 'tension-free' repair. Giddins *et al.*¹⁴ showed in a cadaveric study comparing suture size to the strength of an acute repair of the median nerve that 9–0 nylon withstood the greatest distractive forces. At a lower tension 10–0 snapped, and 8–0 sutures pulled out of the nerve tissue. However, in clinical practice, 10–0

and 8–0 sutures are often used based on the size of the nerve, the thickness of the epineurium and the amount of inflammation.

Fibrin glue may be used in place of suture repair when there is no tension. Experimentally lasers have been used to coapt the epineurium; however, the heat produced causes tissue damage and a suboptimal tensile strength at the repair site. Microsuture on the order of 8–0, 9–0 or 10–0 nylon placed with the use of loupe or microscopic magnification remains the gold standard. Approximately two-thirds of surgeons use a combination of microsutures and glue, whereas about one-third use one or the other. A personal preference is not to use a nerve wrap.

External markers, such as a vessel on the surface and matching the fascicular patterns, assist in aligning the two nerve ends (Figure 56.3). Overlaps should be avoided. By placing the sutures in the epineurium after the fascicles have been trimmed back behind the level of the epineurium, a sleeve is created with the external connective tissue. For larger nerves, a fascicular repair is possible, where the perineurium acts as the epineurium. As long as the fascicles do not overlap, both techniques give similar results.¹⁵ We feel that neither repair is superior to the other. The more critical issues are tension and alignment to avoid fibrosis.¹⁶

Our preferred method for repair is a group fascicular repair with the aim of aligning the sensory/motor groups appropriately. The least number of epineural sutures, using 9–0 nylon to approximate the ends and keep the repair intact through a full range of motion, is used. If there is a slight mismatch in size, as in the setting of a nerve transfer, we can improve that size mismatch by going more proximally on the recipient nerve to make the diameter smaller and more distally on the donor nerve to make a cross-sectional area greater. We will occasionally also use fibrin glue, but do not use nerve wraps as we have seen these remain present years after placement, causing neural ischaemia and pain.

Figure 56.3 Epineurial and fascicular nerve repair. (a) Epineurial nerve repair. (b) Fascicular nerve repair. Source: *Nerve surgery*, Susan Mackinnon (ed.), Thieme 2015. Reproduced with permission.

Figure 56.4 Types of nerve repairs. Primary nerve repairs and nerve grafting occur in a traditional end-to-end fashion with its native nerve. When a nerve is transposed to another nerve, it is described as a nerve transfer. Nerve transfers can have a coaptation of an end-to-end, end-to-side or supercharge end-to-side fashion. Traditional nerve transfers occur from donor to recipient in an end-to-end fashion. End-to-side nerve transfers is described as the recipient nerve end being transferred to the side of the donor nerve. Opposite of an end-to-side, supercharge end-to-side nerve transfers is described as the donor nerve end being transferred to the side of a recipient nerve. Source: *Nerve surgery*, Susan Mackinnon (ed.), Thieme 2015. Reproduced with permission.

Type of repair: end-to-end versus end-to-side

Most nerve repairs, whether primary or with a graft repair, are performed end-to-end. We recommend end-to-end repair for all motor, mixed nerves and sensory nerves in critical distributions. We use sensory end-to-side repair for non-critical sensory nerves (Figure 56.4) such as the dorsal cutaneous branch of the ulnar nerve. We also use end-to-side to restore sensation to a donor sensory nerve graft territory, such as

transferring the distal end of the medial antebrachial cutaneous to the sensory (lateral) side of the median nerve.

When we do sensory end-to-end nerve transfers (for example, the third webspace median to ulnar sensory), we do an end-to-side of the distal end of the donor nerve (third webspace median) to an adjacent normal sensory nerve (ulnar nerve). This transfer is conducted to restore sensation in the donor nerve distribution (third webspace median).

Figure 56.5 Nerve regeneration in end-to-side nerve repairs. The two types of end-to-side nerve repairs or transfers are the traditional end-to-side and supercharge end-to-side. End-to-side nerve transfers have two sprouting mechanisms that are characteristic of either motor or sensory nerves. **(a)** Regenerative sprouting occurs in motor nerves in response to an injury. In order to elicit regenerative sprouting for a nerve transfer, a partial neurectomy and a proximal crush is required. The proximal crush causes an axonometric injury and creates a proximal regenerative front that regenerates into the recipient nerve and backfills the donor nerve. **(b)** Spontaneous collateral sprouting occurs in sensory nerves. Due to the spontaneous sprouting, no injury is required except for a perineurial window for the nerve fibres to regenerate through. **(c)** Supercharge end-to-side nerve transfer is where the donor nerve end is transferred into the side of a recipient nerve. This allows nerve fibres to regenerate into the recipient nerve through a perineurial window without sacrificing the integrity of the donor nerve. Source: *Nerve surgery*, Susan Mackinnon (ed.), Thieme 2015. Reproduced with permission.

While sensory axons can spontaneously sprout collateral axons with respect to end-to-side repairs, motor axons need to have a proximal injury in order for 'traumatic' sprouting to occur (Figure 56.5).¹⁷ One setting where we employ this technique is for the spinal accessory to suprascapular nerve transfer. The suprascapular recipient nerve is transferred end-to-side to the spinal accessory donor nerve via a partial neurectomy in the donor nerve. An area of the spinal accessory nerve proximal to the repair is crushed with micro forceps to initiate sprouting into both the suprascapular recipient nerve and the spinal accessory donor nerve to minimize deficit of the donor nerve.

Based on our experimental studies, we had used a reverse end-to-side nerve transfer to augment recovery in 60 patients with second- and third-degree injuries. The normal anterior interosseous motor nerve branch to the pronator quadratus is transferred to the side of the motor component of the ulnar nerve, about 8–9 cm proximal to the wrist crease. Each of the 2–3 distal anterior interosseous nerve branches are sewn to the side of the ulnar motor fascicular group, which in general

includes 2–3 fascicles. We believe these anterior interosseous nerve axons both innervate and 'babysit' the ulnar intrinsic muscles, in essence creating a Martin–Gruber anastomosis. Results have been very encouraging.

Intraoperative nerve stimulation

In our practice, a detailed clinical examination, combined with preoperative electromyogram/nerve conduction studies (EMG/NCS) completed by our skilled and experienced neurologists have made intraoperative nerve monitoring unnecessary. We do routinely, however, use a handheld nerve stimulator in the operating room. It provides muscle contraction, but no information about sensory recovery and is used when motor nerve transfers are performed. It allows us to pick out redundant motor nerve fascicles, which will be transferred into non-functioning motor nerves to restore function (Figure 56.6). For routine acute lacerations that require grafting or primary repair, there is no additional benefit to

Figure 56.6 Intraoperative electrical stimulation of nerve for identification. Intraoperative electrical stimulation allows for identifying motor and sensory components of a normal nerve, in addition to determining whether a motor nerve has innervated a muscle following an injury. Evaluation within 72 h post injury will allow electrical stimulation of the distal injured nerve for identification. After 72 h, the distal injured nerve will not respond to electrical stimulation due to the degeneration process. (a) This patient had a C7 spinal cord injury, where the peripheral neurons were intact and the central neurons were compromised, and underwent a nerve transfer. Interfascicular neurolysis of the median nerve revealed its fascicular component that were identified through electrical stimulation. (b, c) After proximal transection of the flexor carpi radialis and anterior interosseous nerve fascicles, the nerve fascicles continued to respond to electrical stimulation and are expected to respond for another 72 h post transection. Source: *Nerve surgery*, Susan Mackinnon (ed.), Thieme 2015. Reproduced with permission.

the use of nerve stimulation, unless it is performed in motor and mixed motor nerves transected and repaired within 72 h. For a partial nerve injury with neuroma involving only a portion of the nerve's cross-sectional area, a nerve stimulator can help determine which motor nerve fascicles to preserve, while resecting the damaged tissue. In nerves that are purely or mostly sensory fibres, a handheld nerve stimulator is not useful.

Factors affecting outcome

Many factors beside technique affect nerve repair and age of the patient seems to be the most important factor. From historical data, we know that nerve repair in children and young adults yields better results than in adults. One reason is that the nerve has a shorter distance to travel. Nerves regenerate at 1–1.5 mm/day and in a child, the nerve recovery would be expected to reach the intended target organ earlier than in an adult and thus have a quicker recovery. Secondly, a child's brain has greater plasticity and more neural activity than an adult, thus the child has an enhanced ability to process the reinnervated motor and sensory within the brain cortex.

The type of injury, the location and the degree or depth of the injury affect the outcome. A sharp laceration will have less associated soft-tissue trauma as a crush or avulsion injuries at the same level. Proximal injuries contain may contain mixed nerves and may affect larger muscle or sensory domains. The reconstruction can be more challenging and a minor misalignment of fascicles has greater consequences than a more distal injury. Sensory nerve lacerations in the finger repaired a few days after the injury usually have excellent outcomes while sensory nerve neuromas requiring reconstructed with grafts because of a finger crush months after the injury do not recover as well. Often the internal damage is underestimated and if care is not taken to be outside the zone of injury, the repair may be suboptimal.

When considering the surgical intervention, timing, type of repair, tension and alignment of fascicles have an equally important role in the outcome of nerve recovery. Earlier repair usually results in better outcomes and the best results occur if the repair can be performed within 3 weeks. A good result can still be expected if the repair occurs before 6 months, although a nerve graft will most likely be needed. Functional recovery (FR) is directly proportional to the number of motor axons reaching the target endplate and inversely proportional to the time of denervation. 'Time=muscle.'

$$FR \propto \frac{\text{Number of motor axons reaching target endplate}}{\text{Time of denervation}}$$

Bridging the gap: current techniques

The gold standard for a nerve injury repair is a primary neurorrhaphy within the first few days. The belief that a primary nerve repair with a single coaptation site is superior to a nerve reconstruction with a graft involving two neurorrhaphy sites is supported by multiple animal studies (Figure 56.7).¹⁸ A certain

percentage of fibres may be lost at each neurorrhaphy site, thus limiting the number of repair sites to one should be the goal. Some studies suggest that as much as 50% of regenerating sensory or motor axons may never reach the correct end organ.¹⁹ Tension at the repair is to be avoided as mentioned earlier and a primary repair should never be forced together. Rather, a graft repair should be performed. Making sure to be outside the zone of injury is essential (Figure 56.8) as well as using meticulous microneurosurgical technique, accurately matching the sensory and motor nerve fascicles, and begin early protected motion to allow neural gliding.

Figure 56.7 Primary nerve repair of a sharp lacerating nerve injury. Nerve injuries that are sharp and lacerating induce a small zone of injury, which can allow for a tension-free primary repair. (a) This patient had a sharp lacerating injury to the right palm, which involved the digital nerves and tendons of the flexor digitorum superficialis and profundus. These tendons were repaired in zone 3. (b) Digital nerves of the median nerve were identified and transected. (c) The proximal and distal ends of the digital nerves were trimmed by evenly transecting the ends for healthy nerve fibres. Primary repairs were performed without tension in all range of motion of the fingers, wrist and hand. Source: *Nerve surgery*, Susan Mackinnon (ed.), Thieme 2015. Reproduced with permission.

Figure 56.8 Zone of injury within a nerve. The zone of injury is dependent on the mechanism of injury. A sharp lacerating injury will have a small zone of injury, while blunt, stretch, gunshot and traumatic injuries will have large zones of injury. It is important to excise the injured nerve outside the zone of injury (dotted lines) to allow proximal nerve fibres to regenerate distal without inhibitory factors from the injury. Histological section of proximal nerve exhibits normal nerve fibres. Histological section of neuroma exhibits disorganized patterns of fibres in a dense stroma of connective tissue. Histological section of distal nerve, distal to the injury, exhibits degenerating nerve fibres. Magnification 400 $\times$, Toluidine Blue. Source: *Nerve surgery*, Susan Mackinnon (ed.), Thieme 2015. Reproduced with permission.

When primary neurorrhaphy is not possible, mobilization and elongation of both nerve ends can bridge small gaps usually less than 5 mm in size because of the inherent elasticity of a nerve.²⁰ When there is extreme tension and contamination, scarring of the repair site will invariably occur and a proximal neuroma develop. We recommend reconstructing the nerve with a graft and accepting two neurorrhaphy sites than perform a single neurorrhaphy under unfavourable conditions.^{13,21} Several options for gap reconstruction are listed below with the pros and cons for each option (Table 56.3).²² An autologous nerve graft remains the most common technique for repairing defects in peripheral nerves, although an acellular nerve allograft can be used for short nerve gaps ≤ 3 cm for small diameter/non-critical nerves.^{23–26} In the senior author's opinion, if an acellularized allograft ≥ 4 cm is used, it will not consistently drive axons across the allograft but will help to 'dwindle' nerve regeneration such that a painful neuroma will not develop. In a non-critical digital nerve this would be an acceptable result, as collateral sprouting of an adjacent sensory nerve will occur to provide some sensation and the long ≥ 4 cm allograft will 'dwindle' regeneration to prevent painful neuroma formation.

The purpose of the nerve graft is to act as guide for the regenerating axon. The most common harvested nerve graft is the sural nerve; however, when working in the upper limb we prefer to use an expendable nerve in the field such as the lateral or medial antebrachial cutaneous nerve or the distal anterior or posterior interosseous nerve.^{27–29} Experimental studies comparing motor, mixed and sensory nerve grafts to repair a motor nerve defect shows a motor or mixed nerve grafts is a superior graft choice than a sensory nerve graft.^{30,31} However, in clinical practice, expendable motor nerve grafts are extremely limited. The gracilis muscle nerve and the distal anterior interosseous nerve are the two motor nerve grafts that cause the least morbidity.

Nerve grafts typically are less than 3 mm in diameter, which is a consequence of the historically poor results achieved when full-thickness nerve trunks were used as grafts.³² When necessary, the grafts may be cabled together. It is believed that smaller grafts will revascularize more easily, ultimately contributing to the success of the graft. There is no consensus on what is the maximum length a graft may be and still achieve regeneration of the nerve, although there are a few studies that have shown success with

Table 56.3 Options for management of a nerve gap

Type	Advantage	Disadvantage
Autograft	Gold standard for reconstruction Schwann cells in extracellular matrix	Second operative site Results in donor sensory loss Potential for neuroma formation/pain Sensory nerve autograft do not support motor regeneration as well as motor or mixed sensory nerves Limited available length
Acellularized allograft	Functional recovery is almost equivalent to autograft No donor site morbidity Non-immunogenic	Length limitation (<7 cm) No Schwann cells
Allograft	Functional recovery is almost equivalent to autograft No donor site morbidity	Requires patient systemic immunosuppression (about 18 months) Patient vulnerable to opportunistic infections
Conduit	Guides regenerating nerve to intended target No donor site morbidity	Length limitation Only for small-diameter sensory nerves
End-to-side	No length limitation	Poor sensory results Motor requires donor neurectomy
Reverse end-to-side	Augment partial motor/sensory nerve injury	Requires knowledge of topography Requires knowledge of expendable donors May need nerve autograft or acellular graft
Nerve transfer	Earlier motor/sensory target recovery	Requires expendable donor Requires motor (sensory) re-education Requires knowledge of topography

grafts as long as 20 cm.^{33,34} However, in general nerve autografts ≤ 6 cm seem to be more reliably successful if close to the target, compared with longer nerve autografts. Failure of the long nerve autografts was the stimulus to move towards nerve transfer techniques in the 1990s, just as failure with nerve repair done under tension to overcome longer gaps was the stimulus to the shift towards the nerve grafts by Millesi in the 1970s.

Free vascularized nerve grafts were introduced in 1976 by Taylor and Ham in order to treat these longer gaps.³⁵ For smaller defects, a vascularized graft and conventional graft do not appear to differ in clinical outcome; however, Doi *et al.*³⁶ recommend using free vascularized nerve grafts when the gap distance is greater than 6 cm with associated soft tissue loss over the repaired area. Currently the indication for a free vascularized nerve graft is for reconstruction of large-diameter nerve grafts, such as the ulnar nerve in brachial plexus avulsion surgery.^{37,38}

The gold standard for repairing a nerve gap injury is with an autologous nerve graft. (Figures 56.9 and 56.10) Because the major disadvantage of autografts is the donor site morbidity and the limited number of donor nerves available, new approaches to repairing the gap defect have been created. This has led to the use of vein grafts, biological and synthetic conduits, and nerve allograft as substitutes for short gap injuries. The current consensus is that for a sensory deficit in a non-critical, small-diameter nerve less than 3 cm, any of these options is equally reliable,³⁹ although more recent literature supports the fact that while nerve allografts offer excellent results in this gap range,

the conduit results can vary greatly depending on type of material when the gap is greater than 15 mm.^{40,41} Neither conduits nor allografts are currently recommended for gaps longer than 3 cm or for gaps in motor and mixed motor defects, although clinical trials are in progress assessing the role of allografts in some of these situations.⁴⁰

Acellular human processed nerve allografts have been available for clinical use since 2008 as an alternative to conduits (Figure 56.11). In an animal study, Whitlock²⁴ showed that the acellular allograft was superior to an empty conduit because of its extracellular matrix, but inferior to an autograft, which provides Schwann cells in addition to the extracellular matrix. Initial clinical trials using allografts for short sensory gaps show recovery comparable to autografts and better than a conduit.⁴² Because this is human tissue, it retains its three-dimensional structure, including epineurium, fascicles, endoneural tubes and laminin, and it is believed that the scaffold allows for repopulation of the host cells, as in autologous nerve tissue. The product is expensive; however, since it shortens operative time, it allows the surgeon to be more efficient if working without assistance and may save overall operating room costs.

The patient benefit is no morbidity of an additional scar and associated sensory loss. It handles similarly to autologous nerve and comes in various widths ranging from 1 to 5 mm in diameter and up to 70 mm in length. Interestingly, research studies have not shown successful regeneration at a distance of 40 or 60 mm (Figure 56.12).²³

Figure 56.9 Case of median nerve reconstruction at the wrist with third webspace graft. This patient had a significant injury to the median nerve at the wrist that involved the sensory components. **(a)** The zone of injury was identified and the neuroma was resected with proximal and distal median nerve components identified. The third webspace was further neurolysed proximally to mobilize graft material. **(b)** The proximal end of the third webspace fascicle was transected and used as a nerve graft to repair a portion of the median nerve. The proximal remainder of the third webspace was transposed proximally to prevent a painful neuroma. The distal third webspace was end-to-side transferred to the sensory component of the ulnar nerve to provide rudimentary sensation for donor deficit. Source: *Nerve surgery*, Susan Mackinnon (ed.), Thieme 2015. Reproduced with permission.

Autologous vein grafts are the oldest conduit and are still used both as a primary conduit and as a wrap.⁴³ Biological conduits, including bone, artery and muscle⁴⁴ have been used, but not as conventionally as vein, collagen⁴⁵ or small intestine submucosa (SIS).⁴⁶ Biodegradable synthetic conduits such as polyglycolic acid are currently used, while non-degradable nerve guides made from silicone have fallen out of favour.⁴⁷ Their major disadvantage is leaving foreign material that potentially causes a chronic reaction with excessive scarring (Figure 56.13).

Of the commercial conduits in use today, collagen and polyglycolic acid are biodegradable, while the SIS conduits are resorbed and replaced by the body's natural tissue. Like the original vein graft, they are used as primary conduits or as nerve wraps. They provide at least protective sensation and, in some cases, good sensory recovery.⁴⁸ Since the conduit is essentially a hollow tube with no structure, experimental studies have shown that placing morselized nerve into the tube can help to augment nerve growth.⁴⁹ When using a conduit, we recommend placing a

small portion of the proximal nerve into the conduit to provide a source of Schwann cells.

Nerve transfer: alternative to conduits

The introduction of the nerve transfers in the early 1990s has resulted in a paradigm shift in how nerve injuries are managed and for the severe proximal injuries nerve transfers have resulted in marked improved functional results.

Tendon transfers set the stage for the development of motor nerve transfers. The principles are similar expect that a single nerve transfer can innervate more than one muscle unlike a tendon transfer. The type of muscle fibre unit and the insertion of the tendon will influence the ultimate effectiveness of that muscle's contraction in its new position.^{50,51} Excursion and vectors do not need to be considered in nerve transfers, although the number of axons in the donor nerve will affect the overall

Figure 56.10 Second webspace grafted with a medial antebrachial cutaneous nerve graft. (a) The medial antebrachial cutaneous nerve (MABC) was isolated within the arm for donor material. (b) The MABC was then transected with the distal end transferred to the sensory component of the median nerve through and end-to-side epineurial window fashion. The sensory component of the median nerve is located on the superior aspect of the median nerve. Note that in this image, the median nerve has been rotated so that it appears to be on the inferior portion. (c) The MABC graft was used to repair the remaining portion of the median nerve. The thenar branch and remaining sensory branches to the thumb were protected and were found to be not injured. Source: *Nerve surgery*, Susan Mackinnon (ed.), Thieme 2015. Reproduced with permission.

strength of the recovery. We like to use a donor nerve with a similar number of motor axons as the recipient nerve we are targeting. Expendable nerves and redundant fascicles or branches are used, avoiding nerves that innervate critical functions.

The major advantages of a nerve transfer over that of a tendon transfer are that: (a) sensory nerve transfers can restore sensibility; (b) a nerve that innervates multiple muscle groups can be restored with a single nerve transfer; and (c) the insertion and attachments of the muscle(s) in question are not disrupted, thus the original muscle function and tension are maintained. When choosing donor nerves for transfer, a nerve that innervates a synergistic muscle group is preferable, as it facilitates postoperative re-education. Although a nerve supplying a non-synergistic, or even antagonistic, muscle group may be used, more motor retraining may be necessary to learn to contract the newly reinnervated muscle. Although a synergistic nerve transfer is ideal, antagonistic nerve transfers can be successfully utilized in some cases, such as branches of radial nerve used to restore median nerve function. In median to

radial nerve transfers we are careful to transfer flexor carpi radialis to the posterior interosseous nerve and flexor digitorum sublimis nerve to the extensor carpi radialis brevis nerve (Figure 56.14). Similarly, when we do a double fascicular transfer (DFT) for elbow flexion we will try to always use the median fascicle to transfer to the brachialis nerve and the ulnar fascicle to transfer to the biceps nerve for faster motor re-education (biceps supinates and median nerve pronates, so it is a bit harder to re-educate if done the opposite way).

Nerve transfers offer the advantage of converting a proximal high-level nerve injury to a low-level nerve injury by moving the reconstruction closer to the target muscle or sensory territory of the affected nerve. In high ulnar and high median nerve injuries this is critical. A donor nerve which is close to the injured nerve is used in nerve transfers and usually nerve grafts are not needed. The donor and recipient nerves are neurolysed from the main nerve so that an end-to-end repair between donor and recipient fascicles can be done. Nerve transfers are discussed in greater detail elsewhere.

Figure 56.11 Reconstruction of a non-critical sensory nerve with acellularized nerve allograft. This patient had a lacerating injury at the base of the long finger. (a) Upon exploration, the palmar digital artery was found to be transected. The palmar digital nerve to the radial aspect of the long finger was found to be intact but injured. (b) The digital nerve had been longitudinally injured by the sharp object. (c) The zone of injury was identified and resected until healthy nerve was seen at both proximal and distal ends. (d) A 2 cm acellularized allograft was used to bridge the nerve gap for a tension-free repair. The nerve repair was tested for tension by putting the long finger through full flexion and extension. Figure 56.12 Nerve regeneration through various lengths of isografts and acellularized nerve allografts (ANA) in a fluorescent GFP rat model. Regeneration through a short 2 cm graft were similar between an isograft and ANA, however as the graft length increased, the regeneration distance of the ANA decreased in comparison to an isograft. Source: *Nerve surgery*, Susan Mackinnon (ed.), Thieme 2015. Reproduced with permission.

Most nerve transfers are done with an end-to-end repair. As mentioned, the circumstances in which an end-to-side neurorrhaphy is utilized continues to evolve.^{52–54} The majority of these end-to-side transfers are for sensory restoration; however, when a motor nerve transfers is performed with this technique, a partial neurectomy to facilitate end-to-side regeneration is required.¹⁷

Nerve transfers have evolved because of our understanding of internal topography and the redundancy built into the human nerve. Intraoperative electrical stimulation with a hand held nerve stimulator identifies the motor donor fascicles, allowing for selection of the donor nerve without extensive

neurolysis. Fascicle groups can easily be cleaved from the main nerve even in the proximal extremity without injuring unintended fascicle groups because the nerves do not merge distally as once thought. Instead, the fibres course parallel to each other via an extensive plexus pathway.⁵⁵

Postoperative management

We recommend immobilizing for 1–2 weeks after a simple nerve repair; however, gentle protected range of motion can be started as early as 2–3 days. No consensus exists on what length of time

Figure 56.13 Failed nerve wrap case. Patient presented with a right median nerve injury following a carpal tunnel release that was repaired with a nerve wrap 2 years postoperatively. The sensory component of the median nerve was injured and repaired with a nerve wrap. **(a)** Upon exposure, the median nerve was identified with a large neuroma. **(b)** Histological evaluation revealed scarce nerve fibres in the distal segment. **(c)** The middle segment displayed significant disorganized architecture with no axonal organization, consistent with neuroma. **(d)** The proximal segment revealed healthy nerve fibres. **(e, f)** The neuroma was resected and the motor and sensory components of the median nerve identified. The gap was reconstructed with several medial antebrachial cutaneous nerve cable grafts with an individual graft for repair of the motor component. Source: *Nerve surgery*, Susan Mackinnon (ed.), Thieme 2015. Reproduced with permission.

for immobilization is necessary. However we believe that early, protected range of motion is critical for neural gliding and an excellent result. In patients with concomitant tendon or bony injuries, the postoperative protocol is guided by the injury most

difficult to rehabilitate. For example, in finger lacerations in which both tendon and nerves are transected, a flexor tendon protocol is followed postoperatively in order to maximize tendon gliding. The nerve repair, while important, is easier to reconstruct

Figure 56.14 Illustrative median to radial nerve transfer. Two nerve transfers occur in the median to radial nerve transfer for restoration of wrist/finger extension. The donors (green) and recipients (red) occur in the following specific sets for optimal results with postoperative rehabilitation: (1) flexor carpi radialis to posterior interosseous (PIN) and (2) flexor digitorum superficialis (FDS) to extensor carpi radialis brevis. PIN and FDS are antagonistic. Source: *Nerve surgery*, Susan Mackinnon (ed.), Thieme 2015. Reproduced with permission.

if necessary later. In the case of fractures, in addition to nerve and soft tissue injuries, the bony fixation takes precedence.

Most patients complain in the postoperative period of paraesthesia and electrical shocks, which extend beyond the area of the injury. Most of these can be controlled with neurotropic medications such as nortriptyline or pregabalin. In patients with neuropathic pains, prompt involvement of a pain specialist is critical. Physical therapy and occupational therapy continue for an extended rehabilitative period to prevent joint contractures while the nerve recovery is in progress, to fabricate and adjust protective splints, and to assist in motor and sensory re-education as the recovery process is underway. Whenever possible, our hand and nerve therapists evaluate and advise patients pre-operatively and re-education begins within the first month of surgery, long before results of regeneration are anticipated. Similarly mirror training is used to keep the 'brain open' and receptive for eventual recovery.

Complex regional pain syndrome

Complex regional pain syndrome (CRPS) was documented as early as 1864 during the American Civil War by Silas Weir

Mitchell in his book titled *Gunshot Wounds and Other Injuries of Nerves*, where he describes 'long after the trace of the effects of a wound has gone . . . neuralgic symptoms are apt to linger, and too many carry with them throughout long years this final reminder of the battlefield'.⁵⁶ The term *causalgia* was coined at that time after the Greek words *kausis*, meaning burning, and *algos*, meaning pain. In 1900, Sudeck noted muscle atrophy and demineralization of bone described as 'patchy osteoporosis of the small bones of the hands or feet and the distal metaphysis of the forearm or tibial bones'.⁵⁷ This gave rise to the term *Sudeck's dystrophy*. Almost 50 years later, the term *reflex sympathetic dystrophy* was used to describe what Evans assumed to be sympathetic nervous system involvement with the abnormal activity observed in the affected extremities.⁵⁸ However, the signs and symptoms of this disease did not consistently show sympathetic involvement, a reflex mechanism or the presence of dystrophy. For this reason, the Special Consensus Group of the International Association for the Study of Pain (IASP) created the term *complex regional pain syndrome* in 1994 to allow for a more broad inclusion of patients that showed varying levels of the disease process.

Clinical features and diagnosis

Although there is currently no gold standard to test the diagnosis of CRPS, it is imperative to perform a thorough history and physical examination. The clinical diagnostic criteria developed in 1994 by the IASP consisted of the following:

- 1 Presence of an initiating noxious event or reason for immobilization.
- 2 Disproportional pain, allodynia, or hyperalgesia from a known inciting event.
- 3 Signs or symptoms of any evidence showing oedema, skin changes, blood flow, or abnormal sudomotor activity in the region of the pain.
- 4 No other condition that would otherwise explain the degree of pain or dysfunction.⁵⁹

The sensitivity for this set of diagnostic criteria was high at 0.98 but was unfortunately met with a low specificity of 0.36, leading to an overdiagnosis of the pain syndrome.⁶⁰

In 2007, the Budapest criteria was developed to refine and create stricter guidelines for both research studies and clinical diagnosis.⁶¹

- 1 Presence of continued disproportional pain from the known inciting event.
- 2 Must report at least one symptom in three of the following four categories:
 - Sensory: hyperaesthesia, allodynia
 - Vasomotor: temperature asymmetry, changes in skin colour
 - Sudomotor/oedema: oedema, changes in sweating, sweating asymmetry
 - Motor/trophic: decreased range of motion, motor dysfunction (tremor, weakness, dystonia), trophic changes (hair, nail, skin).
- 3 Must report at least one sign in two or more of the following categories at the time of evaluation:
 - Sensory: hyperalgesia to pinprick, allodynia to touch or joint movement
 - Vasomotor: temperature asymmetry, colour asymmetry
 - Sudomotor/oedema: oedema, asymmetrical sweating, sweating changes
 - Motor/trophic: decreased range of motion, motor dysfunction, trophic changes.
- 4 No other condition that would otherwise explain the degree of pain or dysfunction.

In comparison, the Budapest criteria retained the exceptional sensitivity of the IASP criteria (0.99), but greatly improved upon the specificity (0.68).⁶² CRPS is further divided into two groups (CRPS 1 and CRPS 2), with the distinction being that CRPS 2 has the presence of a definable nerve lesion.

Other common diagnostic tests to aid in the diagnosis of CRPS include three-phase bone scintigraphy which can detect alterations in bone metabolism, quantitative sensory testing which can show impaired mechanical pain thresholds, and infrared thermography which can show differences in temperature in the affected region.

Epidemiology

CRPS is a rare disease with a prevalence of less than 2%.⁶³ The incidence of CRPS (CRPS 1 and 2) is conservatively estimated to be 6.28 per 100 000.⁶⁴ It is more common in younger adults, with a mean age of 41.8 years and with greater frequency in females than males (2.3–3:1).⁶⁵ A survey by Sharma *et al.*, revealed that CRPS more commonly occurs as a result from work-related injuries or surgery and is associated with functional impairment, sleep disturbance and suicidal ideation.⁶⁶

Pathophysiology

Although the majority of patients who develop this syndrome have an initiating inciting event such as trauma, surgery, ischaemia or nerve compression, it is unclear why only some patients develop CRPS. It is becoming increasingly apparent that multiple mechanisms may be involved in the development of this disease. Some of these mechanisms include an alteration to cutaneous sensory innervation with a reduction in C and A-delta fibre density, central and peripheral sensitization, an increase in the release of proinflammatory cytokines and neuropeptides, alterations in sympathetic nervous system function, and altered processing of nociceptive stimuli from cortical reorganization.⁶⁷

Treatment

Unfortunately, there is limited evidence as to the most effective treatment regimens for CRPS. This is partly due to our inadequate understanding of the disease, as well as the greater need for more well-designed, randomized controlled trials. As such, current recommendations are based on treatment modalities for other neuropathic pain conditions, but is largely accepted to be part of a multimodal, multidisciplinary approach. Of utmost importance is that earlier recognition/diagnosis, and thus earlier initiation of targeted therapy, typically achieves greater results.

Pharmacological therapy includes antidepressants such as tricyclic antidepressants (TCAs) and serotonin noradrenaline reuptake inhibitors (SNRIs), which, although not specifically studied for CRPS, have been shown to be quite effective in neuropathic pain. Anticonvulsants and membrane stabilizers such as gabapentin and pregabalin have been shown to be effective in diabetic neuropathy and postherpetic neuralgia. Corticosteroids have been used to help decrease the acute inflammatory process that occurs during CRPS. NMDA receptor antagonists, such as ketamine, showed short-term pain relief, thought to be due to modulation of central sensitization. Bone resorption inhibitors, namely bisphosphonates, has been advocated for use in patients with CRPS as there is often the accompaniment of bone demineralization. Several studies using either intravenous or oral bisphosphonates have shown improvement in both reported pain scores as well as functional assessment in both short-term as well as medium-term outcomes.⁶⁸ More novel pharmacological approaches include the use of free radical scavengers such as dimethyl sulfoxide (DMSO) 50% and *N*-acetylcysteine (NAC), which have shown medium-term benefit.

Interventional strategies include sympathetic nerve blocks, stellate ganglion or lumbar sympathetic, for both diagnostic and treatment purposes. As a diagnostic tool, these blocks to help differentiate sympathetically maintained pain from sympathetically independent pain. Should these blocks provide relief, they typically do not last greater than 7 days. As such, these injections should not be performed as the sole form of treatment, but as part of a multidisciplinary regimen that includes physical therapy where these interventions allow patients to progress further with physical therapy and with modalities such as desensitization to a more restorative functional goal. A small study showed that intrathecal baclofen can be useful for otherwise treatment-resistant dystonia that may develop as a result of CRPS.⁶⁹ Spinal cord stimulation (SCS) has been shown to be beneficial in patients with CRPS who have failed conventional therapy. In a 5-year follow-up study, SCS plus physical therapy (PT) showed a greater reduction in pain than PT alone at 2 years, though at the 5-year mark, both groups had similar results.⁷⁰

Physical and occupational therapy with the goal of functional restoration continues to be the benchmark for successful CRPS treatment. Exercises that target myofascial release, isometric strengthening and increased range of motion as well as desensitization techniques should be instituted as soon as possible for the best results. As an increasing amount of evidence supports cortical reorganization as a component of CRPS, there is also an increasing amount of evidence that supports the beneficial effects of graded motor imagery (GMI). Graded motor imagery is a three-stage programme consisting of implicit motor imagery (left/right handedness), explicit motor imagery (imagined movements) and mirror therapy. A randomized controlled study showed that at 6 and 12 weeks, those patients who underwent GMI had significantly less pain and swelling. There is definitely a role for nerve surgery in the management of CRPS. We have had success in improving pain relief in patients with CRPS 1 when a nerve injury is the inciting factor (e.g. carpal tunnel syndrome following wrist fracture) and of course in CRPS 2 when pain is localized to a specific nerve injury.

Summary

Primary neurorrhaphy remains the gold standard for all nerve repair techniques, whereas an autologous nerve autograft is the gold standard for bridging a nerve defect. Since the first implementation of a nerve allograft in 1870 by Philipeaux and Vulpian, significant contributions regarding suturing technique, neural topography and the biology of nerve regeneration have transformed the way we approach nerve reconstruction. Although primary neurorrhaphy and autografts are the most common methods for repair, several newer options are at our disposal. Nerve transfers have revolutionized our approach for treating devastating brachial plexus injuries, converting them to highly selected upper and lower motor and sensory nerve injuries.

Nerve allografts and conduits offer alternatives to autologous nerve grafting when needed. However, after decades of research towards defining the best nerve substitutes, we still struggle to find an alternative as good as a nerve autograft even for small diameter/short gap injuries. For these short injuries, autograft material is readily available. Intuitively, culturing recipient Schwann cells to repopulate a conduit or acellularized nerve allograft is appealing. This concept has, however, been explored for decades in the laboratory without clinical translation. It is unlikely that modifications of nerve conduits or acellularized allografts are going to provide a nerve graft alternative in the near future for injuries where the need is greatest (long-gap/large-diameter nerve injury). It is likely that other avenues of basic research will lead to the 'next' meaningful advance in this field.⁷¹

CHAPTER 57

Brachial plexus injuries and reanimation

Kirsty U. Boyd,¹ Kristen M. Davidge¹ and Susan E. Mackinnon²

¹Division of Plastic Surgery, The Ottawa Hospital/Ottawa University, Ottawa, ON, Canada

²Department of Surgery, Division of Plastic and Reconstructive Surgery, Washington University School of Medicine, St Louis, MO, USA

Anatomy

The brachial plexus comprises a complex grouping of nerve fascicles, giving function and sensation to the upper extremity. Progressing from proximally to distally, the plexus is divided into regions termed roots, trunks, divisions, cords and branches. Within these nerves, there is a clearly defined internal topography that will guide future reconstructive efforts (Figure 57.1).

Roots

The traditional brachial plexus has contributions from cervical roots C5–C8 and thoracic root T1. Anatomic variations of this included a prefixed plexus, which has additional contribution from C4, and a postfixed plexus, which has additional contribution from T2. The spinal roots pass between the anterior and middle scalene muscles. There are three nerve branches exiting from the root level. The dorsal scapular nerve arises from the C5 nerve root and supplies the rhomboid muscles and the levator scapulae muscle. The long thoracic nerve arises from roots C5, C6 and C7 and supplies the serratus anterior muscle, which stabilizes the scapula. The nerve to subclavius arises from the distal C5 and C6 nerve roots. This nerve supplies the subclavius muscle, which is unable to be tested on clinical examination.

Trunks

In the inferior portion of the posterior cervical triangle, the roots combine to form trunks. The upper trunk is formed from the combination of the C5 and C6 nerve roots. The middle trunk is a continuation of the C7 root. The lower trunk is formed from C8 and T1. There is a single branch off the upper trunk that is critical for shoulder function. The suprascapular nerve departs from the upper trunk, travels deep to the trapezius muscle and runs through the suprascapular notch of the scapula to supply the supraspinatus and infraspinatus muscles.

Divisions

Passing deep to the clavicle, each trunk divides into an anterior and posterior division. There are no extraneous branches at the level of the divisions.

Cords

The divisions pass deep to the pectoralis minor muscle and combine in a predictable fashion to form the cords. The cords are named in relation to their anatomic location around the axillary artery. The anterior divisions of the upper and middle trunks combine to form the lateral cord. The medial cord is the continuation of the anterior division of the lower trunk. All of the posterior divisions combine to form the posterior cord.

Branches

There are several branches that arise from the cords. The lateral cord gives off the lateral pectoral nerve, which innervates the clavicular head of the pectoralis major. The medial cord gives off the medial pectoral nerve, which innervates the sternocostal head of the pectoralis major muscle. The medial brachial cutaneous and medial antebrachial cutaneous nerves also branch from the medial cord supplying sensation to the medial aspect of the upper arm and forearm. More distally, the lateral and medial cords each contribute to the median nerve, supplying the sensory and motor functions of the nerve respectively. This relationship continues distally and is useful for understanding the internal topography of the median nerve, where motor fascicles are located on the medial side of the nerve and sensory fascicles remain more lateral. At the level of the wrist, the most radial fascicles of the median nerve will supply the first webspace. Following its contribution to the median nerve, the lateral cord becomes the musculocutaneous nerve. This nerve innervates the coracobrachialis, biceps brachii and brachialis. The terminal portion of this nerve is the lateral cutaneous nerve of the forearm. After contributing to the median nerve, the medial cord becomes the ulnar nerve, which, after innervating the flexor carpi ulnaris and the small and ring flexor digitorum profundus muscles, is primarily responsible for all of the intrinsic musculature of the hand.

The internal topography of the ulnar nerve can best be remembered as sensory–motor–sensory, where the most medial portion of the nerve will eventually contribute to the dorsal cutaneous ulnar branch, exiting the main portion of the ulnar

Figure 57.1 Internal topography of the brachial plexus. **(a)** Cross-sections of the upper and middle trunks delineating fascicular grouping and **(b)** internal topography at the level of the cords and branches. Source: *Nerve surgery*, Susan Mackinnon (ed.), Thieme 2015. Reproduced with permission.

nerve approximately 9 cm proximal to the wrist crease and providing sensation to the dorsal ulnar aspect of the hand. After this division, the more medial 40% of the ulnar nerve will pass through Guyon's canal to become the deep motor branch and the more radial 60% will contribute to the superficial sensory branch (Figure 57.2).

The posterior cord gives off the upper subscapular nerve, the thoracodorsal nerve and the lower subscapular nerve. These branches innervate the superior portion of the subscapularis muscle, the latissimus dorsi muscle and the lower subscapularis/teres major muscles, respectively. The two most terminal branches of the posterior cord are the axillary nerve and the radial nerve. The axillary nerve travels through the quadrangular space (bounded by the humerus, the long head of triceps brachii, teres minor and teres major) with the posterior circumflex humeral artery. It innervates the deltoid and the teres minor, but also provides sensation to a patch of skin overlying the deltoid, sometimes known as the 'soldier's patch'. This sensory component is located at the most inferior portion of the axillary nerve. The radial nerve travels through the triangular interval (bounded by the teres major and the lateral and long heads of triceps brachii) with the profunda brachii artery. Wrapping around the spiral groove, the radial nerve goes on to supply the elbow, wrist, finger and thumb extensors.

Clinical history and assessment

Brachial plexus injuries occur in approximately 1% of multi-trauma victims, most frequently in young males.¹ The vast majority are due to motor vehicle collisions and of these, up to 84% may involve motorcycles.^{2,3} Due to these circumstances, many patients present with multisystem trauma requiring resuscitative procedures. Associated closed head injuries including loss of consciousness can occur in almost three quarters of patients, which can often result in a delay of recognition of a brachial plexus injury.¹ It is not uncommon for the patient to be the first to identify the injury. In the obstetrical population, approximately 1.6% of deliveries have a shoulder dystocia and of these, almost 20% experience a brachial plexus palsy.⁴

Acquiring a thorough history is critical in the investigation of a patient with a brachial plexus injury. The mechanism of injury may provide information to recognize a pattern of injury or to estimate the degree of injury. In a brachial plexus injury, information about birth weight, gestational age, shoulder dystocia, delivery aides such as forceps and duration of labour are useful. For a trauma, details about a motor vehicle collision, including the speed, direction of impact, use of safety equipment such as seatbelts or helmets, and concomitant injury may

Figure 57.2 The internal topography of the ulnar nerve. Source: *Nerve surgery*, Susan Mackinnon (ed.), Thieme 2015. Reproduced with permission.

be useful in ascertaining risk to certain structures. In the event of a blow or a fall, knowing the direction and weight of impact, location of impact and arm position can contribute valuable information. Knowledge of pre-existing upper extremity injuries and medical comorbidities is also useful. The patient's general medical status may contribute to candidacy for surgical intervention.

An important component of this history is related to pain. Patients should be questioned regarding the severity, location and nature of their pain to assist in determining musculoskeletal versus neuropathic components. Severe pain can be suggestive of root avulsions. Inclusion of a pain questionnaire at the initial assessment and then at subsequent visits can provide both quantitative and qualitative assessment of pain. Having a low threshold for starting neuropathic pain medications or involving a pain specialist is crucial for these patients, as pain management can be a significant problem.⁵ In addition, patients should be screened for depression and mood disorders, as the incidence in this patient population can be as high as 40%.⁶

In this patient population, serial clinical examination is crucial to determine spontaneous recovery. At the initial physical examination, a complete upper extremity sensory and motor examination should be performed with care to document both peripheral and central nervous system examination. Atrophy may not initially be present but will later mark denervated muscle groups. Having a systematic approach to the brachial plexus examination will allow for determination of patterns of injury and more specifically about level of injury. A thorough knowledge of the anatomy of the plexus can help to localize lesions simply by physical examination.

The location of scars on the upper extremity, shoulder and neck should be noted, from either trauma or surgical intervention. Joint mobility should be assessed for the entire extremity, and, in the setting of any decreased passive range of motion or stiffness, early intervention with an occupational or physiotherapist should be arranged to optimize overall outcome.⁷ Assessment should be carried out for concomitant findings such as a Horner's sign (ptosis, miosis and anhydrosis) which occurs due to injury to the cervical sympathetic fibres during avulsion of the C8 and T1 roots.⁸

Perhaps the most critical part of the physical examination is accurate documentation. Careful recording of the Medical Research Council (MRC) scale for muscle strength for each muscle group in an organized fashion will allow comparison over time. Given the known rate of recovery following nerve injury of 1 mm/day, this allows for assessment of whether spontaneous recovery is progressing at the expected rate, or whether surgical intervention may be appropriate. It should be remembered that examination for potential donors is as important as identifying non-functioning muscle groups. The preparation for surgical reconstruction of brachial plexus injuries is the biggest determinant of success.

Aetiologies

The aetiology of brachial plexopathy can be traumatic, iatrogenic, compressive, neuralgic amyotrophy or radiation.

Traumatic

The majority of brachial plexopathies secondary to trauma occur in young males, with up to 90% of cases comprising this patient population.¹ Traumatic injuries to the brachial plexus can be divided into open and closed injuries. Open injuries are those secondary to penetrating injury, such as knives or other sharp objects. These necessitate immediate surgical exploration. The majority of traumatic brachial plexus injuries are closed, and these can be composed of crush injuries or traction injuries. Crush injuries tend to occur after motor vehicle accidents, whereas traction injuries are more likely to be related to motorcycle accidents, skiing, falls and sports injuries.¹ In traction injuries, displacement of the upper extremity inferiorly combined with neck flexion contralaterally causes an increase in the neck-shoulder angle, which results in injury to the upper roots and trunks.⁹ This commonly occurs in both high-velocity injuries such as motorcycle collisions and also in lower velocity accidents such as sports injuries. The opposite can occur with strong upward force or traction on the upper extremity increasing the scapula-humeral angle and causing injury to the lower plexus. The brachial plexus is susceptible to these injuries due to limited mobility secondary to prevertebral fascia and attachment of the cervical roots to the vertebrae. Traction injuries are also responsible for obstetrical brachial plexopathies, most commonly following shoulder dystocia.⁴ Risk factors for obstetrical plexus injury include high birth weight, fetal acidosis, posterior arm involvement and narrow pelvis.¹⁰

Iatrogenic

During long operations, positioning of the upper extremity can contribute to a traction palsy.¹¹ Most commonly these injuries are neuropraxic in nature and will recover spontaneously with time, however occasionally a more severe injury will occur. There are patient factors that contribute to the propensity for developing these injuries, including diabetes, hypothyroidism, prior injury, hereditary neuropathy with liability to pressure palsy (HNPP) and obesity.¹¹

Compression

Compression can be secondary to structures adjacent to the plexus in an enclosed space such as malignancy, callous formation, haematoma or pseudoaneurysm. Anatomic variants may be responsible for compression primarily or may increase the propensity for trauma to the brachial plexus. These variants include cervical ribs, prominent transverse processes and congenital fibrous bands.¹² Compression often occurs in the costoclavicular space as the brachial plexus travels between the clavicle and the first rib. Traumatic injuries can result in swelling

or haematoma that cause compression of the brachial plexus. Occupational injuries where a heavy object lands on the shoulder or neck are an example.

Neuralgic amyotrophy

Brachial neuritis, or Parsonage–Turner syndrome, is a brachial plexopathy of unclear aetiology that most commonly involves the lower brachial plexus; the axillary nerve is implicated in up to 70% of patients.^{13–15} Most commonly, these non-traumatic plexopathies present with a history of severe neuropathic pain that resolves and then is followed by patchy nerve paresis.¹⁶ Possible contributory factors are viral disease, infection, immunization, trauma, surgery and autoimmune mechanisms.¹⁷ The majority of these plexopathies will have a full spontaneous recovery within approximately 3 years, however the prognosis is more guarded in the setting of other medical comorbidities such as diabetes.¹⁸

Radiation

Transient or permanent brachial plexopathy can occur as a result of radiation therapy. Approximately 1.2% of women receiving radiation as adjuvant therapy for breast cancer, higher following chemotherapy, will present with clinical manifestations anywhere from six months to 20 years following treatment (median 1.5 years).¹⁹

Investigations

Imaging

Brachial plexopathy and level of injury are primarily a clinical diagnosis supported by electrodiagnostic studies, however there are several circumstances where imaging contributes valuable information.

Plain films are useful for identifying fractures that might be associated with certain patterns of brachial plexopathy. For example, a transverse process fracture is more likely associated with a root avulsion injury because of the deep cervical fascia that tethers cervical root to transverse process.²⁰ Clavicular fractures can cause sharp injuries to the plexus on bony fragments, or can contribute to compression injuries related to either haematoma acutely, or callus formation in a more delayed fashion.

CT myelography is a useful investigation for assessing for root avulsion. The use of contrast material allows for visualization of the dural sheath around the nerve root, which is not pathognomonic for a root avulsion, but can be suggestive.²¹ The absence of a root at a particular level is diagnostic. When obtained at least one month post injury, which allows time for the dural sheath to heal improving distribution of the dye, CT myelography is associated with a sensitivity of 95% and a specificity of 98% for root avulsion injuries.²²

MRI is becoming a more valuable tool for the imaging of the brachial plexus due to newer techniques and protocols. The

advantage of MRI is that it can directly visualize the entire brachial plexus and is non-invasive. Soft tissue injury is more easily assessed and three-dimensional imaging is possible.

Electrodiagnostic studies

It is crucial that all patients presenting with brachial plexopathies receive electrodiagnostic studies, and in many cases serial studies will confer helpful information in the decision to proceed with surgery. Electrodiagnostic studies are not useful before Wallerian degeneration has occurred and fibrillation potentials have appeared, therefore delaying investigation for approximately six weeks is beneficial. There are two components to the electrodiagnostic study: nerve conduction and electromyography. Nerve conduction studies are traditionally more useful for compression neuropathies, although they can portray valuable information in the setting of a preganglionic lesion to the brachial plexus. In these injuries, the dorsal root ganglion remains intact and the peripheral sensory nerve does not undergo Wallerian degeneration. The motor nerve, however, arising more proximally in the spinal cord, will still be affected. The resultant nerve conduction studies will demonstrate intact sensory nerve action potentials (SNAPs) but no volitional activity.

The electromyography portion of the study also has several components. On insertion of the needle, a denervated muscle will exhibit spontaneous discharges or fibrillations and positive sharp waves. In contrast, a normal muscle will not have any waveform on insertion alone. When the patient is asked to voluntarily contract the designated muscle, the presence of motor unit potentials (MUPs) signifies that the action potential is reaching the desired motor endplate. Nascent units are representative of connections to the motor endplates from regenerating injured axons, while MUPs signify distal motor sprouting from uninjured axons. Both are good prognosticators of a spontaneous recovery without surgical intervention.²² Electromyography often precedes clinical signs of recovery by 1–2 months, and the presence of new MUPs and nascent units can be a promising prognostic sign before the patient notices any changes. In addition, electrodiagnostic studies can be valuable in preoperative planning, especially where nerve or tendon transfers are being contemplated.

Patterns of injury

Brachial plexus injuries can occur in any potential combination, however there are several common patterns of injury that warrant mention, as the approach to treatment can be dictated by the predictable deficits.

Upper plexus injuries

These injuries comprise injuries to the C5 and C6 roots or to the upper trunk. This occurs when the shoulder is wrenched away from the head and neck. Classically these patients will present

with deficits of shoulder abduction, external rotation and potentially loss of elbow flexion. There will be a concomitant loss of sensation over the deltoid muscle. A sulcus sign may be present, identifying the inability of the shoulder girdle to support the weight of the arm (Figure 57.3). Priorities are to re-establish elbow flexion and then to restore shoulder stability and function.

Lower plexus injuries

Injuries to the lower plexus typically involve C8 and T1 roots or the lower trunk. This occurs when the arm is forcefully abducted above the head. In this pattern of injury, wrist and hand flexion will be the most greatly affected, with intrinsic muscle paralysis and potential clawing. Loss of sensation in the ulnar nerve distribution accompanies the lower plexus injury. Priorities include restoration of hand function.

Posterior cord injury

Injury to the posterior cord involves contributions from C5–T1. When injured, extension of the elbow, wrist, thumb and fingers are affected, as is shoulder abduction from the axillary nerve, which is a terminal branch of the posterior cord. Priorities are to restore shoulder abduction and wrist, finger, and thumb extension. Restoration of elbow extension is more controversial.

Pan-plexus injuries

This injury involves the entire plexus (C5–T1) and presents with a flail, insensate upper extremity. Associated with a poor prognosis, this extremity will likely be a ‘helper extremity’ at best. Priorities to restore function include elbow flexion, shoulder stability and abduction/external rotation, and hand function. Often associated procedures such as wrist arthrodesis will be considered given the lack of potential donor nerves or tendons for surgical intervention.

Obstetrical brachial plexus injuries

Classically, these patients present with an Erb’s palsy, which is injury to the upper plexus. This leads to loss of shoulder abduction, external rotation and loss of elbow flexion. These patients are often

Figure 57.3 A sulcus sign secondary to denervation of the left axillary and suprascapular nerves. Source: *Nerve surgery*, Susan Mackinnon (ed.), Thieme 2015. Reproduced with permission.

described as presenting in the ‘waiter’s tip’ position, where the arm hangs by the child’s side with the shoulder internally rotated, the elbow extended, and the forearm pronated. Alternatively, these children can present with a Klumpke’s palsy, which is a lower plexus lesion. These children present with paralysis of multiple muscle groups, including the hand and wrist flexors and the intrinsic muscles of the hand. They will often have an associated claw deformity and potentially an associated Horner’s syndrome, which presents as ptosis, miosis and anhydrosis. They will have a sensory deficit in the ulnar nerve distribution.

Management principles and operative approach

Timing

The management of brachial plexus injuries is determined by the mechanism, level and degree of injury. Open injuries of the brachial plexus should be explored within 72 h to allow for intraoperative stimulation of the distal nerve segment. Depending on the mechanism, acute nerve repair may be warranted. If, however, the mechanism is other than a sharp, transecting injury, it is important to consider the zone of injury. In the event of a crush or avulsion, identification and intraoperative tagging of the nerve may be prudent, followed by re-exploration approximately three weeks after the injury when the zone of injury is well demarcated. If acute repair is desired, both the distal and proximal nerve ends should be resected to ensure healthy fascicular nerve ends. The authors advocate the use of a bread-loafing technique to ensure that adequate scar is resected while preserving optimum nerve length, by sequentially cutting the nerve in thin slices until clearly past the zone of injury and able to visualize healthy cut fascicular ends.

In the event of resection of the damaged nerve, a nerve gap will be present. Addressing the nerve gap is critical to avoid tension on the nerve repair.²³ The nerve gap can be addressed with nerve grafting. Potential donors include the medial antebrachial cutaneous nerve (MABC) or the sural nerve. Our preference is to use the MABC given that it is located within the injured extremity, is expendable, has a larger calibre than the sural nerve, and sensation can potentially be restored into the donor deficit by transferring the distal end to an intact sensory donor in the upper arm. Although nerve grafts can be used to span the distance of a nerve gap, such as following neuroma resection, debridement of nerve ends, or for nerve transfers where the donor and recipient are not in close enough proximity, they involve two coaptations, which reduces the number of successfully traversing axons.^{24,25}

Another potential option for addressing the nerve gap is to use distal nerve transfers. There are several advantages conferred by this technique, including avoiding operating within the zone of injury, conversion of a proximal injury to a more distal one with axon regeneration closer to the motor endplates, and a single coaptation.^{23,24} Tendon transfers and

functional muscle transfers are options for dealing with injuries that present in a delayed fashion or that have minimal donor options.

Closed injuries, such as traction or crush injuries, are significantly more common than open injuries to the brachial plexus. These injuries are not immediately explored, but are instead followed with serial clinical examination and electrodiagnostic studies to evaluate for any spontaneous functional recovery. With these injuries, it is imperative to be cognizant of timing. Peripheral nerve regeneration occurs at a rate of approximately 1 mm/day.²⁶ The distance from injury to the first expected nerve branches to show recovery in an injured nerve should be documented and serially examined for signs of recovery within the anticipated time period. Permanent atrophy and fibrosis of denervated muscle occurs between 12 and 18 months following nerve injury and therefore it is necessary to intervene surgically in a timely manner to achieve reinnervation to the motor endplates prior to this occurring.²³

Priorities to establishing function

The first priority in a complete brachial plexus injury is to restore elbow flexion. This is followed by shoulder stability/range of motion and subsequently restoration of hand and wrist function.

Exploration of the brachial plexus

Exploration of the proximal brachial plexus takes place through a hockey stick shaped incision along the posterior border of the lower sternocleidomastoid muscle and extending transversely above the clavicle. This allows access to the roots with careful dissection and mobilization of the supraclavicular fat pad. The roots travel between the anterior and middle scalene muscles. Caution to avoid the phrenic nerve, which runs longitudinally along the anterior surface of the anterior scalene muscle, is imperative. To explore the more distal plexus, and infraclavicular exposure is performed, with an incision extending from the clavicle to the anterior axillary fold in the deltopectoral groove. We perform this incision in a zig-zag fashion to allow for improved exposure and to prevent scar contracture. The pectoralis major muscle is temporarily divided and reflected medially, as is the pectoralis minor. The patient should be positioned supine with the chest and ipsilateral upper extremity prepped and the arm abducted to 90° and the head turned gently to the contralateral side. Paralytic agents are avoided on induction to allow for intraoperative nerve stimulation. Traditionally, exploration and grafting at the level of the plexus was the gold standard for these injuries, but more recently, there has been a momentum to more distal nerve transfers.²⁷ The authors' preference is for distal nerve transfer.

Restoring elbow flexion

There are a number of different potential donors to re-establish elbow flexion. This necessitates exposing the musculocutaneous nerve in the upper arm. A longitudinal incision is made

along the brachial sulcus on the medial upper arm. The musculocutaneous nerve travels deep to this sulcus in between the biceps brachii and brachialis muscles and can often be palpated against the humerus in the proximal incision. Once this nerve is identified, the branch to the biceps brachii, which branches laterally into the muscle at approximately the upper third, lower two thirds junction of the upper arm, and the brachialis branch, which branches medially closer to the mid-upper arm can be localized and stimulated. The continuation of the musculocutaneous nerve becomes the lateral antebrachial cutaneous nerve, which can be confirmed by the 'tug test', which will put traction on the skin of the proximal forearm when the nerve is gently tugged.

When it has been confirmed that the musculocutaneous nerve does not stimulate, appropriate donors can be selected for nerve transfer. Our preference would be to perform the double fascicular nerve transfer (DFT), which restores function to both the brachialis and biceps brachii branches of the musculocutaneous nerve (Figure 57.4). This procedure involves borrowing redundant fascicles from the flexor carpi radialis or palmaris longus from the median nerve and the flexor carpi ulnaris from the ulnar nerve as donors.²⁸ If the median and ulnar nerves are involved distally, other potential donors include the medial pectoral nerve or the thoracodorsal nerve. In patients presenting with a pan-plexus injury, extraplexal donors are required. The most commonly used extraplexal donor to restore elbow flexion is the intercostals, which can be harvested through a curvilinear incision in the inframammary fold. Approximately three levels are selected as donors and often the nerve to the rectus abdominis is taken as an additional source of motor fascicles. With meticulous dissection distally, the use of a nerve graft can be prevented as the donor nerves are passed through a subcutaneous tunnel in the axilla to the recipient musculocutaneous nerve in the upper arm. Remembering the mantra 'donor distal, recipient proximal' to maximize length and avoid tension on the transfer is essential.

The use of other extraplexal donors has been described, including the phrenic nerve and the contralateral C7, however these are less favourable options due to distance from the recipient nerve and donor deficit.^{29–31}

Restoring shoulder function

Restoration of shoulder function is the next priority and involves regaining shoulder stability, abduction and external rotation. In order to accomplish this, reinnervation of the axillary nerve distribution (deltoid, teres minor) and suprascapular nerve (supraspinatus, infraspinatus) are required. Our preference for addressing the suprascapular nerve is the spinal accessory to suprascapular nerve transfer (Figure 57.5). This transfer is possible from either an anterior or posterior approach. The anterior approach has the advantages of supine patient positioning and the ability to perform the transfer in an end-to-side manner, which preserves spinal accessory nerve function. With the posterior approach, release at the

suprascapular notch, preserving more innervation to the trapezius, and a wider exposure are advantages.

The spinal accessory nerve is located on the deep surface of the trapezius muscle approximately 40% of the way along a line drawn from the spine to the acromion at the level of the superior scapular border.²³ The suprascapular nerve travels through the suprascapular notch at the midway point along the superior scapular border and is most easily accessed by release of the ligament that travels over the notch.

Shoulder abduction is addressed by reinnervation of the deltoid and teres minor. Our preference is to transfer the medial branch of triceps, which travels along the superficial surface of the radial nerve as its own fascicular group, to the axillary nerve (Figure 57.6). This can be performed by an incision on the posterior arm that extends from the quadrangular space, where the axillary nerve can be located, to the distal upper arm. It is easily performed in conjunction with a spinal accessory to suprascapular nerve transfer as a double nerve transfer. Other potential donors include the contralateral C7, the medial pectoral nerve and the thoracodorsal nerve, although the thoracodorsal nerve is harder to rehabilitate.

Restoring hand function

In a pan-plexus injury, restoring hand function is a challenging problem. With limited donors and with priority going to restoring elbow and shoulder function, there are few options for donors to the hand. Although use of the contralateral C7 with a long nerve graft to median nerve transfer has been described, the long distance from the motor endplates and the multiple coaptations results in suboptimal restoration of function.^{29,31} The authors' preference in that setting is to use a free functioning muscle transfer, most commonly gracilis, to restore extrinsic hand function. The first stage of this transfer can be performed at the time of the original plexus reconstruction with inset of a long graft from the intercostal donors. Once enough time has passed to allow sufficient regeneration, the second stage transfer of the muscle to restore finger flexion can be performed.

In lower plexus injuries, where patients present with isolated nerve palsies, more distal nerve transfer is accomplished using synergistic donors. For recovery of a median nerve palsy, establishing anterior interosseous nerve function is a priority and can be performed with a number of potential donors. Options

Figure 57.6 Medial triceps to axillary nerve transfer. (a) Intraoperative photo documenting the location of both the donor medial triceps branch and the recipient axillary nerve and (b) nerves prepared for coaptation under no tension. Source: *Nerve surgery*, Susan Mackinnon (ed.), Thieme 2015. Reproduced with permission.

include the brachialis branch,³² and expendable branches of the radial nerve.³³ The internal topography of the median nerve is now well understood. In the proximal arm, the anterior interosseous nerve fascicles can be found located on the posterior medial aspect of the nerve. More distally, the fascicles wrap under the nerve and become the only branch to exit from the radial side of the median nerve, distal to the branches to flexor carpi radialis, palmaris longus and flexor digitorum superficialis. For exposure, the nerve can be isolated in the upper arm through the same brachial sulcus incision. More distally, the anterior interosseous nerve can be exposed through a curvilinear incision on the volar forearm.

Following ulnar nerve paralysis, recovery of intrinsic muscle function is a priority and is often accomplished by making use of the terminal branch of the anterior interosseous nerve as a donor to the deep motor branch of the ulnar nerve (Figure 57.7).³⁴ This terminal branch can be located on the anterior surface of the interosseous membrane as it penetrates into the pronator quadratus muscle. Harvesting it at its most terminal branching point will allow for enough length to transfer it to the side of the ulnar nerve, allowing this procedure to be used as a supercharging or babysitting option. The internal topography of the ulnar nerve at the level of the distal forearm is such that after the dorsal cutaneous ulnar branch exits the ulnar aspect approximately 9 cm proximal to the wrist crease, the more ulnar 40% of the nerve is motor and the more radial 60% is sensory. It is important to make the epineurotomy window at the motor aspect of the nerve to allow the anterior interosseous fascicles to reach the intrinsic muscles of the hand. If the anterior interosseous nerve is not available, other options include the extensor digiti quinti or extensor carpi ulnaris, both of which will require a nerve graft.

Radial nerve deficits can be addressed by borrowing redundant fascicles from the median nerve as donors. Priorities are to re-establish posterior interosseous and extensor carpi radialis brevis functions.³⁵

Restoring function after brachial plexus palsy

The approach to the brachial plexus in the obstetrical population is slightly different than in adults. Here there remains a significant role for exploration of the plexus and nerve grafting.³⁶ Neuroma excision and sural nerve grafting to obtain sufficient graft length are standard of care. The recent addition of motor nerve transfers, either in combination with nerve grafting or independently, has potentially augmented clinical recovery by providing a source of motor axons closer to the neuromuscular junction.³⁶

Restoring sensation

Significantly improved clinical recovery is achieved in the sensate hand. Similar to options for motor nerve transfers, the authors advocate for the use of sensory nerve transfers to restore sensation to critical areas such as the first webspace for improving pinch. Unlike the motor nerve transfers, these sensory transfers can be performed independent of time.³⁷

Postoperative care

The majority of brachial plexus reconstructions can be performed on an outpatient or brief hospital stay basis. Postoperative pain control is critical and surgeons should have a low threshold for starting patients on an aggressive postoperative pain regimen including targeting neuropathic pain.

The period of immobilization following surgery is largely dependent on operative procedure, but also factors in patient compliance and age. Given that primary repair or nerve grafting should only be performed in the setting of no tension, a brief period of immobilization less than one week is all that is required postoperatively. Similarly, nerve transfers require minimal immobilization so long as they are taken through a full range of motion for the joint above and below at the time of coaptation and there is no evidence of tension. Tendon transfers require a more prolonged period of immobilization, ranging from 3 to 6 weeks depending on the transfer. Early gentle passive range of motion is encouraged to prevent adhesion formation and joint stiffness. Where the plexus has been fully exposed by dividing the pectoralis major tendinous insertion, the patient should be kept in a sling for 4 weeks to avoid tension on the repair. Elbow, wrist and hand range of motion within the sling are encouraged. Hand therapy and physical therapy are critical for optimizing recovery and the role of the therapist cannot be overstated. In addition, cortical retraining, motor re-education, and strengthening will be part of the longer term rehabilitation.

Complications

As with any surgery, the complications associated with brachial plexus surgery can be divided into acute, short term and long term. The majority of these patients are young and otherwise healthy, making their anesthetic risks significantly less, however given that they often require multiple surgical procedures, the risk cannot be completely discounted. Other acute complications include injury to adjacent structures, bleeding and inability to complete the procedure. Locating a paralysed nerve can be humbling, given that the nerve does not function, cannot be stimulated and often the surrounding musculature is denervated and abnormal in appearance. Having an excellent knowledge of nerve anatomy is critical to these transfers and it is not unusual for the authors to bring an anatomy atlas into the operating theatre.

Short-term complications include infection, wound healing problems or dehiscence, seroma and haematoma. Long-term complications include scarring, joint stiffness, pain and ineffective or unsuccessful results from the surgery. For tendon transfers, additional complications would include tendon rupture or adhesion, although using a Pulvertaft weave should make rupture less probable.

Donor deficit, for either nerve or tendon transfer, is a consideration. For the majority of nerve transfers, a transient

Figure 57.7 (Continued)

donor deficit is a possibility, but almost no long-term deficits are reported. Similarly, for tendon transfers, the selection of an expendable donor means that overall function should not be significantly affected.

Outcomes

Outcomes for brachial plexus injuries are related to the level and severity of the injury, the method and timing of reconstruction, and the patient's degree of compliance with postoperative rehabilitation. Due to the proximal level of these injuries, outcomes have been notoriously poor and prior to the advent of nerve transfers, when results were dependent on plexus exploration and grafting 'good' outcomes were only achieved in 20–33% of patients.³⁸ Many of these earlier studies, however, lack an objective outcome measure, and thus it is difficult to compare degree of recovery. A recent publication comparing almost 300 patients with upper trunk lesions found significantly better outcomes following dual nerve transfers than traditional nerve grafting in establishing shoulder function.²⁷

The Medical Research Council (MRC) grading system for strength, along with other objective measures such as grip strength, pinch strength and potentially maximum weight lifted, provides a more acceptable way to compare outcomes.

For recovery of elbow flexion, the results following nerve transfer are generally quite good. Using a double fascicular nerve transfer, 28 of 29 patients regained elbow flexion and of these, 23 regained MRC 4/5 strength or greater.³⁹ Liverneaux *et al.* reported MRC 4/5 recovery of elbow flexion in all patients using the same procedure.⁴⁰ There was no permanent donor deficit in either of these studies. In the obstetrical brachial plexus population, 67% of patients showed good or excellent recovery following nerve reconstruction for the elbow and the results were significantly better for those patients with a C5 to C7 palsy than those with a pan-plexus palsy.⁴¹

When comparing extraplexal donors, Terzis and Kostopoulos found better success when three or more intercostal nerves were harvested as compared to two.²¹ In addition, results were better when the lower intercostal nerves T7–T10 were used compared to the upper intercostals of T3–T6.²¹ They report good to excellent results in almost three quarters of patients undergoing intercostal to musculocutaneous nerve transfer.

Recovery of shoulder function is not as successful as elbow flexion, however is significantly better than results achieved with shoulder arthrodesis. Songcharoen reported on 577 patients undergoing spinal accessory to suprascapular and/or axillary nerve transfer and reported that 80% of patients regained at least MRC 3/5 motor recovery.²⁹ Reinnervation of both the suprascapular and axillary nerves results in improved results compared to transfer to a single nerve.⁴² Leechavengvongs described seven cases where a triceps branch was transferred to the axillary nerve and all patients regained MRC 4/5 deltoid function and 5 of 7 had an excellent result.⁴³

Recovery of hand function has been less successful. Gu reported on 32 patients undergoing contralateral C7 root transfer. Fourteen of the patients had median nerve recipients and half regained MRC 3/5 motor function and 12 regained MRC 3/5 sensory function.⁴⁴ Ray and Mackinnon report on 12 of 19 patients with good to excellent (MRC 4/5 or greater) recovery of finger and thumb extension following median to radial nerve transfers.³⁵ In the same population 18/19 had meaningful recovery of wrist extension.

Regardless of the clinical recovery, patient satisfaction and return to work are important determinants of the success of brachial plexus reconstruction. Of 32 patients with brachial plexus injuries, over three quarters reported at least moderate overall life satisfaction and no patients reported extreme dissatisfaction.³ Ten of the 32 patients reported that the injury greatly affected their overall quality of life. Approximately half returned to work following their injury and of these, 70% reported moderate to high satisfaction with their job. This compares to 85% of the general population.

In a more recent study, Kretschmer *et al.* revealed that 87% of patients undergoing brachial plexus reconstruction were satisfied with their results and 83% would undergo surgery again. This was interesting in light of the fact that 52% of patients who had been gainfully employed prior to injury returned to their former occupation, pain since the injury was expressed in 86% of patients, and 21% suffered from depression and anxiety.⁴⁵ The group did find that occupational retraining was successful for 70% of patients, suggesting that this is an effective option in the patient with a brachial plexus injury.

Summary

Brachial plexopathies are devastating and have a significant impact on quality of life and upper extremity function. Although traditionally surgical intervention has resulted in relatively poor recovery of function, the implementation of new surgical techniques such as nerve transfers, combined with significantly improved knowledge of internal nerve topography, has dramatically improved outcomes. Although there remains a role for surgical interventions such as nerve grafting and tendon transfer, especially in the obstetrical brachial plexus palsy population, nerve transfers are rapidly emerging as the standard of care for the treatment of these difficult patients. This chapter highlights the anatomy, aetiologies, investigations, patterns of injury and surgical options to manage these patients and discusses the outcomes in this emerging field.

Anatomy

Median nerve

The median nerve is formed from the medial (motor contribution) and lateral (sensory contribution) cords of the brachial plexus, then crosses over the brachial artery and courses distally along its medial aspect. In the upper arm, the median nerve lies between the medial intermuscular septum and brachialis muscle and then runs distally through the antecubital fossa under the lacertus fibrosis. The median nerve subsequently passes through the pronator teres (PT) muscle, most commonly between its superficial and deep heads. Less commonly, the median nerve will pass deep to both heads of the PT or through the substance of the superficial head.¹

After emerging from PT distally, the median nerve passes under the fibrous edge of the flexor digitorum superficialis (FDS) muscle, travelling between the FDS and flexor digitorum profundus (FDP) muscles. The median nerve gives off four groups of branches in the proximal forearm: branches to PT (proximal, superficial); branches to flexor carpi radialis (FCR) and palmaris longus (PL) (deep, ulnar); branches to FDS (deep, ulnar, more distal); and, the anterior interosseous nerve (AIN) which arises from the radial aspect of the median nerve, approximately 3 cm distal to the intercondylar line, and innervates the FDP to the index and long fingers, the flexor pollicis longus (FPL) and the pronator quadratus.²

In the distal forearm, the median nerve becomes more superficial and courses between and just deep to the FCR and PL tendons. The palmar cutaneous branch (PCM) arises from the volar-radial aspect of the median nerve 5 cm proximal to the wrist flexion crease, and may course distally up to 6 mm ulnar to the thenar crease.^{3,4} The PCM usually crosses the wrist as a single branch and then arborizes in the palm superficial to the palmar fascia.⁵

At the wrist the median nerve enters the carpal tunnel along with nine tendons (FDS, FDP, FPL). The carpal tunnel is bordered dorsally by the carpal bones, ulnarly by the hamate and triquetrum, and radially by the scaphoid, trapezium and FCR

sheath. The volar roof of the carpal tunnel is formed by the transverse carpal ligament (TCL), with contributions from the antebrachial fascia proximally and the thenar/hypothenar aponeuroses distally.

At the distal aspect of the carpal tunnel, the median nerve divides into the proper digital nerves to the thumb and radial border of the index finger, and the common digital nerves to the second and third webspaces. The recurrent motor branch typically arises from the radial border of the median nerve just distal to the flexor retinaculum (extraligamentous course), turning back to innervate the abductor pollicis brevis (APB), opponens pollicis and superficial head of the flexor pollicis brevis. The recurrent branch may also take a subligamentous (31%) or transligamentous course (23%).⁶ Other anatomic variations described by Lanz include an accessory median nerve branch that can arise distal or proximal to the carpal tunnel, and a bifid or duplicated median nerve.⁶

The Riche–Cannieu anastomosis is an anomalous motor connection from the ulnar to median nerve in the palm that contributes on average 28% of the innervation to APB.⁷ When present, thenar function may be preserved in the setting of severe carpal tunnel syndrome.

Points of compression

There are four main compression syndromes associated with the median nerve: carpal tunnel syndrome (CTS), pronator syndrome, AIN syndrome and compression of the PCM.

Carpal tunnel syndrome

CTS is the most common compression neuropathy in the upper extremity, with an annual incidence of 0.5–5.1 per 1000 persons.⁸ The aetiology of CTS is not fully understood, however the final common pathway is compression of the median nerve within the carpal tunnel resulting in impaired microcirculation, subperineurial oedema and eventually fibrosis. Demyelination occurs, which is at first localized then more diffuse, followed by axonal degeneration. Any condition that reduces the volume of the carpal canal or increases the volume of its contents can initiate this process.

Several systemic factors have been proposed as risk factors for the development of CTS, including female gender, advanced age, diabetes, thyroid disease, pregnancy, rheumatoid arthritis, obesity and smoking.^{9,10} Positioning of the wrist in flexion or extension during sleep may present a common causal pathway for many of these risk factors.¹¹ There is also substantial evidence to support an association between CTS and occupational factors, including repetitive hand use and vibration.¹²

Specific anatomic causes for CTS are identified in a minority of cases. Most commonly, this involves a space-occupying lesion within the carpal tunnel but lumbrical incursion into the carpal tunnel can also compress the median nerve, especially when the lumbricals are hypertrophic.¹³

Pronator syndrome

Pronator syndrome is a mainly sensory neuropathy resulting from compression of the median nerve in the proximal forearm, and is much less common than CTS. Risk factors include female gender, advanced age, and repetitive pronation activities (which can result in a short, tight PT).¹⁴

There are several potential compression points along the median nerve that can contribute to pronator syndrome. The most proximal entrapment points are the supracondylar process, present in less than 5% of patients and located 3–6 cm above the medial epicondyle, and the ligament of Struthers, a fibrous band that may span between the medial epicondyle and the supracondylar process.^{15,16} When the supracondylar process and/or ligament of Struthers are present, the median nerve separates from the brachial vessels and passes posterior to these structures, where it can be compressed. More distally, the lacertus fibrosis, fibrous bands between the deep and superficial heads of the PT, a tendinous deep head of the PT and the fibrous edge of the FDS can also compress the median nerve.^{17,18} Other less common causes of compression have been described, including an anomalous head of the PT, a snapping brachialis muscle, an accessory FPL (Gantzer's muscle), an anomalous palmaris profundus and an anomalous FCR brevis.¹⁸

Anterior interosseous nerve syndrome

The AIN can be selectively compressed by the same anatomic structures described above for pronator syndrome. However, unlike pronator syndrome, AIN syndrome is a motor neuropathy and entails no loss of sensory function. The syndrome usually occurs spontaneously (where no inciting event can be identified), but in some cases can result from local trauma or a tumour. It is important to note that most cases of AIN palsy are not due to mechanical compression, but rather to neuritis (i.e. Parsonage–Turner syndrome) and will usually recover spontaneously without operative intervention.^{19,20}

Compression of the palmar cutaneous branch

The PCM pierces the antebrachial fascia 2 cm proximal to the wrist flexion crease and, at this location, travels through a tunnel 3 mm to 2 cm in length. The tunnel may pass through the thickened antebrachial fascia or TCL.²¹ Compression of the

PCM results in altered sensation over the thenar eminence and radial palm.

Ulnar nerve

The ulnar nerve is formed from the medial cord (C8–T1) of the brachial plexus, lying medial to the axillary artery at its origin. In the middle third of the arm, the ulnar nerve pierces the medial intermuscular septum and travels distally between this septum and the medial head of triceps. At the elbow, the ulnar nerve enters the cubital tunnel. This fibro-osseous tunnel is bordered superficially by a fascial band spanning the olecranon and medial epicondyle, and on its deep surface by the ulnar groove of the medial epicondyle proximally, as well as the joint capsule and medial collateral ligament distally.²²

The ulnar nerve then enters the forearm between the two heads of the flexor carpi ulnaris (FCU) muscle, coursing distally between FCU and FDP on the medial aspect of the ulnar artery. The most proximal motor branch innervates the FCU approximately 1.6 cm distal to the medial epicondyle.²³ Subsequent branches to the FCU and ulnar two FDP muscles originate from both the medial and lateral sides of the ulnar nerve.²³ The dorsal cutaneous branch (DCU) of the ulnar nerve, which gives sensation to the dorsal aspect of the ring and small fingers, originates 10 cm proximal to the wrist crease.

At the wrist, the ulnar nerve enters Guyon's canal along with the ulnar vessels. Gross and Gelberman divided this area into three zones according to the internal topography of the ulnar nerve.²⁴ In zone 1 (proximal), the ulnar nerve lies superficial to the TCL, deep to the antebrachial fascia and radial to the FCU tendon. Just distal to the pisiform, the motor and sensory fascicles of the ulnar nerve separate. In zone 2 (distal-motor), the motor branch courses radially around the hook of the hamate and deep to the leading edge of the flexor digiti minimi muscle to innervate the intrinsic muscles of the hand. At this level, the floor of Guyon's canal is formed by the opponens digiti minimi, the medial wall by the abductor digiti minimi, and the roof by the volar carpal ligament and palmaris brevis. In zone 3 (distal sensory), the sensory branch of the ulnar nerve travels superficial to the hypothenar musculature to innervate the volar aspects of the small finger and ulnar half of the ring finger. The ulnar artery and its tributaries remain radial and superficial to the ulnar nerve as it travels distally into the wrist and palm.

The Martin–Gruber anastomosis is an anomalous median-to-ulnar connection in the proximal forearm present in 10–25% of cases.²⁵ The 'anastomotic' nerve branch may arise from the median nerve proper or the AIN and, when present, can result in preserved ulnar function in the hand in the setting of severe proximal ulnar neuropathy.

Points of Compression

Cubital tunnel syndrome

Cubital tunnel syndrome (CuTS), or compression of the ulnar nerve at the elbow, is the second most common compression neuropathy in the upper extremity. Potential sites of entrapment include (Figure 58.1): the arcade of Struthers, a thick fascial

Figure 58.1 Potential sites of compression along the ulnar nerve at the elbow and wrist. Source: *Nerve surgery*, Susan Mackinnon (ed.), Thieme 2015. Reproduced with permission.

connection between the medial head of the triceps and the medial intermuscular septum located approximately 8 cm proximal to the medial epicondyle; the bony retrocondylar groove, which may be altered by trauma, arthritis, heterotopic ossification, and soft tissue masses; and Osborne's band, a thickened confluence of fascia between the two heads of FCU.²⁶ More distally, the ulnar nerve may be compressed where it exits the FCU, by fibrovascular bands coursing over the nerve from the ulnar artery to the distal FCU, and by a fascial aponeurosis between the FCU and FDS to the ring finger (ligament of Spinner).^{27–29}

Congenital anatomic variations, such as cubitus valgus, an anconeus epitrochlearis muscle, a low-lying or prominent medial triceps muscle, and a hypoplastic roof of the cubital tunnel (allowing subluxation of the ulnar nerve) may also contribute to proximal ulnar compression.^{30,31} Other associated risk factors include female gender, advanced age, systemic neuropathy (i.e. diabetes), external compression (i.e. above-elbow cast), occupations involving repetitive or persistent elbow flexion and sleeping with the elbows in a flexed position. Several mechanisms have been proposed to explain why elbow flexion contributes to ulnar neuropathy, including dynamic compression, traction, ischaemia, extraneural scar and recurrent nerve subluxation.²⁰

Guyon's canal syndrome

Compression of the ulnar nerve at the wrist is the second most common site of ulnar nerve impingement, but is substantially less common than CuTS.³² A thickened antebrachial fascia can compress the ulnar nerve at the wrist (zone 1), whereas the tendinous leading edge of the hypothenar musculature can cause isolated compression of the deep motor branch (zone 2) (Figure 58.1). Additional aetiologies include compression by extra-anatomical structures (i.e. ganglion cysts, tumours, vascular malformations, anomalous musculature) and trauma (i.e. hypothenar hammer syndrome, hook of hamate fractures, distal radius fractures, carpal dislocations).^{20,32,33}

Radial nerve

The radial nerve is a terminal branch of the posterior cord of the brachial plexus (C5–T1). It lies dorsal to the axillary vessels at its origin then courses beneath the lateral head of the triceps, where it gives off the motor branches to the triceps, the posterior cutaneous nerve of the arm and the posterior cutaneous nerve of the forearm. At the mid-humeral level, the radial nerve travels within the spiral groove of the humerus, crossing from the posterior-medial to posterior-lateral aspect of the upper arm. It pierces the lateral intermuscular septum approximately 10 cm

proximal to the lateral humeral epicondyle and can be found between the brachialis muscle and the origin of the brachioradialis muscle just above the antecubital fossa.³⁴ Here, motor branches to the brachioradialis and extensor carpi radialis longus (ECRL) muscles arise. The radial nerve then bifurcates into the posterior interosseous nerve (PIN; motor component) and the superficial radial nerve (SRN; sensory component).

The PIN courses dorsolaterally over the radiohumeral joint, around the radial head through the substance of the supinator muscle and distally along the dorsal surface of the interosseous membrane. The PIN supplies the majority of the forearm and hand extensors, including the extensor carpi radialis brevis (ECRB), supinator, extensor digitorum communis (EDC), extensor digiti quinti, (EDQ), extensor carpi ulnaris (ECU), abductor pollicis longus (APL), extensor pollicis longus (EPL) and brevis (EPB), and extensor indicis proprius (EIP). Of note, the nerve branch to ECRB arises proximal to the entrance of the PIN into the supinator muscle. The terminal branch of the PIN travels at the base of the fourth extensor compartment to provide sensation to the dorsal wrist capsule and intercarpal ligaments.

The SRN travels distally on the undersurface of the brachioradialis muscle in the volar-radial aspect of the forearm. About 10 cm proximal the radial styloid, the SRN exits between the brachioradialis and ECRL tendons dorsally to become subcutaneous. The SRN provides sensory innervation to the dorsal-radial aspect of the hand.

Points of compression

Proximal radial nerve compression

Proximally, the radial nerve may be compressed by the lateral intermuscular septum or a fibrous arch formed by the lateral head of triceps.²⁰ More commonly, however, the proximal radial nerve is compressed by external forces, such as leaning on a chair resulting in 'Saturday night palsy' or a pneumatic tourniquet; these transient compression neuropathies tend to resolve spontaneously without surgical intervention.³⁵

Radial tunnel syndrome/PIN syndrome

Compression of the radial nerve and its branches in the proximal forearm is usually anatomic in nature, although other aetiologies such as fractures of the radial head have been documented.³⁶ The anatomic structures responsible for radial tunnel syndrome and PIN syndrome are similar, but patient symptomatology differs: radial tunnel syndrome is predominately sensory in nature, whereas PIN syndrome causes motor paralysis.

The radial tunnel is a region of the proximal forearm and elbow approximately 5 cm in length, starting distal to the motor branches to the brachioradialis and ECRL and ending distal to the supinator.²⁰ Here, the radial nerve is bordered medially by the brachialis muscle and biceps tendon, laterally by the brachioradialis muscle, and posteriorly by the lateral epicondyle.

Structures that may compress the radial nerve or PIN include fibrous adhesions at the radiocapitellar joint (i.e. from lateral

epicondylitis), the tendinous margin of the ECRB, the tendinous superficial head of the supinator muscle commonly known as the arcade of Frohse, the fascial border at the distal edge of the supinator and the vascular leash of Henry.^{37–40} Rare anatomic variations, such as fusion of the brachioradialis and brachialis muscles, may also predispose the radial nerve and PIN to compression.^{36,41}

Wartenberg's syndrome

Compression of the SRN is known as Wartenberg's syndrome.⁴² Anatomic compression of the SRN can occur by the brachioradialis tendon, which may be aggravated by activities requiring hyperpronation. However, the superficial location of the SRN distally and its complex branching pattern renders it highly susceptible to traumatic and iatrogenic injury (i.e. DeQuervain's tenosynovitis release, thumb carpometacarpal joint arthroplasty). Other less common aetiologies include compression by space-occupying lesions, haematomas, thrombosis of radial recurrent vessels, muscle anomalies and external compression from a watchband or bracelet.^{43,44}

Clinical history and assessment

A thorough history and physical examination is essential to identify all potential compression points and musculoskeletal disorders contributing to patient symptomatology. The history should explore the nature and time course of symptoms, and address all relevant comorbidities, medications and risk factors for nerve compression. Typical symptoms of compression neuropathy include numbness, paraesthesias, pain and/or weakness in the distribution of the affected nerve(s). A pain evaluation questionnaire is a useful adjunct, especially in patients with diffuse symptomatology.

The physical examination should consist of a complete sensory and motor evaluation of both upper extremities, to localize the site of compression and determine the severity of neuropathy. All potential entrapment sites of a nerve should be evaluated owing to the double crush mechanism, wherein compression of a nerve at one site renders it more susceptible to compression at a second site.⁴⁵ Failure to identify and address all involved compression points can lead to ongoing or residual symptoms following treatment.

Multiple techniques to evaluate sensation have been described, but there is no accepted gold standard. Sensory examination may include: light touch (i.e. the Ten Test⁴⁶); vibration and cutaneous pressure thresholds (i.e. Semmes-Weinstein monofilament testing); and, static and dynamic two-point discrimination. Abnormal sensory thresholds are an early finding in compression neuropathy, whereas abnormal two-point discrimination is a late finding.

Provocative tests using percussion (i.e. Tinel's test), direct pressure or joint movement can elicit patient symptoms by increasing compression on a nerve at known entrapment sites.

The recently described scratch collapse test (SCT) is also a useful tool to identify areas of compression.⁴⁷

Motor testing should include inspection of both upper extremities for atrophy and abnormal posture/positioning, as well as quantification of muscle strength using the Medical Research Council grading system, dynamometers (i.e. for pinch and grip), and special tests specific to each nerve. Motor weakness is usually a late finding in compression neuropathy.

Median nerve

Carpal tunnel syndrome

CTS classically presents with numbness, pain and paraesthesias in the volar aspect of the thumb, index, long and radial borders of the ring fingers. Since the PCM arises proximal to the carpal tunnel, sensation over the thenar area is preserved. Symptoms are often exacerbated by gripping and wrist flexion, and are usually worse at night. With severe or long-standing compression, thenar weakness and atrophy may occur.

Provocative tests for CTS include the SCT, Tinel's test, Phalen's test (wrist flexion to 90° for up to 60 s), the median nerve compression test, and the fist test for lumbrical incursion (gentle flexion of the fingers into the palm). The latter four tests are positive when paraesthesias occur in the median nerve distribution. In general, clinical tests for CTS have high specificity but moderate sensitivity.^{47,48}

Pronator syndrome

Unlike CTS, sensory abnormalities in pronator syndrome include the PCM distribution as well as the radial three and a half digits. Patients frequently describe pain in the volar forearm, exacerbated by pronation against resistance and direct pressure. Less commonly, patients with pronator syndrome will report weakness or difficulty with small object manipulation.

On examination, pain is reproduced by passive supination with digital pressure placed over the median nerve at the leading edge of PT. The PT may also be tender and occasionally a ligament of Struthers may be palpated.^{20,49} A positive Tinel's sign and SCT may be present, with the latter being performed by firmly pressing over the median nerve to elicit a response (owing to the deep location of the median nerve at this location). Additional provocative manoeuvres for pronator syndrome consist of resisted forearm pronation (PT), resisted elbow flexion with the forearm supinated (lacertus fibrosis) and resisted long finger proximal interphalangeal (PIP) joint flexion (FDS). Weakness may also be present in median nerve innervated muscles, but sensory symptoms predominate.¹⁴

AIN syndrome

The hallmark feature of AIN syndrome is atrophy and weakness of the AIN-innervated muscles. Unlike CTS and pronator syndrome, there are no sensory deficits. A history of severe pain for several weeks followed by weakness in the AIN distribution suggests neuritis rather than mechanical compression.²⁰

Ulnar nerve

Cubital tunnel syndrome

Cubital tunnel syndrome presents with sensory changes in the ulnar nerve distribution, as well as hand weakness that manifests as clumsiness, cramping, difficulty opening jars and difficulty manipulating small objects. Symptoms are worse at night and with activities requiring prolonged elbow flexion.

Sensory testing in CuTS will reveal diminished sensation in both the volar and dorsal aspects of the ring and small fingers. Provocative tests include Tinel's sign in the retrocondylar groove, the SCT and the elbow flexion test with or without simultaneous digital pressure over the ulnar nerve. Provocative manoeuvres should also evaluate for compression distal and proximal to the cubital tunnel.

Motor examination may demonstrate wasting and weakness of the interossei, hypothenars, FCU and FDP to the ring and small fingers. Specific findings related to ulnar intrinsic weakness include clawing of the ring and little fingers (Duchenne's sign), an abducted posture of the little finger (Wartenburg's sign), compensatory FPL flexion when attempting key pinch (Froment's sign), inability to cross the long and index fingers, reduced key pinch strength, and weakness of index and small finger abduction against resistance.⁵⁰

When evaluating a patient with CuTS, a systemic sensory neuropathy should be considered if sensory loss is much worse than motor loss. If motor deficits predominate, a C8–T1 cervical radiculopathy or a systemic motor neuropathy should be excluded. Combined thenar and ulnar intrinsic wasting is also indicative of cervical radiculopathy.

Guyon's canal syndrome

Patients may give a history of hand trauma or fullness in the hypothenar region, and often report worse hand function than patients with CuTS. Sensory testing will show loss of sensation on the volar aspect of the ring and small fingers but sensation on the dorsal-ulnar hand (DCU distribution) is spared. Signs and symptoms of ulnar-innervated intrinsic weakness may be present, but FCU and ring/small finger FDP function are intact. The examiner may also elicit a positive Tinel's sign, SCT and pressure provocation test at the wrist, and holding the wrist in extension may aggravate patient symptoms.

Radial nerve

Proximal radial nerve compression

Radial nerve compression in the upper arm will result in loss of sensation in the SRN distribution, as well as weakness of the brachioradialis, ECRL and PIN-innervated muscles. If there is sensory loss in the distribution of the posterior cutaneous nerves of the arm and forearm, and/or weakness in the triceps, the site of compression is even more proximal. A posterior cord lesion should be considered if there is axillary or thoracodorsal nerve involvement, and a C7 radiculopathy should be suspected if altered sensation is present in both the palmar and dorsal aspects of the middle finger and if there is concomitant

weakness in muscles innervated by the median nerve (i.e. PT, FCR, FDS, FPL).

Radial tunnel syndrome

Patients with radial tunnel syndrome typically describe aching pain in the proximal forearm that is worse with activity, and are tender to palpation over the radial tunnel. No distal sensory changes are present and motor dysfunction of the wrist and finger extensors is uncommon.

The main differential diagnosis of radial tunnel syndrome is lateral epicondylitis. In lateral epicondylitis, pain is maximal at the bony lateral epicondyle and is aggravated by resisted wrist extension. In radial tunnel syndrome, tenderness is present over the mobile extensor wad and is worsened by resisted middle finger extension.⁵¹ The SCT is also routinely positive in radial tunnel syndrome.

Provocative tests may help localize the site of radial nerve compression: compression due to fibrous bands at the radial neck will be aggravated by elbow flexion plus forearm supination with the wrist in neutral; compression by the ECRB will be aggravated by forearm pronation, elbow flexion to 45–90° with the wrist in full flexion; and, compression at the arcade of Frohse will be aggravated by isometric active supination from a full pronated position.²⁰

PIN syndrome

PIN syndrome presents as weakness of finger metacarpophalangeal joint extension (EDC function) and inability to lift the thumb off a table when resting flat (EPL function). Finger interphalangeal joint (IPJ) extension is preserved owing to the function of the intrinsics, and weak thumb IPJ extension may be present due to preserved function of the thenar muscles. Wrist extension is present but radially deviated and weak due to preserved ECRL function, but loss of the PIN-innervated ECU and ECRB. No sensory deficits are present, and the same provocative manoeuvres as for radial tunnel syndrome can help to distinguish the exact site of compression.

Wartenberg's syndrome

SRN compression presents as isolated sensory complaints in the dorsal-radial hand and wrist. A Tinel's sign, SCT and digital pressure test may be positive where the SRN exits dorsally between the BR and ECRL tendons. Motor examination is normal. Use of local anaesthesia can help differentiate symptoms related to the lateral antebrachial cutaneous nerve.

Investigations

Imaging

In general, imaging alone cannot establish the diagnosis of compression neuropathy, but may assist in identifying pathology contributing to the development of nerve compression at a specific location. Plain radiographs and/or CT are

useful for any compression neuropathy where trauma or bony abnormalities (i.e. a supracondylar process in pronator syndrome) are suspected as a causative factor. Ultrasonography and MRI can rule out cysts or other space-occupying lesions as a source of compression. Both ultrasound and MRI have also been used for diagnosis of CuTS with reasonable sensitivity and specificity: ultrasound evaluates the cross-sectional area of the ulnar nerve at the elbow, whereas MRI looks at ulnar nerve hyperintensity.⁵²

Electrophysiological studies

Electrodiagnostic studies are a useful adjunct for evaluating upper extremity nerve pathology. They can help to accurately localize a site of compression, assess the severity and progression of neuropathy, and exclude alternate diagnoses (i.e. cervical radiculopathy, myopathy, systemic polyneuropathy, disuse atrophy). However, they should be interpreted with an awareness of their limitations. Nerve conduction studies (NCS) evaluate large, myelinated fibres but not the smaller unmyelinated pain fibres. Since the latter are affected first in compression neuropathy, NCS may be normal early on.⁵³ Similarly, early ischaemia of a nerve resulting from compression cannot be detected on electrophysiologic studies. This accounts for the false-negative rates seen with electrophysiology.^{54,55} History and physical examination therefore remain a critical component to the diagnosis of compression neuropathy. Carpal tunnel syndrome, in particular, remains a clinical diagnosis.⁵⁶

As compression continues, demyelination and focal conduction block occur, resulting in increased latency and decreased conduction velocity on NCS, and fibrillation potentials on electromyography (EMG). Axonal loss often develops late in the pathophysiology of nerve compression, resulting in decreased action potential amplitude on NCS, and increased fibrillation potentials and reduced motor unit potential recruitment on EMG. In the very late stages of compression neuropathy, NCS may show absent sensory or motor action potentials and EMG will show marked fibrillations with no motor unit potentials.²⁰

Management principles and options

Carpal tunnel syndrome

The initial management of mild-to-moderate CTS should be non-operative. Common recommendations include activity modification, wrist splints, oral anti-inflammatory agents and/or corticosteroid injection. Nocturnal splinting with the wrist in neutral has been shown to significantly improve symptoms, and there is no advantage to wearing splints full time versus just at night.⁵⁷ Blocking the metacarpophalangeal joint in extension additionally helps to prevent the lumbricals from entering into the carpal tunnel. Corticosteroid injection into the carpal tunnel is effective at relieving CTS symptoms, although the results tend to be short-lived and is most useful for patients who require

temporary relief (i.e. pregnancy-related CTS).⁵⁸ Steroid injections may also be used for diagnostic and prognostic purposes. A Cochrane review of other non-operative modalities in CTS showed no benefit.⁵⁹

Surgery is indicated when conservative measures fail, and in severe CTS with motor involvement. Carpal tunnel release (CTR) can be performed via endoscopic or open techniques; the latter includes a spectrum of incision lengths from limited-access to full-length incisions. Multiple randomized controlled trials have been performed comparing open versus endoscopic CTR, none of which have demonstrated significant differences in outcomes or complications.⁶⁰ The potential advantages of endoscopic CTR include less scarring and pain in the immediate postoperative period, which may result in earlier return to work. However, there is a substantial learning curve to the endoscopic approach, during which time there is a higher risk of iatrogenic injury to the median nerve and a longer operative time. Limited incision open techniques also carry a higher risk of iatrogenic nerve injury owing to the reduced visualization afforded by the small incisions, and have no proven advantage over full open CTR.⁶⁰ Since even a small injury to the median nerve can be life-altering for a patient, the author's preferred approach remains open CTR with a full-length incision.

Author's preferred technique (Figure 58.2)

The procedure is performed under tourniquet control, with a Bier block or local anaesthesia plus sedation. A 2–3 cm incision is made in the palm, with the proximal extent abutting the wrist crease (except in obese patients, where the incision extends proximal to the wrist crease in a zigzag fashion to allow complete visualization). The incision is placed 5 mm ulnar to the interthenar depression to avoid injury to the PCM and to avoid dividing the TCL directly over the median nerve. The skin is incised and dissection is carried through the subcutaneous tissue to the palmar aponeurosis, which is divided longitudinally with a scalpel. Dissection then proceeds until the TCL is identified, which is divided sharply along its ulnar aspect. The distal extent of the release is the 'V' intersection between the hypothenar and thenar muscles. Proximally, any tight bands of antebrachial fascia are divided. The distal- and proximal-most division of the TCL is best performed with tenotomy scissors under direct visualization. Adequate release is confirmed by visual inspection of the proximal and distal extents of the carpal canal. Neurolysis of the median nerve, epineurotomy, and tenolysis should not be routinely performed in primary CTR.⁶¹ Following tourniquet release, haemostasis is achieved, and the skin closed with simple interrupted sutures. A well-padded wrist splint is applied for comfort and is removed in 2–3 days. Immediate range of motion (ROM) of the digits and light hand use are encouraged. The wrist is splinted at night for 2–3 weeks postoperatively to prevent bowstringing of the flexor tendons. Sutures are removed at 14 days and a gradual return to full activity is permitted 5–6 weeks after surgery.

Pronator syndrome

Non-operative management consists of stretching exercises for PT, activity modification, splinting and anti-inflammatory medications.

Surgery is indicated when conservative measures fail (Figure 58.3). A longitudinal S-shaped incision is made in the proximal third of the volar forearm, extending to the antecubital fossa proximally. Dissection is then carried down to the lacertus fibrosis, which is divided sharply. The tendon of the superficial head of PT is identified just radial to the radial artery, and is lengthened in a step-cut fashion. The superficial head of PT is then retracted ulnarly and the median nerve is identified proximally, medial to the brachial vessels. The deep head of PT is then identified, and its tendinous portion resected. The tendinous leading edge of FDS is divided. Any crossing vessels compressing the median nerve should also be ligated and divided. Proximally, the surgeon should be able to easily run a finger along the median nerve. If any compression is felt or if a ligament of Struthers or supracondylar process is identified preoperatively, the incision should be extended above the antecubital fossa to allow resection of these structures. Following haemostasis and a layered closure, a sterile dressing and a well-padded splint keeping the elbow in slight flexion are applied. The splint is removed in 3 days, and the patient is instructed to perform full ROM exercises.

Cubital tunnel syndrome

A 2- to 4-month trial of non-operative management is recommended for patients with mild to moderate symptoms. Patient education, consistent nocturnal splinting using a soft elbow pad to maintain the elbow in extension, and modifications to reduce elbow flexion during daytime activities can effectively reduce symptomatology.⁶² Cortisone injections are not recommended due to risk of intraneural injection or subcutaneous placement.

Operative management is indicated when conservative measures fail and when advanced motor dysfunction is present (nerve conduction velocities below 40 m/s, fibrillations, abnormal motor unit potentials).²⁰ Multiple surgical techniques have been described for the treatment of CuTS and there is continued controversy as to which technique is best.⁶³ Surgical options include simple decompression, medial epicondylectomy and anterior transposition in a subcutaneous, transmuscular, intramuscular or submuscular position.

In-situ decompression of the ulnar nerve entails releasing all relevant entrapment sites through a 6–10 cm incision posterior to the medial epicondyle, without disturbing the ulnar nerve from its bed and without performing neurolysis. Endoscopic and limited incision techniques have also been described, although the risk of haematoma, nerve injury and inadequate release of nerve compression is increased.⁶⁴ Potential advantages of in-situ decompression over transposition include reduced technical complexity, lower complication rates, and lower risk of nerve devascularization,⁶⁵ yet it does not address tension on the nerve during elbow flexion. A recurrence rate of 7% has been recently reported.⁶⁶

Medial epicondylectomy or ulnar nerve transposition should be considered if intraoperative subluxation of the ulnar nerve is seen following decompression. Complications of medial epicondylectomy include pain, weakness, and instability of the elbow joint.⁶⁵

Proponents of transposing the ulnar nerve anterior to the medial epicondyle cite several benefits, including reduced tension and compression forces on the ulnar nerve during elbow flexion, definitive treatment of nerve subluxation, and provision of a well-vascularized bed for the nerve.²⁰ In a subcutaneous

transposition, the new anterior position of the ulnar nerve can be maintained by suturing the dermis to a fascial flap elevated off the flexor/pronator mass.⁶⁷ The subcutaneous technique involves less muscle dissection, but extensive mobilization of the ulnar nerve is required to avoid proximal or distal kinking.

To perform an intramuscular transposition, a groove is dissected in the flexor/pronator mass in line with the transposed position of the ulnar nerve, and a soft tissue or fascial sling is then created to maintain the nerve in its anterior position.⁶⁸ Relative to subcutaneous transposition, the intramuscular technique offers greater protection and places the ulnar nerve in a straighter axis. It also necessitates less dissection than submuscular transposition, but carries a risk of iatrogenic nerve compression.

Transposing the ulnar nerve under the flexor/pronator mass is advocated as the 'definitive' procedure for CuTS, especially in revision cases.^{69,70} The flexor/pronator mass is directly reattached to the medial epicondyle, with or without step-lengthening to minimize compression on the transposed nerve. Disadvantages of the submuscular technique include a longer incision, more extensive muscle dissection, heterotopic bone formation, and the potential for iatrogenic nerve compression.^{20,65}

Author's preferred technique (Figure 58.4)

Anterior transposition of the ulnar nerve in a transmuscular plane minimizes nerve tension during elbow motion, and requires less muscle dissection than submuscular techniques. The procedure is performed under regional or general anaesthesia using a sterile tourniquet. A 6–10 cm incision is made posterior to, and centred at, the medial epicondyle. During subcutaneous dissection, care is taken to identify and protect the medial antebrachial cutaneous nerve (MABC). The ulnar nerve is identified proximally below the medial intermuscular septum, which is then excised. The nerve is followed distally as it enters the retrocondylar groove, where the fascial roof of the cubital tunnel and Osborne's band are released. Distal to the elbow, another fascial septum exists between the ulnar-innervated FCU and the median-innervated flexor/pronator muscles; this is removed to avoid kinking of the nerve after transposition. Motor branches to the FCU and FDP are identified and preserved.

A step-cut incision in the flexor/pronator origin is made. The proximally based flap elevates easily with some muscle attached, whereas the distally based flap must be elevated with sharp dissection and close to the medial epicondyle to preserve innervation. Enough muscle should be released distally so that it does not kink the ulnar nerve when the nerve is transposed anteriorly. Intermuscular fascia must also be excised to avoid compression.

The ulnar nerve is then transposed anterior the medial epicondyle. Motor branches to the FCU or FDP that inhibit tension-free transposition should be neurolysed proximally. The entire course of the nerve is re-evaluated to ensure it lies in a straight line with no further proximal or distal sites of

compression. The fascial flaps are then closed loosely over the nerve with two non-absorbable sutures, leaving enough space to pass at least one finger.

The tourniquet is then removed, and meticulous haemostasis achieved. The ulnar nerve is palpated proximally to assess for an arcade of Struthers, which is released if present. The MABC branches are then inspected. If inadvertent avulsion or injury has occurred, the distal end of the injured branch should be crushed, cauterized and transposed proximally away from the incision. A layered closure is performed over a Jackson–Pratt drain. The arm is immobilized for 2–3 days with a well-padded splint to maintain the wrist in neutral, forearm pronated, and elbow flexed at 45–60°. ROM exercises are then initiated. Progressive strengthening starts at one month postoperatively, with return to full activities at two months.

Guyon's canal syndrome

Management of ulnar nerve compression at the wrist is primarily surgical. The technique for surgical decompression of Guyon's canal entails six steps (Figure 58.5), and is performed under tourniquet control in the main operating room.²⁰ Step 1: a Taleisnik incision is made approximately 1 cm ulnar to the thenar crease, crossing the wrist in a zigzag fashion; dissection is carried through the subcutaneous tissue and palmaris brevis muscle, while preserving the cutaneous branch that is often present in the distal third of the palmar incision. Step 2: the ulnar neurovascular bundle is identified, exposed and retracted medially. Step 3: the tendinous leading edge of the hypothenar musculature is identified by palpating the hook of the hamate and looking just medial to it; the deep motor branch lies just deep to this tendinous leading edge. Step 4: the tendinous leading edge is carefully released with tenotomy scissors; often the deep motor branch is not visible until the initial 2–3 mm of the leading edge is divided. Step 5: decompression of the deep motor branch is completed by releasing the tendinous leading edge around the hook of the hamate to the small finger flexor tendons. Step 6: in order to adequately visualize and release the antebrachial fascia, the surgeon must incise and dissect proximal to the wrist crease. The ulnar nerve is then inspected proximally and distally to ensure there are no further sites of compression. The incision is closed with interrupted sutures, and a well-padded wrist splint is applied. Immediate ROM of the fingers are encouraged. The splint is removed in 2–3 days, and a gradual return to full activity is permitted over 6–8 weeks.

Radial tunnel/PIN syndrome

Conservative measures should always be attempted first, especially in radial tunnel syndrome. We have a lower threshold to operate in PIN syndrome owing to the motor deficits involved. Non-operative approaches include splinting and activity modification to help limit elbow extension, forearm pronation and wrist flexion. Anti-inflammatories and corticosteroid injections have also been utilized, especially if concomitant lateral epicondylitis is thought to be contributing to patient symptoms.²⁰

A wrist cock-up splint and ROM exercises for the wrist and hand are also useful in PIN syndrome.

Surgical decompression of the radial tunnel and PIN is approached in a standard manner that addresses all potential entrapment points on the radial nerve (Figure 58.6). Preoperatively, the patient is asked to flex the elbow against resistance with the forearm in neutral to identify the brachioradialis muscle. An inci-

sion is marked on the posterior aspect of the brachioradialis muscle in the proximal forearm. Dissection is carried through the subcutaneous tissues to fascia, where the interval between the brachioradialis and ECRL is identified. There are two landmarks to properly identify this interval: (a) the posterior cutaneous nerve of the forearm runs exactly longitudinally along this interval, superficial to muscle fascia; and (b) there is a colour

difference between the two muscles, with the brachioradialis appearing more red (thinner fascia) and the ECRB appearing lighter (thicker fascia). The posterior cutaneous nerve of the forearm is then elevated and protected, and the avascular plane between the two muscles is finger dissected down to the radial nerve. Deep retractors are placed to improve exposure.

The branches of the radial nerve can always be found in the same orientation: the SRN is most volar and large, the ECRB branch is thinner and lies between the SRN and PIN, and the PIN is large and most dorsal. The PIN is also obliquely oriented as it courses under the superficial head of the supinator. The fascial edge of the ECRB is released first, which allows the supinator muscle to be visualized. The fascial edge of the superficial head of the supinator (arcade of Frohse) is then completely released, which decompresses the underlying PIN. Any crossing vessels (vascular leash of Henry) compressing the PIN should be ligated and divided.

If the preoperative history and physical examination suggest radial nerve compression in the proximal radial tunnel (as indicated by aching pain over the radial nerve above the elbow), more proximal dissection and release may be required to release conjoined fibres of the brachioradialis and brachialis muscles. Occasionally, a second incision is required to achieve adequate visualization and release. If there is associated lateral epicondylitis, then a proximal tenotomy of the ECRB tendon is also performed.

The radial nerve and its three branches should then be once again inspected to ensure no residual compression points are seen. Neurolysis should be considered in patients who present with significant motor weakness or paralysis in the PIN-innervated muscles, especially if scarring of the nerve is identified intraoperatively. Neurolysis should progress until a good fascicular pattern and bands of Fontana are seen.

Postoperatively, the patient is placed in a well-padded dressing. This is removed in 2–3 days, at which point gentle, full ROM exercises are encouraged. Strengthening begins at one month, and return to full activities with no restrictions at two months postoperatively.

CHAPTER 59

Dupuytren disease

Paul M.N. Werker

Department of Plastic Surgery, University Medical Centre Groningen, Groningen, The Netherlands

Definition

Dupuytren disease is a benign fibromatosis, which may lead to finger joint flexion and webspace contractures. The disease usually commences in the ring and little finger ray in the sixth or seventh decade of life and males are more affected than females. Systematic meta-analysis of all published work on prevalence has revealed that it ranges from 0.6 to 31.6.¹ The disease is most prevalent in white people from the north-western part of Europe and their offspring, but also affects other races.

Associated fibromatoses are *Ledderhose disease*, coinciding in 15% of cases with Dupuytren disease² and giving rise to nodules in the instep area of the foot; *Peyronie disease*, which encompasses the formation of plaques within the tunica albuginea of the penis, leading to penile curvature sometimes causing hinderance to sexual intercourse;³ and *knuckle or Garrod pads*, which are nodules at the dorsum of the proximal interphalangeal joints.⁴

Dupuytren disease generally does not disturb finger flexion, although it may be related to trigger finger.⁵ Awkwardness and functional impairment worsen with increasing contracture, especially when the total contracture of a ray becomes more than 90°, and contractures may interfere with job-specific tasks.⁶

There is a subset of patients in whom a more aggressive disease course (Dupuytren diathesis) develops. In these patients, the disease starts early, affects both hands and more family members, and associated fibromatoses are usually present.⁷ As a consequence, treatment is needed earlier and recurrences are more frequent. These patients also have more often radial involvement of the hand.⁸

Dupuytren disease should be regarded as a chronic disease that cannot be cured. In this chapter the current knowledge of this disease will be summarized.

Surgical anatomy

In the palm the fascial structures form a complex three-dimensional network.^{9,10} The longitudinal fibres are organized in a fan shape and form the palmar aponeurosis (Figure 59.1).

The fibres form the pretendinous and the prelumbrical bands, and all pass superficial to the transverse ligament of palmar aponeurosis (TLPA), which is situated at a line joining the proximal and distal palmar crease.¹² The ulnar border of the TLPA blends with the hypothenar fascia and the radial border is continuous with the proximal commissural band, which runs through the first webspace and ends in the thenar fascia at the level of the first metacarpophalangeal joint. Just beyond TLPA, the pretendinous bands divide into three layers (Figure 59.2): Layer 1 is the most superficial layer, which has its insertion in either the skin of the distal palm or that of the proximal phalanx. Layer 2 fibres spiral underneath the neurovascular bundle towards the lateral side of the fingers and form a spiral band, which is present in all fingers, except for the ulnar side of the little finger. Layer 3 fibres dive deep into the hand on both sides of the flexor tendon sheath to insert on either side of the corresponding metacarpophalangeal joint.

The natatory ligament lies just underneath the skin in the distal palm and superficial to the neurovascular bundles (see Figure 59.1). On its ulnar end it is continuous with the hypothenar fascia, and on the radial side with the distal commissural band. The natatory ligament has attachments to the flexor tendon sheath, lines the webs and has extensions along the lateral sides of the digits, where it blends with fibres from the spiral band and is continuous with the lateral digital sheet.

Important sagittal ligaments in the palm are the septa of Legueu and Juvara and are usually just as wide as TLPA and, except the thumb, connect the aponeurosis palmaris with the deep transverse palmar ligament that links the volar plates of all metacarpophalangeal (MCP) joints. Together these structures form nine boxes which on alternating basis hold either the lumbrical muscle and neurovascular bundles, or the flexor tendons (Figure 59.3). Much smaller vertical fibres are dispersed throughout the palmar aponeurosis and anchor it to the overlying skin.¹⁵

The most important digital fascial structures bear the names of Cleland and Grayson.^{16,17} Their detailed anatomical description has undergone significant changes over time and drawings

Figure 59.1 Anatomy of the superficial fascial structures of the palm of which the skin and subcutaneous fat has been removed. Source: Smith, 2002.¹¹ Reproduced with permission of Elsevier.

depicting the exact course of their fibres have been conflicting. Basically, there is a structure located palmar to the neurovascular bundle, which is known as Grayson ligament, and a ligamentous structure that lies dorsal to these structures, which bears the name of Cleland. Further detailed dissection studies are necessary to reveal their exact anatomy and that of the lateral digital sheet and retrovascular sheet.

Where the hypothenar muscles pass into the little finger there is a crossroads of fibres which all seem to play a role in Dupuytren disease.¹⁸ At the thenar and in the first webspace there is also a complex three-dimensional network of bands, which may also be involved.¹⁹

Already in the days of Baron Guillaume Dupuytren there was disagreement about the origin of the disease. Some authors, including Dupuytren himself, believed that the disease starts within the fascia. Others felt that it originates also in the tissues between the skin and the fascia.²⁰ There is mounting evidence that the latter theory may be true²¹ and there is consensus regarding the role in disease of some (but not all) of the mentioned fascial structures (Table 59.1). If a well-defined 'band' becomes affected by disease, it is then referred to as 'cord'. McFarlane tried to simplify the often complex phenotype of the disease in the finger by defining anatomic patterns of disease, such as central cord, lateral cord and spiral cord.¹⁰ Further work is required to be able to explain all these findings, including the double spiral around the digital nerve during surgery.²²

Table 59.1 Various fascial structures in palm and in fingers of interest in Dupuytren disease

Anatomical structure	Name if affected by DD	Clinical relevance
Fascial structures in the palm		
Pretendinous band (PTB)	Pretendinous cord (PTC)	Situated immediately beneath the skin in palm. Responsible for earliest signs of disease in most patients. Divides in three layers distal to transverse ligament of palmar aponeurosis
Prelumbrical band (PLB)	Prelumbrical cord (PTC)	
Layer 1 of PTB	Pretendinous cord in palm; central cord in finger	Situated immediately beneath the skin, distal to line joining proximal and distal palm crease. May cause MCP and PIP joint contracture. Does not displace neurovascular bundle
Layer 2 of PTB (spiral band)	Spiral cord	Contracture causes displacement of neurovascular bundle medially and palmarly. May cause MCP joint contracture. Warning sign: Short–Watson sign
Layer 3 of PTB	Vertical cord	Dives deep into the hand on both sides of MCP joint. May cause painful triggering
Transverse ligament of palmar aponeurosis (TLPA)	–	Runs along line joining proximal and distal palm crease, deep to PTB/PLB. Not affected by DD. Can be left behind during fasciectomy. Will facilitate subsequent surgery when left intact
Ligaments of Legueu and Juvara	–	Connect TLPA to deep transverse ligament
Natatory ligament (NTL)	Natatory cord	Situated immediately beneath the skin and superficial to neurovascular bundle. May cause web contracture
Proximal/distal commissural band	Proximal/distal commissural cord	Proximal band is extension of TLPA; distal band is extension of NTL. Situated immediately beneath the skin in the 1st web; may cause 1st web contracture
Abductor digiti minimi fascia	Abductor digiti minimi cord (ADMC)	Forms Y-shape together with pretendinous band and ulnar neurovascular bundle can always be found proximal to junction. ADCM may have multiple levels
Deep transverse ligament (DTL)	–	Connects volar plates of MCP joint. Together with ligaments of Legueu and Juvara and TLPA forms nine boxes through which flexor tendons and lumbrical muscles and neurovascular bundles pass
Fibres of Grapow	–/nodules in palm?	Dispersed over palmar aponeurosis. Anchor palmar skin to TLPA
Fascial structures in the digits		
Lateral digital sheet	Lateral digital cord	Situated immediately under the skin on each side of each finger; may displace neurovascular bundle towards midline. May cause MCP and PIP joint contracture when involved together with spiral cord and Grayson's ligament inserting to A4 pulley. May also cause DIP joint contracture as lateral cord
Grayson's ligament	Central cord (CC)	Harbours nodules and cord at proximal phalanx. May cause PIP contracture
Cleland's ligament	–/Retrovascular cord ??	Not easily visualized, since situated behind neurovascular bundle. May cause PIP and DIP joint contracture
Transverse retinacular ligament	–	Connects mid slip of the extensor apparatus at PIP joint to the lateral bands and the volar plate. Palmar portion may shorten in severe PIP joint contractures, preventing the lateral bands from sliding back after contracture release
Oblique retinacular ligament (Landsmeer)	–	Connects volar plate of PIP joint to dorsal capsule of DIP joint. May shorten and cause Boutonnière deformity

DD, Dupuytren disease; MCP, metacarpophalangeal; PIP, proximal interphalangeal.

Aetiology

Interplay of both genetic and environmental factors (smoking and alcohol use) sets the stage for the emergence of the disease. Additionally, the disease occurs more frequently when diseases such as diabetes mellitus are present or following long-term barbiturate use.^{23,24} In addition, a recent meta-analysis underscores the association between manual labour and vibration and the development of Dupuytren disease.²⁵

A number of older population studies have suggested that the disease has an autosomal dominant trait with variable penetrance. Using a Genome Wide Association Study it was recently shown that Dupuytren disease is a polygenetic disease. Nine regions in the genome were identified that are strongly associated with Dupuytren disease.²⁶ In six of these regions, genes were located that play a part in the WNT-signalling pathway. In a subsequent study a clear correlation between the genetic load and the presence of certain diathesis factors came to light.²⁷ It has been calculated that the sibling recurrence risk for Dupuytren disease is 4.5 and that the currently known loci that predispose to Dupuytren disease account for 12.1% of the total heritability of the disease.²⁸

Pathophysiology and histology

The cells responsible for the deposition of superfluous extracellular matrix (ECM) proteins in Dupuytren disease are specialized fibroblasts with contractile properties named myofibroblasts.²⁹ Myofibroblasts derived from Dupuytren disease nodules exhibit an abnormal response cycle to mechanical tension with anchorage to the ECM and shortening, which is thereafter locked by the secretion of collagen type I and III and other ECM molecules.^{30,31} Stiffness of the ECM has been found to be crucial in myofibroblast behaviour and research is underway to identify modulating factors of this process.³²

In this respect the work of Luck in 1959 and Lam *et al.* in 2010 is relevant.^{33,34} The former proposed a subdivision in three phases and the latter analysed the respective collagen content:

- The *proliferating phase* is where there is an abundance of disorganized cells present in nodules. Over 35% of the collagen that is deposited is of type III.
- The *involutional phase* is where the number of cells declines but alignment along lines of stress becomes obvious. The amount of collagen type III diminishes (20–35%), whereas the amount of type I collagen increases.
- The *residual phase* of scar-like hypocellular tissue consists of less than 20% of collagen type III.

Clinical assessment

The first manifestations of Dupuytren disease are subtle subcutaneous irregularities in the palm, which may be difficult to discern. Although nodules and skin pits suggest the diagnosis,

the differential diagnosis in that stage should include ganglia and inclusion cysts, occupational hyperkeratosis, callous formation, tenosynovitis, giant cell tumours and epitheloid sarcoma or even metastatic disease.^{35,36}

The natural progression is towards cords that may cause contracture. Once contractures emerge, the diagnosis is usually evident (Figure 59.4), although differential diagnosis of contracture includes dermal scars, congenital conditions (i.e. camptodactyly), stuck trigger finger, tendon bowstringing from pulley incompetence, tendon adhesions or imbalance (as in sagittal band rupture), intrinsic joint contractures and spasticity. Cords can cause extension deficit of any finger joint, although distal interphalangeal (DIP) joint contracture is rare. More often, long-standing proximal interphalangeal (PIP) joint flexion position leads to an attenuation of the central slip, forcing the DIP joint into hyperextension and thereby causing a Boutonnière deformity of the affected finger (Figure 59.5).

Figure 59.4 Left hand of 63-year-old patient with pretendinous cord in the ring and middle finger ray, and a lateral digital sheet cord on the radial side of the ring finger with skin pitting in the palm and just proximal of the proximal interphalangeal joint crease and radial deviation of the affected finger. Photograph courtesy of Bert Tebbes. Reproduced with permission of University Medical Center Groningen (UMCG).

Figure 59.5 Patient with Dupuytren disease of right little finger with Boutonnière deformity.

Figure 59.6 Sixty-year-old male with severe Dupuytren disease of the left thumb, middle ring and little finger and of the right little, ring, middle and index finger. Photograph courtesy of Bert Tebbes. Reproduced with permission of University Medical Center Groningen (UMCG).

Dupuytren disease often affects both hands, without synchronicity and may cause pathology in any ray (Figure 59.6). Nodules may be painful when compressed but this sign usually disappears with time. Cords are almost always insensate. The most practical grading systems are those of Iselin, and Tubiana and Michon (Table 59.2).^{37,38} Iselin's staging system is very practical for quick scoring, such as during prevalence studies. Tubiana's system is more sophisticated and its 1986 modification makes the system relatively complex, hampering its widespread application.³⁹ The down side of this system is that progression into a higher stage may take 5–40° and is therefore

Table 59.2 Grading systems for Dupuytren disease: every ray is given a stage number

Described by	Stage	Meaning
Iselin	1	Dupuytren disease nodules and cords without contracture
	2	MCP joint contractures
	3	MCP and PIP joint contracture
	4	Boutonnière deformity with MCP and PIP joint contracture and DIP joint hyperextension
Tubiana	0	No signs of Dupuytren disease
	N	Nodules only. No contracture
	I	Total passive extension deficit (TPED) smaller than 45°
	II	TPED in between 46 and 90°
	III	TPED in between 91 and 135°
	IV	TPED in between 136 and 180°

MCP, metacarpophalangeal; PIP, proximal interphalangeal.

not linear, but stepped. Therefore, for follow-up studies it is better to register and report the passive extension deficit (PED) by joint and its sum by ray (TPED). Apart from these objective data, patient-rated outcome measures (PROMs) have become increasingly important to evaluate outcome and there is an increasing demand to harmonize their use among researchers.^{40,41}

Management principles

In the discussion of the treatment strategies for Dupuytren disease, the following aspects need to be addressed (Table 59.3): how the method manages skin, fascia and joints; indication for and best timing of treatment; specific treatment benefits, risks and complications; immediate outcome and time of disability; late outcome including definition and rate of recurrence; additional treatment options.

Description of treatments, short-term outcome and complications

Non-operative treatments

To relieve pain in early-stage (stage N) Dupuytren disease, patients may be advised to wear padded (biking) gloves. Steroid injection is also advocated by some.⁴²

The newest injection treatment modality employs collagenase, which weakens pathological Dupuytren disease tissue. The drug (Xiaflex®/Xiapex®) is injected into the palpable cord that is responsible for a joint contracture of at least 20°, and at a minimum of 24 h later the treated joint is extended using light force to rupture it. If the obtained result is not satisfactory, the treatment may be repeated after 30 days. Skin ruptures occur frequently and the risk of skin rupture may be reduced by delaying the extension manoeuvre for as long as two weeks.⁴³

In double-blind studies, collagenase injection was found to be significantly more effective than placebo in releasing

Table 59.3 Overview of the treatments for Dupuytren disease, including results and recurrence risks

Treatment	Indication	Mean disability time	Results	Complications	Recurrence	Disadvantages	Level of evidence
Limited fasciectomy ^{53,71,79}	>30° contracture; painful nodules ^{53,71,79}	6 weeks	79% reduction of contracture ⁷¹	19% Haematoma, skin necrosis, neurovascular damage ⁷³	In 21% within 5 years increase of TPED of >30° compared to 6 weeks result ⁷⁹	Invasive treatment. Complications in 19% of patients. 6 weeks of rehabilitation ^{71,73}	Level 2
Dermofasciectomy ^{5,4,85,86}	Recurrences. Aggressive type in patients younger than 40	8 weeks	Comparable to limited fasciectomy	Haematoma, loss of skin graft, infection, neurovascular damage	8.4% after 6 years; ⁵⁴ 12.2 after 3 years ⁸⁶	Most invasive treatment, further disadvantages same as with limited fasciectomy + those of skin grafting	Level 3
Percutaneous needle fasciotomy ^{57,76,79,103}	Isolated cord patients; wish for minimal invasive treatment	<1 week	63–99% reduction of contracture ^{76,103}	Nerve damage, tendon damage skin fissures especially in the treatment of recurrences	In 85% within 5 years increase of TPED of >30° compared to 6 weeks result ⁷⁹	‘Blind technique’ high risk of recurrence	Level 2–4
Clostridial collagenase ^{44,104,105}	Contracture associated with a palpable cord	<2 weeks	Mean clinical success 65%. MCP joint 77%; PIP joint 40% (correction within 0–5° of full extension)	Local, temporary reaction to injection	In 37% ⁷⁷ increase of PED of >20° after 3 years ⁸⁰	Treatment of more than one cord is still off label; expensive drug	Level 1–3
Radiotherapy ^{47,82}	Disease in nodular phase	2× 1 week: 2 treatment sessions of 5 irradiations on consecutive days	Stable in 59%; progression in 31%; regression in 10%	32% erythema and other skin conditions ⁴⁷	NA	Only effective when applied early in early-stage disease	Level 3

PED, passive extension deficit; TPED, total passive extension deficit; MCP, metacarpophalangeal; PIP, proximal interphalangeal.

contractures.⁴⁴ In 77% of the MCP joints and in 40% of the PIP joints, collagenase injection released the contracture to 0–5°. Adverse events, such as swelling and pain, occurred in 97% of cases. Because Xiaflex/Xiapex action is limited to type I and III collagen, but digital nerves and arteries are primarily type II and IV collagen, they are not at risk from enzymatic damage.

Halfway through the twentieth century, the first report on radiotherapy emerged as a possible treatment modality for Dupuytren disease.⁴⁵ Keilholz reported results of a protocol of irradiating the affected area and surrounding margin five times a week in two sessions, 6–8 weeks apart with a total of 30 Gy. After three months, the authors found that disease was stable in 92% of Tubiana stage N, N/I and I cases, had regressed in 7% and had progressed in 1%. In 75% a non-significant reduction in size and consistency was found.⁴⁶ Complications related to the treatment are only minor late toxicity (skin atrophy, dry desquamation) in 32% of the patients. Radiotherapy is most effective when applied early after disease onset.⁴⁷

Operative treatments

Management of the diseased fascia

Limited or selective fasciectomy (LF) is still the most commonly performed surgical procedure for Dupuytren disease.⁴⁸ Only the diseased tissue is removed. The generally accepted indication for treatment is a painful nodule that does not respond to conservative measures or a progressive flexion contracture of MCP joints of 20–30° or any PIP joint contracture.^{49,50}

Segmental fasciectomy (SF) is a less invasive variant of LF in which only 1-cm-long pieces of diseased fascia at strategic places are removed.^{51,52} As with all surgical techniques for Dupuytren disease, MCP joint contractures can be very well corrected, but the technique is less successful for PIP joint contractures and the complication rate is similar to that for LF.⁵³

Dermofasciectomy (DF) is the removal of both skin and underlying fibromatosis. It is advocated by some for primary Dupuytren disease cases, since they have found that recurrences are more delayed.⁵⁴ Most only apply it in cases with aggressive disease and early recurrence.

Open fasciotomy (OF) was first proposed by Henri Cline in 1787 for Dupuytren disease,⁵⁵ although there is no record that he ever performed it. Through transverse incisions, cords responsible for contractures are identified, isolated from the neurovascular bundles, and divided. In the short term it is just as effective as LF.⁵⁶

All above-mentioned procedures are usually performed under regional or general anaesthesia. This is one of the major differences with percutaneous needle fasciotomy (PNF). With PNF, cords are percutaneously divided at multiple levels with a needle under local anaesthesia during the same session.⁵⁷ By using intradermal local anaesthesia only, nerve conduction can be maintained and monitored during the procedure, enabling the patient to warn the surgeon if the needle stimulates a nerve. Some authors advocate combining PNF with steroid injection, but the evidence that supports this is debated.^{58,59}

PIP joint management

One approach for persistent PIP joint contractures after fasciectomy is sequential transverse division of the flexor tendon sheath, the check rein ligaments and the release of the accessory collateral ligaments.^{60,61} Another just as effective approach is intraoperative gentle manipulation.⁶² Attenuation of the central slip of the extensor may also be a significant factor in the inability to sustain correction of PIP joint contractures greater than 60°.⁶³

Messina and Messina advocated continuous traction via an external fixator to reduce higher Tubiana contractures to such an extent that fasciectomy became easier,^{64,65} and various progressive distraction mechanisms have since been developed and successfully applied.⁶⁶

Skin management

When there is only limited shortage of skin, common fasciectomy incision options include a longitudinal incision from palm to finger, a zigzag-type incision, or a transverse incision at the level of TLPA and at the joint creases, or a combination of these. For SF, small C-shaped incisions are used. McCash has shown that transverse incisions can be left open as long as bare tendons are not exposed.⁶⁷ For the fingers, one or more Z-plasties in the longitudinal incisions or YV-plasties in the zigzag incisions can be employed to gain extra length for closure.

If skin transposition is not sufficient to close a defect, or if the skin is removed, it can be augmented or replaced using skin grafts. Skin grafts have also been advocated as 'firebreaks' and in some hands proved very successful in the prevention of recurrence.⁶⁸ Full-thickness skin grafts are recommended because they are more durable and undergo less secondary contraction than split-thickness skin grafts. Full-thickness skin grafts are usually taken from the ipsilateral extremity or the groin. Donor sites are closed primarily but leave scars, one of the disadvantages of this treatment. Other drawbacks are the increased duration of the procedure, a prolonged rehabilitation period, and increased risk for complications: a graft may not take, thereby extending the recovery period to a mean of eight weeks.

Apart from grafts, a great variety of local (homo- or heterodigital), regional⁶⁹ or even free flaps can be used to manage skin shortage with very good long-term results in one case report.⁷⁰

Postoperative management

Following LF, SF and DF, the treated hand is usually put in a soft bulky dressing for a week, sometimes reinforced by a splint. After PNF, a very small dressing for just one day suffices. As soon as the wound permits, patients begin flexion and extension exercises and this process is often supervised by hand therapists.

Early outcome

With LF an average reduction of total passive extension deficit (TPED) of 79% at six weeks postoperatively has been reported.⁷¹ Results were best at the MCP joint (87% reduction of passive

extension deficit (PED)) and worst at the PIP joint (49% reduction of PED). Most authors agree that surgical prognosis of Dupuytren disease of the PIP joints is worse, especially in the little finger, regardless of treatment technique.⁷²

Treatment-specific complications of surgery are common.⁷³ The cumulative complication rate for LF has been found to be 19% and even higher in DF. Skin slough can usually be treated conservatively. Haematoma formation should be evacuated before settling, thereby preventing fibrosis and early recurrence. Joint stiffness is most difficult to treat and functionally is sometimes worse than the original flexion deformity. Nerve injury occurs in approximately 1% of primary and, if feasible, should be handled by direct repair. Surgery may also cause injury to the digital arteries, the incidence of which is most likely underreported. In a worst-case scenario, especially after repeated surgery, vascular injury may result in gangrene of the finger, necessitating partial or complete amputation. Mean recovery period to normal hand use is for LF on average six weeks and for DF two weeks longer.⁷⁴

PNF is also very effective for MCP joints, but less so for PIP joint contractures. Early outcome of PNF is similar to that for LF when the initial TPED is less than 90°, but significantly less successful above this.⁷¹ Complications are limited to skin tears and the risk to damage nerves or tendons is less than 1%. The cumulative risk of serious complications of PNF is much less than that for the more invasive treatments.^{75,76} Skin fissures may occur with adherent skin, and in recurrent cases are almost the rule, although one can try to prevent this by releasing the skin from the cord.⁵⁷ Since they heal without leaving a trace they usually do not bother the patient.

Long-term outcome: recurrence and extension

One problem with recurrence is the wide disparity in definitions, with few randomized studies that compare treatment modalities and few studies with sufficient follow-up.⁷⁷ Another issue is differences in treatment modalities: diseased fascia may be incised (OF, PNF), partly removed (SF), fully removed (LF, DF; with or without skin grafting), injected with proteolytic enzymes, or subjected to ionizing radiation. In some studies, recurrence is defined qualitatively as any sign of new tissue in a previously operated spot.⁷⁸ In others, recurrence is defined quantitatively by measuring the PED of each joint and the TPED for each ray, and recurrence is defined as an increase of TPED by a certain number of degrees (20° in the collagenase studies, 30° in most other studies).^{44,79}

Long-term outcome of non-operative treatments

Ketchum investigated the efficacy of triamcinolone injections. Fifty per cent of his patients experienced reactivation of disease in the nodules 1–3 years after the last injection, necessitating one or more injections.⁴²

The recurrence rate in collagenase studies is defined as increase of more than 20° of PED in joints, which had an initial complete correction. Because this definition excludes recurrence in joints that were not initially fully corrected (and have higher

recurrence rates,⁵⁰ it skews results favourably and cannot be compared to other definitions of recurrence which include all treated digits. Using this definition of recurrence, recurrence following collagenase was 19% after 2 years and 37% after 3 years.⁸⁰ At present, there is only one very small study with long-term follow-up (8 years) data from only eight patients. Recurrence was found in 67% of the MCP joints and 100% of the PIP joints.⁸¹

The progression rates of radiotherapy is as follows: After a mean of 10 years, 87% of Tubiana stage N patients and 70% of Tubiana stage N/I patients remained stable or regressed. In more advanced stages, the rate of disease progression increased to 62% (stage I) or 86% (stage II). Sixty-six per cent of the patients showed a long-term relief of initially reported side effects (i.e. burning sensations, itching and scratching, pressure and tension).⁴⁷ A recent non-randomized trial with long-term follow-up showed a benefit of radiotherapy over observation alone.⁸²

The basic issue that needs further study, however, is the time versus progression relation in Dupuytren disease which, in the author's experience, is more likely exponential than linear. Since radiotherapy has only been found to be effective in early stages of the disease, it is unclear what it is actually being accomplished.

Long-term outcome of operative treatments

Using reappearance of deformity necessitating additional surgery as the definition of recurrence, Dias reported 15% recurrence at a mean of 27 months after LF.⁸³ Others, using the reappearance definition, have published recurrence figures of up to 73% 7 years after LF.⁸⁴ A randomized controlled trial (RCT) comparing LF and PNF with a follow-up duration of 5 years showed a recurrence rate following LF of 21%.⁷⁹

For the long-term outcome of skin grafting in Dupuytren disease, the work of Ketchum is instructive.⁸⁵ He found no recurrent disease in 36 hands of 24 patients an average of 4 years after fasciectomy and 'firebreak' skin grafting. The incidence of extension outside the grafts was 8%. Other authors, however, have not been able to achieve similar results with this technique. In a very well-executed RCT, no difference in recurrence rate was found at 3 years comparing LF with or without firebreak skin grafting, with a recurrence rate at the PIP joint of 12.2% in both groups.⁸⁶ It is, however, critical to distinguish the above technique of simple intercalated 'firebreak' skin grafting and dermofasciectomy and skin grafting. Armstrong *et al.* reported a recurrence rate with the latter technique of 8.4% of 143 treated rays.⁵⁴

Recurrence rates of SF are similar to those of LF.⁵² Recurrence rates at PIP joint are always higher than those at MCP joints and irrespective of the technique used.⁸⁷ PNF recurrence rates are relatively high compared to more aggressive treatment modalities. After 3 years, Foucher found, just as we did, recurrence rates in approximately 60% of cases and our 5-year recurrence rates were 85%.^{79,88} Hovius *et al.* are in the process of

testing if this high recurrence rate can be reduced by adding grafted fat by means of lipofilling to the cord that has been extensively divided. Long-term results are pending.⁸⁹

Some patients experience recurrence earlier than others. Van Rijssen *et al.* and Pess *et al.* showed that there is a strong correlation between age at the moment of treatment and chance for recurrence.^{76,79} This is probably the most important diathesis characteristic that influences recurrence. In an effort to prevent or postpone recurrence, especially in such cases, researchers have found that drugs such as tamoxifen and 5-fluorouracil *in vitro* were able to delay fibroblast proliferation.^{90,91} Subsequently, some added these measures to their treatment regimen. Systemic treatment with 5-fluorouracil in an RCT unfortunately proved ineffective.⁹² In a similar design, Degreef *et al.* found that highly dosed neo-adjuvant tamoxifen improved the surgical outcome of segmental fasciectomy.⁹³ The same group has successfully attempted to delay recurrence by placing cellulose implants in the gap created by segmental fasciectomy.⁹⁴

Treatment of recurrence

Evidence for the best treatment for recurrence is scarce and there is a need for comparative studies in this respect. What is known is that there is a greater risk of complications during LE.⁹⁵ PNF can also be used safely for the treatment of recurrences and is just as effective as during primary PNF.⁷⁹ With skin involvement and skin scarring, the likelihood for a skin fissure or rupture becomes greater and more effort needs to be directed to the release of the pathology from the skin.⁵⁷ Collagenase can also be used safely in recurrences.⁹⁶ Surgery following PNF is in my personal experience not more difficult than virgin surgery. No unequivocal opinion exists with regard to surgery after treatment with collagenase.⁹⁷ The role of radiotherapy for recurrent disease is yet unclear.

Rehabilitation

Splinting and hand therapy are commonly advised in the treatment of Dupuytren disease after surgery and a variety of protocols are used.⁹⁸ Evidence for the use of either of them is lacking, however.^{99–102} And some are of the opinion that only patients with rapidly reoccurring extension deficits may benefit from night splints.

Acknowledgement

Dr Charles Eaton, MD from Jupiter, FL is thanked for critically reading this chapter.

CHAPTER 60

Fractures and dislocations in the hand

Barbara Jemec and Nicola Burr

Department of Plastic Surgery, The Royal Free Hospital, London, UK

Introduction

Hand surgery always involves teamwork between the surgeon, the patient and the therapist. One cannot get a successful outcome without the cooperation of the other two. The following chapter deals with the diagnosis and management of fractures of the phalanges and metacarpal bones in adults and children.

Paediatric fractures of the digits

Assessment, classification, management and complications

The differences between paediatric and adult hand fractures lie in the elasticity of children's bones and the potential disruption of their growth. Children's bones have increased water content and plasticity; and tend to fracture incompletely with trauma. Incomplete fractures are seen as bows (bending forces), buckle fractures (one cortex buckles with compression) or greenstick fractures (one cortex ruptures under tension, the other is intact or buckles). The plastic deformation may prevent complete reduction of the fracture when manipulated, but most fractures still do not require open operations, but can be managed with closed or percutaneous techniques, due to the remodelling potential.

The assessment of the fracture is clinical and radiological. The child will have point tenderness in the non-displaced fracture over the physis, which should increase suspicion of a fracture. If plain X-rays in two, if not three planes, cannot explain pain or deformation, MRI or CT will. The tenodesis test adequately demonstrates any rotational deformity, as the fingers all point to the scaphoid tubercle. If in doubt; compare with the other hand. Angular deformities in children may remodel; rotational deformities will not and need to be corrected.

Any fracture interfering with the growth plate has a potential for disrupting normal growth. Paediatric fractures involving growth plates are classified according to Salter and Harris,¹ Ogden² expanded this in 1984 (Table 60.1).

The most common fracture pattern encountered in the fingers is a Salter–Harris II, which is satisfyingly corrected using

a simple manoeuvre with a pen, over which the finger is manipulated (Figure 60.1).

Crush distal phalanx fractures and nailbed injuries are the most common paediatric fracture. These occasionally need a K-wire or an orange needle to pin the distal fragment in place if large enough. A special type of nailbed injury called Seymour fractures are displaced Salter I or II fractures of the distal phalanx, with avulsion of the proximal edge of the nail from the eponychial fold and the germinal matrix often interposed in the fracture itself (Figure 60.2). Accurate and timely debridement and repositioning of all tissues is paramount to adequate growth of both digit and nail. The clinical presentation can be confused with a mallet finger (because the extensor tendon inserts itself in the epiphysis whereas the flexor tendon inserts itself in the metaphysis), but a true lateral X-ray and a thorough examination under anaesthetic should reveal the injury.

Fractures through the neck of the phalanges are usually only found in children and mostly involve some unfortunate interface between fingers and doors. Al-Qattan divided them into three categories, which determined prognosis and treatment: type I fractures are undisplaced, type II fractures are displaced but maintain some bone-to-bone contact, and type III fractures have no bone-to-bone contact.³ Type III is furthermore subdivided according to the location of the distal fragment, type IIID especially being associated with an avascular fingertip. Since the smallest displacement is poorly tolerated, all types apart from type I require open reduction and K-wiring, but have progressively worse prognoses (Figure 60.3).

Hand therapy intervention for these patients is minimum as they rarely become stiff at the distal interphalangeal (DIP) joint and start functional use once the bulky bandage or splint has been removed. Older children may require a small volar splint of the affected digit until pain has settled and oedema control work is completed as necessary.

It is worth remembering that there is no gain in changing the dressings in nailbed injuries before 10 days, unless you are worried about infections, which of course is a different matter.

Table 60.1 The paediatric fracture: the management and potential complications according to the Salter–Harris classification, including later additions

Classification	Clinical	Configuration	Management	Complication
I: Through physis, showing increased width of physis	Point tenderness only		Conservative	Possible shortening
II: Through physis and metaphysis	Occurs >10 years old		Manipulation under anaesthetic if displaced	Minimal shortening
III: Through physis and epiphysis	>10 years old		Accurate surgical reposition	Can result in chronic disability as extending into joint
IV: Metaphysis, physis and epiphysis	Any age, rare in hand		If displaced consider open reduction internal fixation	Intra-articular so can result in chronic disability and can cause premature focal fusion of the joint
V: Compression of the epiphyseal plate	Usually from axial loading		Conservative	Growth disturbances
VI: Open fracture in which part of the physis is missing	Open fracture		Initial fat grafting to prevent physeal bar; later reconstruction with bone graft	Growth disturbances
VII: Epiphyseal plate only			Requires accurate repositioning as intra-articular fracture	No impact on growth
VIII: Isolated injury to the metaphysis			Usually can be manipulated under anaesthetic or, if necessary, fixed with K-wire	Potential injury related to endochondral ossification
XI: Injury to the periosteum				May interfere with membranous growth

Adult fractures

I always consent my patients for bone grafts, just in case I need it and I have never regretted speaking to the patient about this option before the operation.

Metacarpal fractures

Metacarpal fractures can be divided into their anatomical location or configuration but most commonly occur in the little or ring fingers and the thumb.

Neck

Neck fractures of the fourth and fifth metacarpal are usually treated conservatively. They can be manipulated and the digit neighbour-strapped, accepting that the patient will lose the knuckle and may have some extensor lag, unless there is a rotational element. If there is rotation, the rotation must be corrected surgically.

Neck fractures in which the head is completely off the metacarpal or that involve the index or little fingers may be treated with mini-condylar plates, or for all fingers with H-plates (the

two-hole fixation on each side of the fracture can be transverse (remember) or intramedullary K-wiring.

Intra-articular

Intra-articular metacarpal head fractures are best seen on Brewerton's views and can be fixed with countersunk screws, if the fragments are large enough. The fragment must be three times the size of the screw head to hold it. If this is not possible a primary joint replacement or a free joint from the second toe must be considered. Very rarely does this joint get considered for fusion in the fingers.

Shaft

Metacarpal shaft fractures can be divided according to their configuration into transverse, spiral, short and long oblique, butterfly fragments and comminuted.

If the fracture can be held in position with one or two bone-holding forceps, you can fix it with screws (which must be placed perpendicular to the fracture) (Figure 60.4).

Figure 60.4 Screw fixation of spiral fracture. Note the spiral placement of screws.

Figure 60.5 (a) Rotation: spot the odd one out. (b) Volar hand splint.

If you cannot maintain position with a bone-holding forceps, you must consider a fracture fixation which involves a plate (or even an external fixator for the first or fifth metacarpal). For a simple transverse fracture intramedullary K-wiring is also a possibility. Crossed K-wires often distract the fragments rather than compressing the fracture and should be discouraged.

It is important to keep checking the position of the fingers, even when the fracture looks to be perfectly aligned, before drilling and inserting screws, to avoid rotation (Figure 60.5).

When applying plates to fractures it is important to understand the difference between locking and non-locking plates. Conventional plates require precise adaptation of the plate to the aligned bone. The bone is pulled towards the plate when the screws are tightened and screw insertion can therefore alter the fracture position if everything is not precisely positioned. In locking plates the threaded screw head fits into the threaded plate hole and locks when tightened, thus providing a stable constellation of plate and screws. The bone is therefore not pulled towards the plate when the screws are tightened: the underlying cortical bone perfusion is not disrupted and the screws are unlikely to loosen from the plate, even if they have been inserted into a bone graft or fracture gap.

There are two plates to consider in metacarpal shaft fractures: a normal plate and a bridging plate. If the fracture is simple (i.e. transverse or short oblique), a normal plate can be used, bent appropriately to produce compression of the far cortex. A bridging plate (which is also a locking plate) is best viewed as an extramedullary splint, which 'bridges' the part of the bone which is unsuitable for direct fixation, as in very comminuted or bone-grafted fractures. With a dorsally placed locking plate, it is not necessary for the screws to reach the far cortex.

Plates may be placed on the lateral cortex of the metacarpals, to avoid the adherence of the extensor mechanism, though this

flies in the face of fracture fixation principles, which are based on the forces exerted on the fracture when clenching the fist.

If unsure whether a fracture needs operative intervention, splint the fracture and re-X-ray after one week; if the position is not maintained, it needs to be surgically corrected, but remember to act on the X-ray no later than a week to 10 days maximum.

Base

A reversed oblique view is a useful additional view to a true lateral and three quarters radiograph in demonstrating injury at the base of the fourth and fifth metacarpals (in addition to the adjacent carpal bones and carpometacarpal (CMC) joints).

Metacarpal base fractures, which cannot maintain position, are almost always fixed with percutaneous K-wires, rarely plates, as there is not enough proximal bone for a plate.

Stable simple metacarpal fractures can be treated with buddy strapping, compression bandage and reduced function for 3–4 weeks until they are pain free and stable. Patients must limit their movement, otherwise they will develop large amounts of callus as the fracture heals.

Many patients experience swelling and pain. Resting in a custom-made thermoplastic volar/dorsal splint in the position of safe immobilization (Figure 60.5b) can help ease this and allow the patient some light hand-function using the unaffected digits while fracture healing occurs. Feehan and Bassett discuss how custom-made splints reduce complications compared with off-the-shelf splints or plaster of Paris.⁴ Hand-based splints are made for head and neck fractures, and longer splints for shaft and base fractures. Unfortunately the research on rehabilitation is limited. Cochrane reports by Poolman *et al.* showed there was no evidence of which method to splint and protect a fifth metacarpal neck fracture was the most effective.⁵

Feehan discussed how experienced hand therapists can mobilize the adjacent joints around a potentially unstable fracture, as an alternative to immobilization, in the first three weeks to achieve good long-term function.⁶

Early active mobilization of the affected digits by removing the splint just for exercises is often used to prevent stiffness and allow good tendon glide. Passive exercises will be introduced once healing has occurred, normally around six weeks and patients will have movement controlled until this time.

After surgical repair, scar management is essential to avoid adhesions of the extensor mechanism. Depending on the nature of the fracture, an extensor lag at the metacarpophalangeal (MCP) joint may be visible, and the therapist can work with the patient to resolve this.

After basal fractures of the little and ring finger metacarpal bones some patients complain of discomfort when shaking hands again. This is due to intermetacarpal stiffness and the inability to arch the hand and oppose the little finger to the thumb utilizing the hypothenar muscles. This motion must always be restored with targeted exercises.

Thumb metacarpal fractures

Two base-of-thumb fracture patterns must be mentioned separately: Bennett's and Rolando's:

- A *Bennett's fracture* is an intra-articular fracture dislocation of the thumb metacarpal base that has a fragment attached to the palmar beak ligament and is usually fixed with K-wires.
- A *Rolando's fracture* is also an intra-articular fracture of the base of the thumb metacarpal, but consists of three fragments, with a T or Y configuration and is usually fixed with a T or Y plate.

Thumb metacarpal fractures, which are treated conservatively, are usually put in a forearm-based thumb splint, immobilizing the fracture for 3–4 weeks and protecting it for 6 weeks. This splint must maintain the first web space so patients do not develop adduction contracture. All finger joints are mobilized fully.

Phalanges

Distal phalanx

Distal phalanx fractures are classified into tuft, shaft or intra-articular fractures. They account for about half of all digital fractures seen.

Tuft fractures rarely need treatment themselves, but are often associated with nailbed injuries which must be treated as open fractures and the nailbed matrix meticulously apposed.

Shaft fractures can usually be treated conservatively, but a longitudinal K-wire for a transverse fracture or the occasional cerclage wire or even screw may be necessary for the longitudinal fracture.

The treatment of *intra-articular fractures* depends on the size of the fragment. Small fragments can be treated conservatively

in a mallet splint, but when the dorsal or the volar fragment in a fracture/dislocation of the distal phalanx is large enough, the collateral ligaments are attached to the fragment, and the rest of the distal phalanx becomes unstable on the middle phalanx.

In volar fractures the flexor digitorum profundus (FDP) pulls the attached fragment away from the distal phalanx, and in dorsal fractures the fragment is held in place by the extensor tendon while the FDP pulls the distal phalanx volarly, the latter resulting in a bony mallet or a mallet fracture. When the fragment is dorsal, Ishiguro's method of fixation is recommended.⁷ The dorsal wire supports the dorsal fragment and is placed first with the DIP joint in flexion; the fracture/dislocation is then reduced and the longitudinal wire is placed under image intensifier guidance (Figure 60.6a). In volar fractures the fragment, if large enough, can be secured with a screw. If, however, it is too small to withstand instrumentation, then the FDP can be fixed to the distal phalanx by bony anchors, pull-out sutures, or by sutures passed through the distal phalanx transversely using a white needle drilled through the bone. If the joint is unsalvageable a primary fusion is best.

Therapy for tuft fractures often includes a small volar splint if this helps settle the pain and rest the DIP joint (Figure 60.6b). Patients should not perform strong gripping with this digit until the fracture has healed. Active motion at the DIP/PIP joints and oedema control is commenced as soon as possible. Desensitization techniques and scar management are also often needed before the patients feel comfortable to use the digit normally.⁸

Mallet fractures must be treated with DIP joint immobilization for six weeks, followed by a weaning period of two weeks. The splint used varies from centre to centre but a small dorsal splint seems to be the most effective at holding full DIP joint extension and preventing complications such as skin maceration (Figure 60.7). Off-the-shelf stack splints often provide sub-optimal correction of DIP joint extension and are often so long that they limit PIP joint flexion. This can lead to unnecessary stiffness of this joint.

Proximal and middle phalanx

Proximal phalanx fractures are more common, can be the most challenging to treat and can lead to deformities due to soft tissue imbalance and alteration of bone length. Shaft fractures of the proximal and middle phalanges are managed according to their configuration, though splinting and percutaneous screw fixation or wiring is preferred. Plates can be used, but complication rates are high, probably due to the extensor mechanism getting irretrievably stuck to the scar tissue.⁹

Stable proximal and middle phalanx fractures are often placed in a custom-made hand splint for protection, pain relief and to ensure that the interphalangeal joints do not contract while oedema resolves. The splint keeps the interphalangeal joints in neutral and Coban wrap is often used as the first line of intervention for oedema control and prevention of joint contractures. Early motion and tendon glide of both the flexor and extensor mechanism is essential. Protection splints are worn until fracture

Figure 60.6 (a) Ishiguro frame. (b) Volar gutter distal interphalangeal joint splint.

Figure 60.7 Dorsal mallet splint.

union occurs clinically. Dorsal blocking splints are very useful if there is also soft tissue damage or instability at the PIP joint as the patient can easily mobilize the joint within this splint.

It makes no sense to fix these fractures and then keep them immobile because tendon adherence occurs quickly.¹⁰

The most common complication found is PIP joint extensor lag or fixed flexion deformity and once these occur it is very difficult, if not impossible to correct fully with therapy if over 30°. This most commonly occurs after proximal phalanx fractures of the little and ring fingers when the patient can easily hyperextend their MCP joint and after surgical repair when the tendons become adhered. The hyperextension of the MCP joint must be controlled by dorsal blocking splintage (Figure 60.8) or strapping to allow the extensor mechanism to improve the lag. Longer term night splintage may be required for PIP joint fixed flexion deformities. If the PIP joint has a very tight end-feel many therapists use plaster of Paris serial casting to improve range of motion.

These fractures take at least six weeks to heal, so protection is required for longer than some metacarpal fractures. Many patients experience intrinsic tightness and will require flexion strapping to improve flexion once healing has occurred.

Intra-articular proximal interphalangeal joint fractures

PIP joint fractures are difficult and can potentially lead to severe disability and multiple operations and therefore have many solutions.

External frames rely on the principle that the periosteal sleeve of the fractured bone, when pulled, will push the bony fragments together rather like a Chinese finger-trap. There are

Figure 60.8 Example of a dorsal splint for proximal phalanx injuries.

many methods. Some rely on an elastic band pulling on the frame (Suzuki frame¹¹ and the Banjo frame¹²), some rely on the bend in the K-wires to put the periosteum under tension,¹³ and yet again others rely on springs or hinges to achieve the same effect (S-Quattro¹⁴) (Figure 60.9a).

The success of these frames relies on the joints involved being mobilized while maintaining the fracture in a stable position. However, for the majority of these fixators the degree of traction exerted depends on how much the finger is flexed (the joint surfaces are not round), which is, to some degree, compensated for by the elastic element of the frame. The Banjo addresses this point because the wire frame is made so that the forces pulling on the digit are constant through the whole range of motion.

If the fracture/dislocation of the PIP joint still tends to dislocate after the two main K-wires have been inserted in a rubber band or spring system, a third transverse wire (reduction wire) can be placed through the base of the middle phalanx. When the finger is bent, the long proximal wire of the frame pushes against the reduction pin and the dislocation is reduced.

Unicondylar fractures have been classified according to their radiological appearance and on the four different types of forces hypothesized to produce the fractures.¹⁵ All fractures were treated with screws, single or multiple wires: the statistical analysis revealed no difference in outcome according to the fracture types or how long after the operation they were mobilized, though screw fixation seemed to give better results (Figure 60.9b).

(a)

(b)

Figure 60.9 (a) Spring-based traction frame for intra-articular fracture. (b) Weiss-Hastings classification of unicondylar fractures of the proximal phalanx. Arrows indicate direction of force. Source: Weiss & Hastings, 1993.¹⁵ Reproduced with permission of Elsevier.

For unstable dorsal fracture/dislocations of the PIP joint (dorsal coronal, class III, Weiss-Hastings) a method similar to the Ishiguro method described for the DIP joint has been described recently.¹⁶ The primary K-wire is drilled through the fragment from the volar surface of the middle phalanx after the fracture has been reduced percutaneously with a bone-holding forceps; the K-wire is then retracted dorsally until it is flush with the volar cortex, and then finally a dorsal blocking wire is inserted through the head of the proximal phalanx.

For the PIP joint that has an unsalvageable fracture, there are a few other options: fusion, volar arthroplasty, hemi-hamate, a joint replacement or a free joint transfer.

A volar arthroplasty¹⁷ is used when the volar lip is beyond salvage: through a volar incision all but the most volar collateral ligaments are excised, the joint is hyperextended, an incision between the volar plate and collaterals is made and the volar plate is advanced into the joint to cover the defect (usually up to 5mm). The volar plate is secured through pull-out sutures, taking care to avoid pinning down the lateral bands.

A hemi-hamate graft¹⁸ is employed because the dorsal portion of the hamate looks like the volar lip of the PIP joint: the joint is approached from the volar side, the volar plate is detached distally and the ruined volar lip is excised (with a saw) to make room for the dorsal portion of the hamate (taken with

an osteotome). The graft is secured with a couple of screws and the position checked with a lateral X-ray (as a hamate graft must provide adequate volar support (lip)). The volar plate is then reattached.

The choices for PIP joint replacements are many: proximal interphalangeal replacement (PIPrTM),¹⁹ total metacarpophalangeal replacement (TMPrTM), the Saffar, the Digitos,²⁰ DJ03A, the Mathy, Avanta PIP SRA, RM finger joint replacement system²¹ and Swanson's.²² Some joint replacements do well; some have failed repeatedly and been taken off the market, confirming the PIP joint as one of the hardest joints to replace well. Free joints taken from the second toe are a life-long solution and give useful movement, though not a full range.²³

Early hand therapy after any PIP joint injury is essential for a good outcome. Small fractures within the PIP joint can be treated with a dorsal blocking splint, which prevents hyperextension, Coban wrap for early oedema control and early mobilization. Controlling oedema is very important as if it persists especially in this joint it can limit joint motion for many months. As well as PIP joint motion it is essential for the patient to perform good DIP joint motion as often intrinsic tightness occurs and remains a concern for months. Flexion straps are often used to try to resolve this tightness once the fracture has healed (Figure 60.10).

If external fixation has been utilized to stabilize the fracture again oedema control around the fixation is important and Coban works well for this. Early motion and tendon gliding of both the PIP joint and DIP joint is important. Patients are generally supplied with a custom-made splint to protect the fracture and fixation and prevent flexion deformities.

Figure 60.10 Example of a flexion strap to increase interphalangeal joint flexion.

Postoperative management and hand therapy

Volar plate injuries

Volar plate injuries can occur at any of the above joints but are usually diagnosed at the PIP joint with point tenderness, if not a dorsally unstable joint. Ninety per cent of these injuries occur dorsally and they are common in ball sports. Severe volar plate avulsion can occur after dislocation of the PIP joint and will require surgical repair to restore stability of the joint. This type of injury commonly occurs together with injury to other soft tissue structures around the PIP joint, such as the collateral ligaments, and if untreated can lead to flexion contractures of the affected joint.

Most injuries are treated conservatively and the healing time is usually 4–6 weeks.

In adults with stable PIP joints, buddy strapping may be enough to protect the volar plate and collateral ligaments while healing. Oedema control around the affected joint is essential, as is early motion of all the digit joints.

In children and hyperextending adults a dorsal blocking splint prevents hyperextension and tension on the volar plate while it heals. This blocking splint may start in slight flexion at the injured joint but should be straightened as pain eases so the patient does not end up with a flexion deformity. Early active motion of the digit is essential to prevent adherence of the flexor tendons, especially in more severe injuries (Figure 60.11).

A volar PIP joint injury will need treating in an extension splint if the central slip has been damaged.

Ulnar and radial collateral ligament injuries to the MCP joint

All ligamentous injuries can be classified into three grades:²⁴

- Grade I: Pain, but no laxity
- Grade II: Laxity, but a firm endpoint, stable arc of motion
- Grade III: Grossly unstable, no firm endpoint.

The most common ligament to be injured in the hand is the ulnar collateral ligament (UCL) of the thumb. Thumb radial collateral ligament (RCL) damage can occur, but it is uncommon, however RCL tears of the MCP joints can occur if lateral force is applied to the digits when in flexion at MCP joints.

When the thumb UCL is injured, X-rays and high-resolution ultrasound will show whether there is an associated fracture and Stener lesion, indicating a complete tear of the ligament. The clinical diagnosis is made by stressing the ligament with the thumb in flexion and comparing with the other side. Incomplete injuries are treated by splinting, complete injuries by bony anchor fixation of the ruptured ligament, with screw fixation of the bone if the fragment is large enough. It is important to fix the concomitant tear in the capsule as well to obtain stability. Complete tears will never heal by splinting alone as interposition of the adductor aponeurosis prevents apposition of the torn ends.

The thumb acquires a Z-deformity in chronic UCL tears, which may be repaired surgically by a bony anchor, free tendon

Figure 60.11 Dorsal blocking splint and exercises.

graft or adductor advancement (adductor pollicis in detached and reattached to the ulnar side of the proximal phalanx at the MCP joint), or as a last resort the joint can be fused.

Damage to the RCL of the digits is diagnosed by passive flexion of the MCP joint and ulnar pressure causing pain, and X-rays (Brewerton's views) may show avulsed bone. Grade I and II can usually be treated conservatively with buddy strapping and splinting, while the ligament in grade III is fixed with a bone anchor with the MCP joint at 45° when tensioning the repair or splinted in radial deviation.

Chronic injuries can be repaired with tendon grafts or the joint fused.

Collateral injuries of the digits are effectively managed by buddy strapping of the affected digit with its neighbour until stability and pain improves, usually after 4–6 weeks.

Sometimes a small thermoplastic splint is made to support the affected joint if extra protection is required while allowing good tendon glide at the other joints.

Protection of the thumb MCP joint UCL is essential, as stability is required at this joint. A custom-made thumb Spica splint which only immobilizes the MCP joint is the splint of choice for most hand therapists. This is worn full time whether the ligament has been surgically repaired or is being conservatively treated for 4–6 weeks. Commonly after surgical repair the splint is removed after two weeks for scar massage as this often becomes sensitive. Gentle exercises may commence after four weeks.

Management principles and operative options

As a rule, any major injury starts with the bony fixation to provide stability for the finer neurovascular repairs and for the forces exerted by the repaired tendons. This stabilization is ideally so stable that it allows immediate mobilization. Therapy aims must include early controlled motion, pain and oedema control to prevent stiffness, joint contracture and tendon adherence. The therapy programme must be tailored to the individual

needs of the patient and their injury. Surgeons must be confident that they can stabilize a fracture to allow early motion before intervening, otherwise a longer period of immobilization can lead to a poor result. Immobilization of the hand/digit after soft tissue injuries or digital fractures can lead to very poor functional outcomes for the patient. Although the literature on early mobilization of fractures is limited and not always robust,⁴ hand therapists would agree that early referral and mobilization has a direct effect on final outcome after these injuries.

If immobilization of a hand fracture is requested by the hand surgeon for a high-risk unstable fracture, it should be limited to a period of less than four weeks and preferably three weeks.^{4,25}

All fractures that can be stabilized with a bone-holding forceps can be stabilized by screws, but the bony fragment must be three times the size of the screw head to hold it. Otherwise it will shatter when the screw is inserted and tightened. Periosteal stripping is always held at a minimum, and if at all possible soft tissue interposed between metal and tendons. Positioning of the reduced fracture is checked on I-I and rotation is checked before the first screw hole is drilled. Deviation usually remodels in children, but not rotation, which must be corrected.

Closed versus open

All open fractures should be washed out immediately and given antibiotics. They should, of course, be fixed on the next list.

The main open fracture involving the metacarpal bone is a fight bite, which is when the tooth of the person your patient has punched breaches cartilage of your patient's metacarpal head. If this is not recognized and appropriately washed and treated with antibiotics it will result in septic arthritis and possibly osteomyelitis.

Complications

Complications from fractures can be in the bones itself, such as osteomyelitis, in the fracture itself, such as non-union and mal-union, including rotation and more generalized problems, such as cold intolerance, complex regional pain syndrome (CRPS) and overall persistent swelling and pain which results in a reduced range of movement and ultimately use.

Importantly, a hand fracture can mean the end of an occupation and the beginning of chronic disability. Luckily, most fractures, however, heal well and the patient returns to near pre-injury functional levels.

Osteomyelitis is diagnosed by persistent pain, fever and sometimes swelling. X-Rays only become helpful after osteopenia sets in and therefore MRI is the investigation of choice. If the infection is connected with metal, it must be removed, even if this means the fracture becomes unstable. Temporary external fixators can be the solution in this situation. Any dead bone, such as a sequestrum, must be removed surgically and long-term antibiotics administered. The choice of antibiotics will vary from place to place but usually includes fucidic acid, which penetrates bone especially well.

Blood cultures can sometimes give the actual bacterium causing the infection, but bone biopsies are the most secure way of obtaining appropriate specimens for the microbiologist if the infection is not resolving.

Non-unions needs to be opened again and bone grafted, to bring growth factors and scaffolding material to the site. Mal-unions can either be corrected at the fracture site, but more often a mal-union, say with a rotational element, at the level of the digits, is corrected with a derotational osteotomy of the metacarpal.

The overall chance of getting CRPS after hand trauma is unknown, and the only known factor to reduce the likelihood of getting CRPS postoperatively, is ingestion of large doses of vitamin C for a minimum of six weeks preoperatively. It is, of course, rare that one can predict injury with this accuracy, but it is a useful tool in elective surgery. The earlier CRPS is diagnosed and treated the better the outcome. When suspecting the diagnosis, the patient is issued with an increasing dose of gabapentin or pregabalin, possibly amitriptyline for night time and enough simple analgesia to tidy them over, before they are seen by the expert pain consultant, who can design an individualized treatment plan.

Cold intolerance affects up to 38% of digital fractures²⁶ and can be worse if metalwork is left in. This usually improves after a couple of winters, but can be permanent and is best treated by local heat and warm gloves in winter.

Therapy complications include the following:

- Persistent oedema which influences joint deformities and reduces range of motion of these small joints.
- Joint stiffness which can mostly be prevented by early motion but may occur in some intra-articular fractures despite extensive therapy.
- Intrinsic muscle tightness which often occurs in digit injuries and may take many months to be completely resolved by function and intrinsic stretch exercises.
- Weakness of grip which needs to be assessed and treated with strengthening work once the fracture has healed.
- Reduced function and delayed return to work which can be improved with rehabilitation for most patients.
- Scarring and tendon adhesion which can often be alleviated

by scar management and exercises but sometimes requires tenolysis or removal of any internal fixation.

CRPS is generally prevented by early referral to hand therapy, good early pain relief and extensive advice and education of the patient.

Outcomes

Outcomes can be objective, such as total range of motion or DASH score, or subjective, such as pain analogue score and discussion about functional ability and return to work.

The aim for therapy is to prevent chronic oedema, restore normal range of motion by the time the fracture has healed at 8–10 weeks post these injuries. The patient can then concentrate on increasing strength with the aim of returning to work with full capacity. Many patients will have been able to return to work in some reduced capacity much earlier due to the fact the therapists can make much smaller bespoke splints for them.

Last comments

Close liaison with the hand therapy team is essential as early therapy intervention is crucial to ensure the best outcomes and prevent stiffness.

Surgeons should only intervene if they are certain they can improve stability and fracture configuration or the injury is open. Immobilizing hand fractures post surgery as the surgeon is anxious about stability will lead to poorer outcomes, more stiffness and potential tendon tethering. Gentle early controlled motion 24–36 h post injury/surgery is ideal for the best functional outcomes.

Although hand fractures may be forgiving, soft tissue injuries are not.²⁶ Providing hand splints which protect and rest only the affected digits instead of full plaster casts should limit complications and improve outcomes.

CHAPTER 61

Osteoarthritis and prosthetic joints in the hand

Adam C. Watts and Ian A. Trail

Centre for Hand and Upper Limb Surgery, Wrightington Hospital, Wigan, UK

Osteoarthritis

Aetiologies

Osteoarthritis of the hand is a multifactorial condition with an interplay between biomechanical and biochemical entities. It is the end stage of a number of processes within the joint. It can be secondary to mechanical derangement of the joint (fracture, dislocation, instability), infection or metabolic processes (secondary osteoarthritis) or occur as a primary idiopathic condition (primary osteoarthritis). The causes of osteoarthritis in the interphalangeal joints, metacarpophalangeal joints and first carpometacarpal joints may be different. Anatomical factors may play a part in the predisposition of women to the development of osteoarthritis in the latter of these.

Primary osteoarthritis is typically a polyarthropathy in the hand, often affecting multiple proximal and distal interphalangeal (PIP and DIP) joints as well as the first carpometacarpal (1st CMC) joint. This appearance in conjunction with the presence of Heberden's or Bouchard's nodes is recognized as nodal generalized osteoarthritis (NGOA) and is predictive of osteoarthritis in other joints. Women are more frequently affected and Heberden's nodes are a particular feature of this condition. Epidemiological studies have indicated that lifestyle factors can contribute to the development of osteoarthritis in the hand. There appears to be a relationship between obesity and hand osteoarthritis.¹⁻³ An association has been demonstrated between osteoarthritis in the hand and shorter time spent in education, low income, marital status and having a child.⁴ The relationship to offspring was stronger in men than women, indicating that it is an effect of environment rather than biology that increases this risk. Genetics also appear to play a role in the development of osteoarthritis in the hand, and may interact with environmental factors. An association has been demonstrated between *COL2A1* gene, vitamin D receptor gene and IL-1 gene cluster polymorphisms, repetitive tasks and hand osteoarthritis (Figure 61.1).⁵⁻⁷

A less common form of osteoarthritis, erosive osteoarthritis, displays a more florid inflammatory component, subchondral

erosive changes and a tendency toward instability and ankylosis. Endocrine causes of erosive osteoarthritis include hypothyroidism and renal dialysis. Hyperparathyroidism may be associated with periarticular erosion, especially of the metacarpophalangeal (MCP) joint, but there is debate as to whether this is associated with the development of osteoarthritis. Haemochromatosis should be considered in patients presenting with polyarticular disease in the hand, especially in those with younger age of onset, males and those with involvement of the MCP joint or wrist.⁸

Joints

Primary osteoarthritis predominantly affects the DIP joints, the CMC joint of the thumb and the PIP joints in descending order of frequency. The MCP joints are rarely affected in primary disease but may be involved in secondary osteoarthritis. The incidence of MCP joint osteoarthritis is equal in men and women, whereas women are more frequently affected by osteoarthritis in the other joints. The presence of osteoarthritis within a joint of a row (DIP, PIP or MCP joints) increases the risk of developing osteoarthritis in another joint within that row. Similarly there is also a risk of developing arthritis within another joint within the same ray.⁹ The association of within-row osteoarthritis is stronger than the within-ray association in all populations studied. Symmetry of symptomatic osteoarthritis in the hands has been reported in a number of studies.

Clinical history and assessment

Pain and stiffness are the typical presenting symptoms of osteoarthritis in the hand. DIP joint involvement is often first noticed as hard swellings either side of the joint known as Heberden's nodes. The appearance of these nodes often precedes the onset of pain, if indeed these joints ever become symptomatic in this way. Heberden himself is quoted as stating 'What are those little hard knobs, about the size of a pea, which are frequently seen upon the fingers, a little below the top, near the joint? . . . they continue for life; and being hardly ever attended with pain, or disposed to become sores, are rather unsightly than inconvenient, though

Figure 61.1 Clinical appearance of osteoarthritis of the hand.

they must be some little hindrance to the free use of the fingers.¹⁰ In a randomly selected population of white women aged 45–65, 26% were found to have clinical signs of osteoarthritis of the DIP joint, namely bony swelling, tenderness or pain on movement, of whom 68% reported the joints to be symptomatic.¹¹ In comparison, only 17% and 16% had signs at the PIP and 1st CMC joints, respectively. In this cohort, bony swelling was found to be the most sensitive finding for the presence of radiographic changes of osteoarthritis at the DIP and PIP joints. Tenderness and pain on movement are the most specific signs and all signs have high negative predictive value at the PIP joint.

In the 1st CMC joint the clinical findings are different. Here deformity and tenderness are the most common and the most sensitive findings. ‘Shouldering’ of the joint, due to subluxation of the metacarpal on the trapezium is often seen. This subluxation may lead to a compensatory hyperextension at the MCP joint. Angular coronal plane deformity of the joints is less common but may be seen. It should be noted that for all these joints the clinical signs have quite low sensitivity in the general population but their sensitivity is increased in patients who report that they are symptomatic.

Patients may present with other sequelae of osteoarthritis, such as mucous cysts. These may result in pain or swelling and may rupture, discharging a clear straw-coloured jelly. Occasionally the presenting complaint may be nail deformity as a result of pressure symptoms on the germinal matrix from an occult cyst.

The American College of Rheumatology (ACR) has defined clinical criteria by which a diagnosis of osteoarthritis can be made in the hand.¹⁰ These are given in Table 61.1. The presence of all of criteria 1, 2 and 3 plus one of 4a or 4b yields a sensitivity of 92% and specificity of 98% for the diagnosis of osteoarthritis in a patient presenting with hand pain.

Investigation

The diagnosis of osteoarthritis can be made on clinical grounds in most cases. The primary role of investigation is to guide treatment and more rarely determine cause. Plain postero-

Table 61.1 American College of Rheumatology Criteria for the diagnosis of osteoarthritis in the hand

Level	Criteria
1	Hand pain, aching or stiffness
2	Hard tissue enlargement of 2 or more of the ring or middle DIP joints, ring or middle PIP joints or 1st CMC joints
3	Fewer than 3 swollen MCP joints
4a	Hard tissue enlargement of 2 or more DIP joints
4b	Deformity of 2 or more of the ring or middle DIP joints, ring or middle PIP joints or 1st CMC joints

DIP, distal interphalangeal; PIP, proximal interphalangeal; CMC, carpometacarpal; MCP, metacarpophalangeal.

Figure 61.2 Radiographic appearance of osteoarthritis of the hand.

anterior (PA) radiographs can be used to confirm the diagnosis (Figure 61.2) and assess severity of the disease using radiographic grading systems. A lateral radiograph of a particular joint may be helpful where treatment is planned. A widely used classification is that of Kellgren and Lawrence, which defines five categories; no radiographic features of osteoarthritis, doubtful changes, minimal, moderate and severe (Table 61.2).¹² They defined the radiological features of osteoarthritis: formation of osteophytes on the joint margins,

Table 61.2 Kellgren and Lawrence radiographic grading of osteoarthritis

Grade 0	None	No features of osteoarthritis
Grade 1	Doubtful	Minute osteophyte, doubtful significance
Grade 2	Minimal	Definite osteophyte, no joint space narrowing
Grade 3	Moderate	Moderate joint space narrowing
Grade 4	Severe	Joint space narrowing with subchondral sclerosis

periarticular ossicles, narrowing of joint cartilage associated with sclerosis of subchondral bone, small pseudocystic areas with sclerotic walls situated in the subchondral bone, and altered shape of the bone ends. However many different interpretations have been placed on the definition of the changes present in each category. This has led to substantial variation in categorization between studies and makes interpretation difficult. Even Kellgren and Lawrence in their original paper recognized that 'personal bias may result in a very different assessment of severity and prevalence'.¹²

The Kellgren and Lawrence classification has been criticized for depending on the presence of osteophytes to make the diagnosis of osteoarthritis. Kallman *et al.* observed that in many cases of osteoarthritis of the hand joint space narrowing and cyst formation can occur without their presence. They proposed a classification that provided a 4-point Likert scale of severity for features such as joint space narrowing and osteophytes, and dichotomous scores for the presence or absence of subchondral sclerosis, subchondral cysts, lateral deformity of at least 15° and collapse of the central joint cortical bone.¹³ This results in a scale from 0 to 10 for from no to severe arthritic changes. They compared their new scoring system with the Kellgren/Lawrence scale and found that both had good reliability and reproducibility for most variables with the exception of the presence of cysts.

For basal thumb arthritis the Eaton Littler classification, refined in the paper by Eaton and Glickel to include a treatment algorithm, is still widely used.^{14,15} This is based on radiographic features of joint space, subluxation of the metacarpal on the trapezium, cysts and sclerosis. This approach has been shown to yield only moderate interobserver agreement, and the treatment indicated fair agreement (Table 61.3).¹⁶

Other imaging modalities such as ultrasound, bone scintigraphy, MRI and CT have little utility in clinical practice due to the relatively low cost and ease of access to plain radiographs. Ultrasound has the advantage that it does not involve the use of radiation, however only superficial pathology is visible. Osteophytes, synovitis and periarticular erosions may be assessed. Ultrasound may more easily determine the presence of active inflammation or erosion than plain radiographs, with the use of power Doppler. MRI is used largely for research purposes. It is possible to visualize all osteoarthritis joint pathology, but overdiagnosis of synovitis may be a pitfall.

Table 61.3 Eaton classification of thumb carpometacarpal joint osteoarthritis

Stage	Radiographic appearance	Possible treatment options
I	Normal or slight joint space widening due to effusion. Possible mild subluxation	Ligament reconstruction or Metacarpal extension osteotomy
II	Joint space narrowing and osteophytes less than 2 mm present	Trapeziectomy ± ligament reconstruction and tendon interposition
III	Joint space narrowing, subchondral sclerosis and osteophytes greater than 2 mm	or Arthrodesis or Arthroplasty
IV	Advanced degenerative changes involving the trapeziometacarpal and scaphotrapezial joint	Trapeziectomy ± ligament reconstruction and tendon interposition

Management principles and operative options

Non-operative

Consideration of the management of any condition must start with an understanding of the natural history, and for musculoskeletal disease the deficits that need to be addressed. For patients with osteoarthritis pain is a predominant feature of the condition. Radiographic progression is minimal over a 10-year period with most progression seen radiographically at the DIP joints.¹⁷

Functional deficits in NGOA may be minimal. The patient may have more difficulty, may employ trick movements and have a reduced grip strength but are able to complete daily activities.¹⁸ Those with erosive osteoarthritis have been reported to have more functional difficulties and more severe pain.

Non-operative treatment modalities include activity modification, splintage and pharmacological intervention with oral or topical anti-inflammatory analgesia, or corticosteroid injection. The use of splints can effectively control symptoms for some patients but their utility is limited by functional restriction. Intra-articular corticosteroid injection has been shown to be an effective treatment, either using X-ray guidance or blind injection. For basal thumb arthritis it has been reported that only one quarter of patients will go on to further intervention within 2 years of injection.¹⁹ The effectiveness of corticosteroid injection and splinting decreases with higher Eaton stages of disease, with most of those that are Eaton stage I and 35% of those Eaton stage II and III achieving sustained relief.²⁰

Specific joints

First carpometacarpal joint

First CMC osteoarthritis is a very common condition, particularly among elderly females. A number of prostheses have been developed to address this problem but comparative studies have not demonstrated an advantage of prosthetic replacement over

simple trapeziectomy with or without tendon interposition. As a result, many surgeons have been reluctant to expose patients to the risks of 1st CMC joint arthroplasty.

Imaeda *et al.* studied the surgical anatomy of the 1st CMC joint and described five major ligaments: the anterior oblique, ulnar collateral, first intermetacarpal, the posterior oblique and dorsal radial ligaments.²¹ Of these, the anterior oblique, also known as the beak ligament, was thought to be the most important for stability of the joint and should be retained for successful joint reconstruction.

More recently, there has been greater interest in the role of the dorsal ligaments to joint stability. Anatomical studies have suggested that in fact there are three robust dorsal ligaments: the dorsal radial, dorsal central and posterior oblique ligaments.²² The double saddle-shaped articular surface is asymmetrical, the convex surface is an ovoid arc (similar in cross-section to an aircraft wing where the radius of curvature decreases from back to front). The opposing concave surface has a small radius of curvature centrally that is maintained on one side of the central ridge but has a gentler slope on the other. Xu *et al.* demonstrated that the joint is incongruent, allowing flexion, extension, adduction and abduction. The contact area is small, particularly in females, which may account for the increased female susceptibility to osteoarthritis of the 1st CMC joint.²³ The forces that the 1st CMC joint must withstand are considerable. Cooney and Chao calculated that a tip pinch of 1 kg will generate 12 kg of joint compression. For power grip the load may be as high as 120 kg.²⁴

The surgical approach to the 1st CMC joint may be dorsal radial or volar. The dorsal radial approach is centred over the 1st CMC joint in line with the first extensor compartment. Care must be taken to identify and protect the branches of the superficial radial nerve as injury may result in painful neuromata. The radial artery should be mobilized and protected, any fine branches being cauterized with diathermy. A distally based T-shaped capsulotomy is performed to expose the joint. The volar approach is through a curvilinear incision on the radial border of the thenar eminence centred over the 1st CMC joint. Cutaneous branches of the median nerve should be protected. The thenar muscles are elevated from the underlying capsule by sharp volarward dissection and the abductor pollicis brevis tendon is mobilized dorsally before a longitudinal capsulotomy to expose the joint is performed. For successful arthroplasty, capsular stability is essential. If there is instability as a result of the previous pathology then ligament reconstruction may also be performed using tendon grafts such as a split flexor carpi radialis tendon graft. At Wrightington the joint is immobilized in a static splint for six weeks with the thumb abducted and the nail plate aligned at 90° to the palm.

Signs and symptoms

Pain at the base of the thumb is the chief presenting complaint of 1st CMC joint osteoarthritis. Swelling and tenderness occur early in the disease and are sensitive indicators of the

presence of osteoarthritis within the joint. Metacarpal subluxation leads to squaring or 'shouldering' of the joint. Osteophytes may be palpable. Use of the grip and grind test should be avoided. Instead a more subtle, and possibly kinder, manoeuvre of reduction and shift may reproduce the symptoms. Hyperextension at the metacarpophalangeal joint may be present and will often worsen with key pinch. Pain on radial and ulnar deviation of the wrist is suggestive of coexistent scaphotrapezial osteoarthritis. Provocative tests for carpal tunnel syndrome should also be performed as the two will coexist in up to 43% of cases.²⁵ Release of the carpal tunnel can be undertaken simultaneous to trapeziectomy either through the same or separate incisions.²⁶ Other causes of radial-sided wrist pain, such as de Quervain's tenosynovitis, should be excluded.

Operative treatment

Eaton stage I

Where the joint surfaces are preserved, non-operative measures described above may be employed but will not prevent progression of the condition. In their original description of stages of CMC joint osteoarthritis, Eaton and Littler proposed a technique of ligament reconstruction that they argued could arrest the progression of symptoms. Their technique was intended to reconstruct the anterior oblique or 'beak' ligament that they felt was the primary restraint to dorsal subluxation of the metacarpal and was deficient in CMC joint osteoarthritis. This used a distally based graft from the flexor carpi radialis (FCR) tendon passed through a drill hole in the base of the thumb metacarpal that runs from the radial surface in the plane of the nail plate, to the volar proximal ulnar corner of the metacarpal. The graft is then brought back beneath the remaining 50% of FCR tendon and sutured to the base of the metacarpal, thereby supporting the joint in orthogonal planes. Numerous other techniques have been described using other local tendon grafts.

Over the past 20 years anatomical and histological dissections have challenged the pre-eminence of the anterior oblique ligament in thumb CMC joint stability. Work by Ladd *et al.* has defined seven consistent ligaments: three dorsal, two volar and two ulnar ligaments.²² They found that the anterior oblique ligament was thin and hypocellular with disorganized collagen fibres. In contrast, the three dorsal ligaments – dorsal radial, dorsal central and posterior oblique ligaments – were thick, highly organized and cellular with profuse neural innervation. Furthermore, it was their impression that these ligaments restrained subluxation of the metacarpal. A procedure to reef the dorsal ligaments has recently been described but with only five cases with follow-up from 8 to 50 months. More data are required before this can be recommended.²⁷

Closing wedge metacarpal extension osteotomy is an alternative to ligament reconstruction for early arthritic changes with good results reported for Eaton stages I, II and III. Wilson described the technique in 1973 of excising a dorsal and radially based 30° wedge from near the base of the metacarpal. This is

then held with a transosseous cerclage wire and percutaneous K-wires. The concept, supported by biomechanical studies, is that by extending the metacarpal the joint mechanics are altered such that the joint is more stable and loads are moved away from areas of damaged cartilage on the volar articular facet to prevent disease progression.²⁸ Hobby *et al.* from Cambridge reported 80% good or excellent results with this technique at a minimum of 2 years for all Eaton stages other than those with stage IV arthritis. The longest follow-up in this series of 41 thumbs was 12 years with satisfactory outcome maintained.²⁹ Their series contained only two patients with stage I osteoarthritis, but Tomaino has reported on a series of 12 patients with stage I osteoarthritis in whom an osteotomy successfully relieved pain in all but one case. He reported an average time to union of 7 weeks.³⁰ Trapezial opening wedge osteotomy of 15° has been shown mimic the effects of metacarpal osteotomy in cadaveric experiments.³¹

Eaton stages II and III

Simple trapeziectomy remains the gold standard treatment against which alternative interventions are compared. CMC fusion can reliably relieve pain, and has the advantage of maintaining pinch strength but at the cost of higher risk of complications, stiffness of the thumb and the potential for degenerative changes in adjacent joints. Synthetic arthroplasty, which may be interpositional, hemiarthroplasty or total joint replacement, can produce excellent short-term outcomes but the complication rate remains high. Where these techniques fail they can be salvaged by excision of the trapezium with equivalent outcomes to primary trapeziectomy,³² however to date there is no evidence that these procedures produce a superior outcome to trapeziectomy with or without interposition or suspension, so the added cost and risk is questionable.^{33,34} Arthroscopic debridement with interposition or distraction arthroplasty have been reported to produce good short-term outcomes.^{35,36}

Isolated trapeziectomy was described in 1949 by Gervis, who reported promising results.³⁷ Concerns emerged, however, regarding reduced pinch strength, proximal migration of the metacarpal and the potential for hyperextension of the MCP joint. A range of soft tissue interposition or suspension procedures were devised to try to counter these issues. These techniques variably use whole or hemi-FCR grafts, abductor pollicis longus or palmaris longus interposition. More recently, suture button techniques have been reported to produce equivalent results, although index metacarpal fracture has been reported with this technique.^{38,39} The ligament reconstruction and tendon interposition (LRTI) procedure gained a deal of popularity and involved passage of 100% of the FCR divided proximally, maintaining the distal attachment, that is then passed through a drill hole in the base of the metacarpal and the remaining tendon interposed and an anchovy within the joint. This construct is augmented with K-wires. Distraction arthroplasty after simple trapeziectomy has been reported to achieve similar outcome to more complicated procedures.⁴⁰

Despite the proliferation of procedures and their apparent widespread acceptance, there remains little evidence of their benefit over simple trapeziectomy. Indeed repeated randomized trials have shown equivalent outcomes in terms of pain relief, grip strength and recurrence.^{41–49} This may be because these studies are not designed to identify problems within subgroups of patients, such as the young or manual workers, in whom reduced pinch strength may pose more of an issue. Alternatively, the problem of ray collapse and degenerative change at the metacarpal scaphoid pseudoarthrosis may be overstated. Although undoubtedly there are some patients who will develop symptomatic degeneration following trapeziectomy, the majority will remain asymptomatic.⁵⁰

Fusion of the trapeziometacarpal joint is favoured by some for patients with high functional demands, such as younger manual workers. These patients are unlikely to tolerate a weak pinch. Achieving union can be challenging, however, and failure to do so is associated with low rates of patient satisfaction and poor pinch strength. Various techniques have been employed, including K-wire fixation, tension band wires, plates and screws, compression staples and headless compression screws. Non-union rates vary widely in cases performed for osteoarthritis and complication rates and the risk of further surgery is higher following arthrodesis than other surgical techniques for management of 1st CMC osteoarthritis.⁵¹ Long-term studies of the outcome of CMC joint fusion in osteoarthritis have demonstrated significant improvement in pinch strength, low pain scores and excellent patient satisfaction.

In the patient with coexistent compensatory hyperextension of the MCP joint some have considered the value of surgical remedy with K-wire fixation, capsulodesis, sesamoid bone fixation or MCP joint fusion if the joint can be passively hyperextended 35° or more.⁵² Although correction can be achieved, this does not appear to improve hand function, and gradual loss of reduction is seen following soft tissue procedures over time.

Eaton stage IV

Patients with pan-trapezial osteoarthritis are not likely to be helped by procedures addressing only the CMC pathology. CMC joint fusion, hemiarthroplasty and total joint arthroplasty will not address the scapho-trapezium-trapezoid (STT) pathology. In these cases, total trapeziectomy with or without interposition, or suspension is the only operative procedure likely to be of benefit. Evaluation of the scapho-trapezoid joint must be undertaken, and if this articulation is also arthritic then hemitrapezoidectomy should be undertaken simultaneously to eliminate this secondary source of radial-sided wrist pain. Concerns have been raised surrounding carpal collapse as a result of trapezial excision and consequent volar STT ligament disruption.⁵³ In one series the incidence of dorsal intercalated segment instability (DISI) deformity was raised from 39% preoperatively to 62% post-trapeziectomy in those with Eaton stage IV osteoarthritis.⁵⁴ These authors reported a correlation between the presence of DISI deformity and lower patient satisfaction.

MCP joints

The MCP joint is a condylar joint with a convex, cam-shaped surface on the metacarpal head and an incongruent (larger radius of curvature) concave surface on the proximal phalanx. This allows 150° of flexion/extension and up to 57° of radio-ulnar deviation in extension, although most activities of daily living are achieved in an arc of 10–70° of flexion.^{55,56} The primary stabilizers of the joint form a sling, whose sides are formed by the collateral ligaments, which originate from the tubercle on the metacarpal head and insert onto the base of the proximal phalanx, the accessory collateral ligaments, which insert into the floor of the sling, and the volar plate, which is mobile at the MCP joint.

Work from the Mayo Clinic in 1984 showed that the collateral ligaments have differing actions at various positions of the joint. The ligaments are, however, at full stretch in MCP joint flexion, thereby preventing abduction and rotation but are relatively slack in full extension in order to allow these movements.⁵⁷ The secondary stabilizers are the musculotendinous units that cross the joint, the long extensors (primary extensors of the MCP joint), the long flexors (primarily act on the PIP and DIP joints) and the intrinsic interosseous and lumbrical muscles, which are the primary flexors of the MCP joints.

The MCP joint is subjected to significant forces, up to 190 N during a pinch manoeuvre and probably more with power grip.⁵⁸ The centre of rotation is unlikely to be through a fixed point on the metacarpal head because of the latter's cam shape. Despite this, most prostheses are designed to incorporate a fixed point of rotation.

The MCP joint is best approached through a dorsal incision, orientated either longitudinally over the MCP joint or transversely if multiple joints are to undergo surgery. It is important to preserve the vascular bundles that run in the gutters between the metacarpals in order to retain venous drainage and prevent swelling. We would advocate a radial paratendinous approach, as the radial sagittal band often requires imbrication to centralize the tendon. The tendon can be elevated from the underlying capsule and a median capsulotomy performed. With anatomical joint replacement, any soft tissue release should be limited and, in particular, care must be taken to retain the attachments of the collateral ligaments.

For the less frequent cases of MCP joint osteoarthritis, motion-preserving surgery is preferred to maintain grip and function of the hand. Silicone and anatomical arthroplasty techniques can result in satisfactory outcomes. Arthrodesis, in the main, is a salvage procedure for painful failed arthroplasty. The position of fusion depends on the digit involved and increases by 5° for each digit from 25° for the index finger through to 40° for the little finger. For all small joint arthrodesis it is our preference to use a 'cup and cone' technique, whereby the articular cartilage is removed with rongeurs to create matching concave and convex surfaces, rather than using an oscillating saw to produce flat surfaces. The most common indication for arthroplasty of the MCP joint is rheumatoid arthritis; in these cases silicone arthroplasty with soft tissue rebalancing is most usually

indicated and does well.^{59,60} In patients with primary and post-traumatic osteoarthritis, it is reported that the silicone implant may not fare as well. Early failure may occur as a result of the high demands placed through the implant in an otherwise normal hand.⁶¹

Proximal interphalangeal joints

The PIP joint is a bicondylar joint with an intercondylar concavity on the proximal phalanx.^{62,63} On either side of the head of the proximal phalanx are pits from which the collateral ligaments originate. On the middle phalanx are two concavities, incongruent with the middle phalanx possessing a larger radius of curvature, separated by a saddle-shaped ridge that dorsally extends into a tubercle for the attachment of the central slip. On the volar margin of the articular surface is a rough, flat area for insertion of the volar plate; this takes origin proximally from the checkrein ligaments attached to the neck of the proximal phalanx. The accessory collateral ligament takes origin close to the true collateral near the pit on the proximal phalanx and inserts into the volar plate.

Movement of the PIP joint varies from 0° to 30° of hyperextension to 100° of flexion. The PIP joint is not a true hinge joint as there is a small amount of rotation and angulation of the coronal plane during flexion; the axis of rotation is centred on a fixed point on the head of the proximal phalanx. Minamikawa *et al.* demonstrated that with a lateral stress, 5° of adduction and 9° of supination is seen at the PIP joint.⁶⁴ In full extension and flexion the joint is more stable.

Enthusiasm for PIP joint arthroplasty has increased as a result of the success of MCP joint replacement. PIP joint fusion can result in acceptable hand function and excellent pain relief. However, where there is concomitant disease of the MCP or DIP joints, fusion of the PIP joint will result in a stiff finger and impaired function, and a motion-retaining arthroplasty may be preferred. Equally, an adequately counselled patient may choose to accept the risk of arthroplasty in order to maintain some movement in the joint rather than opt for a fusion. The only contraindications to arthroplasty in our practice are young active patients, manual workers and patients with significant bone loss, gross instability or previous infection.

Arthroplasty of the PIP joint can be performed under local anaesthetic (if only one joint), regional block or general anaesthesia. Wide-awake surgery gives the advantage that soft tissue balance can be assessed on the operating table through active movement. The joint may be approached through dorsal or volar approaches, or through the ulnar lateral border. The dorsal approach allows for excellent exposure and is of particular benefit where large osteophytes are present. Our preferred technique is to split the extensor hood in the midline, elevating the central slip insertion off the middle phalanx as a continuous sleeve for reattachment with a transosseous suture. Alternatively, a dorsal, distally based chevron Chamay approach may be used.⁶⁵ The central slip is divided in a chevron shape with the base on the middle phalanx. The lateral bands are preserved and

allowed to sublux volarward to allow the joint to be hinged open. Here too, retention of soft tissue attachments is critical to the stability of the prosthesis (Figure 61.3).

In the operation note the surgeon should document the stability of the PIP joint, and whether the joint is suitable for early active mobilization. The finger should be splinted immediately with a volar slab, with the wrist in neutral, the MCP and PIP joints in slight flexion and the hand elevated to reduce swelling. Rehabilitation should begin on day 2, preferably under the supervision of an experienced hand therapist. If suitable, early active mobilization can be commenced with a resting splint to block extension at 20°. If a lateral approach has been used, the collateral repair should be protected with a radial outrigger or by buddy strapping. At six weeks protective splints can be discontinued but a resting night splint should be worn for a minimum of three months.

Osteoarthritis of the PIP joint may present with swelling, stiffness and pain. Isolated stiffness in the absence of pain is not an indication for surgical intervention. Specifically, arthroplasty of the PIP joint is not indicated as the current body of literature indicates that preoperative range of movement governs the postoperative range, with minimal, if any, functional gains. Function is often well preserved but where pain affects daily life intervention is required.

Denervation of the PIP joint under local anaesthesia has been described as a joint-preserving alternative to fusion or replacement with successful relief of pain in 80% of patients.⁶⁶ This technique is not widely used currently. Joint replacement has been available for several decades but has failed to gain widespread acceptance due to high rates of complication and re-operation (approximately 40%). The need to preserve motion is greatest in the little and ring fingers to allow finger flexion for power grip. In the middle, and most especially the index finger, stability to lateral forces such as in key pinch are essential. This may be achieved with resurfacing arthroplasty as long as the radial collateral ligament is not disrupted. In the author's view silicone arthroplasty should not be performed in the index finger

PIP joint as the collaterals will be defunctioned and the digit will not be able to resist valgus forces.

PIP joint arthrodesis can be performed as a primary treatment or for salvage of failed arthroplasty. The benefits of fusion are a stable, painless PIP joint but at the cost of joint motion. The optimum position of fusion depends on the digit, with progressive flexion from 40° at the index finger through to 55° at the little finger PIP joint, however the kinematics of precision pinch will be altered with sacrifice of pinch precision.⁶⁷ Various methods have been described for arthrodesis. Dorsal compression plate fixation and tension band arthrodesis have been reported to achieve 100% union at the PIP joint.^{68,69} Biomechanical analysis supports the use of a tension band wire technique over crossed K-wires or intraosseous wiring because of superior anteroposterior bending and torsional strength.⁷⁰ Headless compression screws have been shown to achieve similar biomechanical strength on three-point bending to tension band wires with 98% successful fusion reported in a series of 51 joints (Figure 61.4).⁷¹

Arthrodesis performed as salvage for arthroplasty is a challenge. Bone loss may be considerable due to implant subsidence or due to difficulty removing the implant. Restoration of digit length is essential to maintain functional length of the flexor and extensor apparatus, otherwise the DIP joint may become floppy. This can be achieved with an intercalary autograft but the risk of non-union is increased. In one series union was achieved in 8 of 13 digits at an average of six months.⁷² Stern was able to demonstrate a 100% fusion rate using an intramedullary Steinmann pin and cerclage wire but with PIP joints fused in full extension functional limitations were reported.⁷³

Distal interphalangeal joint

The painful osteoarthritic DIP joint is most commonly managed with fusion although success with silicone arthroplasty has been reported in small series. The joints are commonly fused in full extension or 10° flexion to allow for precision pinch and grip. Fusion can be achieved with crossed K-wires, bioabsorbable

Figure 61.3 Proximal interphalangeal arthroplasty through a dorsal approach.

Figure 61.4 Fusion of proximal interphalangeal joint with dorsal plates.

poly-l-lactide pins, tension band wires, cerclage wires, headless compression screws, lag screws, intramedullary devices or compression staples with comparable rates of union.^{74,75} Biomechanical studies have indicated superior strength with use of a headless compression screw compared with a tension band wire technique.⁷⁶ However, the complication rate with headless compression screws is high when compared to alternative techniques, with infection rates as high as 15% and soft tissue complications of over 10%.^{77,78} Arthroscopic DIP joint fusion has been described but there are clearly technical and cost considerations for this technique, and the benefit over open surgery has not been proven.⁷⁹

Postoperative management

As with all complex surgery of the hand, the involvement of a hand therapist is strongly recommended. Traditionally, patients have been advised to take oral analgesia and use high elevation to reduce swelling. Where fusion is required non-steroidal anti-inflammatory analgesia should not be taken due to the deleterious effect on bone healing. Recent evidence suggests that high elevation is not effective in limiting swelling in the postoperative phase although it may prevent throbbing pain from the limb.

There is substantial variation in periods of immobilization and rehabilitation regimen between units and depending on the joint involved, the surgery performed and the technique used. The ethos within the Wrightington upper limb unit is to allow protected mobilization as early as possible with splintage where this aids rehabilitation. Dorsal splints are applied to the PIP or DIP joints to protect fusions with K-wire fixation for a minimum of four weeks (Figure 61.5). Where memory staples or headless screws are used, this period can be shortened. Tendon glide is assisted by early active mobilization of the adjacent joints. For small joint arthroplasty mobilization is begun at day 2 as long as

Figure 61.5 Postoperative splint for proximal interphalangeal joint replacement.

the joint is stable and a resting splint is worn between exercises and at night for six weeks. The position of immobilization depends on the operated joint. For the PIP joint the MCP and wrist are at neutral and PIP at 30° flexion. After trapeziectomy with or without ligament reconstruction the period of immobilization varies from six weeks to immediate mobility. Current evidence would suggest that prolonged immobilization does not confer advantage over immediate mobilization.⁸⁰

Complications

Complications of the surgical management of osteoarthritis in the hand depend on the reconstructive technique selected. It is important to consider the effect that surgery to one joint can have on adjacent joints within the ray and also to consider the exquisite balance of the flexor and extensor apparatus, where even minor alterations can lead to dramatic consequences. Iatrogenic swan-neck or boutonnière deformity is common after small joint arthroplasty. Painful neuromata are frequently reported after basilar thumb surgery and can be difficult to treat. They are best avoided by appropriate care being taken at the initial surgery. For refractory cases some success has been seen with excision of the tender skin and a full-thickness skin graft.

Arthrodesis is associated with the unique problem of non-union. The risk of this is greatest at the trapeziometacarpal joint, but wide variation has been reported of between 8 and 20%. In our experience at Wrightington Hospital the rates of union following arthrodesis are equivalent using headless screws or memory staples, but the use of K-wires is associated with higher rates of non-union. The risk of non-union must be balanced against the complications arising from hardware. At the DIP joint fusion is associated with a rate of non-union of just over 10% in osteoarthritis, regardless of technique used. Headless compression screws are associated with more minor complications than crossed K-wires because the metalwork is retained. Implant fracture, prominent metalwork requiring removal, nail growth disturbance and screw cut-out have all been reported.^{81,82} In one series the rate of dorsal skin necrosis was 14% with the use of a Herbert screw.⁷⁸ Salvage of non-union at the DIP joint can be challenging because of retained hardware and loss of bone stock. Owusu and Isaacs have described a technique using a corticocancellous iliac crest bone plug inset to the middle and distal phalanges, having removed the hardware through a dorsal wedge corticotomy of the middle phalanx, but more data is required before this technique can be recommended.⁸³

Arthroplasty of the small joints of the hand is most commonly complicated by joint stiffness. In few cases a specific cause is discernible, such as heterotopic ossification, and re-operation in these cases rarely improves the arc of movement. Recognition that, on current evidence, preoperative arc of movement will dictate the postoperative outcome may reduce the rate of re-operation in a vain attempt to improve movement. Where tendon imbalance results in swan-neck or boutonnière deformity

Figure 61.6 Dislocated proximal interphalangeal joint replacement.

there may be value in attempting rebalancing surgery in some cases, as long as mobility has been retained. If a fixed deformity exists, re-operation is unlikely to be successful. Dislocation and implant loosening (Figure 61.6), squeaking due to friction and both implant fracture and peri-prosthetic fracture have been reported, resulting in overall complication rates of around 30% for small joint arthroplasty.⁸⁴ For silicone implants there appears to be a linear relationship between time since implantation and implant fracture, although this does not appear to translate to surgical revision.⁵⁹

Outcomes

For early stage 1st CMC joint arthritis (stage I or II) surgery can produce good outcomes in over 80% of patients with either a metacarpal osteotomy or ligament reconstruction. Longitudinal

studies have indicated that successful early intervention can prevent progression of radiographic changes.^{85,86} Where osteoarthritic changes are more advanced, satisfactory long-term pain relief can be achieved with trapeziectomy with or without suspension, prosthetic replacement or fusion with no clear superiority in outcome with any procedure, although complication rates will vary.

For the PIP joint arthroplasty with either a silicone spacer or metalloplastic or pyrocarbon anatomical prosthesis can maintain joint motion and provide satisfactory pain relief. The long-term outcome of anatomical replacement is not known but medium-term results indicate favourable outcomes but with high rates of re-operation. Arthrodesis may produce a more durable outcome at the expense of joint motion and the ideal indication for each is yet to be determined. Joint fusion remains the favoured treatment at the DIP joint although the best method of achieving union is debated.

Arthroplasty

Classification of implants

Small joint arthroplasty is performed in the hand to reconstruct MCP joints, PIP joints, the CMC joint of the thumb and less frequently the DIP joint. A number of implants are available and these can be classified variously depending on location, materials, design, constraint or fixation. We prefer to categorize the implants into three main groups: interposition implants, ball and socket joints and two-part anatomical implants. Metallic hinge designs have been trialled but their use has been discontinued due to early implant loosening.⁸⁷

Interposition implants are the earliest and arguably the most successful group of arthroplasty designs in the hand. Silicone implants were popularized by Al Swanson in the late 1960s, primarily for use in inflammatory arthropathy.⁸⁸ These and all subsequent designs for the MCP and PIP joints have been of a flexible hinge design. Although they are designed as a hinge, many authors consider them as flexible internal splints or spacers that augment a soft tissue balancing procedure. For arthritis of the base of the thumb, a trapezium spacer was conceived by Swanson with a silicone stem into the thumb metacarpal (Figure 61.7).⁸⁹ Latterly, other materials have been employed to circumvent issues of silicone fragmentation, especially at the base of the thumb, including a number of prostheses made from pyrolytic carbon.

Ball and socket joints have been employed most successfully at the CMC joint, with a number of implants of this type in use. These designs do not attempt to replicate normal joint anatomy. The implants can be designed to be implanted uncemented or with polymethylmethacrylate (PMMA) cement. This ball and socket concept has been trialled in the MCP joint but with high rates of early failure.⁹⁰

Two-part anatomical implants are designed to restore as closely as possible the normal anatomy of the joint with the aim

Figure 61.7 Silicone arthroplasty first carpometacarpal joint.

of returning normal kinematics. This implant group necessitates retention of soft tissue stabilizing elements and restoration of soft tissue balance. These implants have bearing surfaces of metal on ultra-high molecular weight polyethylene (UHMWPE) or pyrocarbon contoured to mimic the anatomical joint surface. The implants have stems that are fixed by a variety of methods, including osseointegration, cementation and press-fit.

Evolution

Early attempts to address painful arthritic joints in the hand involved excision arthroplasty that was later augmented with interposed soft tissues. At the base of the thumb excision arthroplasty remains the 'gold standard' against which the success of alternative interventions must be judged.³³ On the back of the success of hip arthroplasty there was a wave of enthusiasm for

metalloplastic articulations and a number of ball and socket designs were introduced for MCP joint and even the PIP joint. Early failure occurred due to implant loosening and these were abandoned.

Then came silicone interposition arthroplasty. The concept was to provide a flexible internal splint with interposition and encapsulation. In patients with inflammatory arthropathy, poly-articular involvement and low functional demands, silicone arthroplasty was very successful, especially in reconstruction of the MCP joints, and remains a useful tool in the hand surgeon's armament. Of the silicone implants, those of Swanson became the most widely used. Expansion of the indication for arthroplasty to those with post-traumatic or primary osteoarthritis resulted in a perception of less favourable outcomes and alternative designs were sought.

Two-part anatomical prostheses were thought to have advantages, especially in high-demand individuals. It was proposed that anatomical designs would restore joint kinematics and improve outcomes. The lack of constraint can minimize the risk of implant loosening as seen in early hinge designs, or of implant fracture observed in silicone arthroplasty, however, new risks present, with joint instability, angulation and dislocation all commonplace.

Outcomes

Reported outcomes: first carpometacarpal joint

The unique anatomy of the 1st CMC joint has resulted in significant challenges for arthroplasty design. Ball and socket designs have shown mixed results with high rates of loosening of the 'cup' within the trapezium, although satisfactory long-term pain relief and function have been reported.^{91–94} When combined with an STT arthrodesis for treatment of pan-trapezial osteoarthritis, loosening was observed in most cases.⁹⁵ Rates of failure have been reported to be higher in men of working age and this has been proposed to be a relative contraindication for this type of arthroplasty.⁹⁴ Cemented implant designs appear more successful for basal thumb arthritis than uncemented equivalents, with high rates of early loosening observed with the Ledoux, Moje and Elektra uncemented ball and socket designs although, as with the cemented arthroplasties, this does not always lead to revision or have a detrimental effect on the outcome.^{96–102}

As with other joints in the hand, the initial experience of 1st CMC joint arthroplasty was with silicone implants. Silicone arthroplasty, despite early promising reports, has been shown to be associated with high rates of joint subluxation, implant fragmentation and silicone synovitis in osteoarthritic patients at 15 years follow-up.^{103–109} Comparative studies have not shown significant benefits of silicone replacement over trapeziectomy with or without interposition, although pinch strength at 1 year may be superior with the silicone implant.^{106,110,111} A systematic Cochrane review identified no benefits of arthroplasty over simple trapeziectomy, with the latter producing fewer complications.¹¹²

The SR trapezometacarpal prosthesis (Avanta Orthopaedics, CA, USA) was the first anatomical design, with biconcave cobalt–chrome on UHMWPE-bearing stemmed implants. Initial results reported by the originators were encouraging and were supported by other authors and impressive kinematic studies.^{113–116} However, an independent study by Perez-Ubeda *et al.* reported 70% failure in 20 implants followed for between 24 and 45 months, with loosening in 55% and ankylosis in 15%.¹¹⁷ In 1982 Braun reported the initially favourable results of a titanium metacarpal component and a polyethylene trapezium component, both cemented with PMMA cement.¹¹⁸ Good outcomes were also reported at a mean of 59 months with only one patient complaining of minimal pain, and one revision for post-traumatic loosening.¹¹⁹

These problems with implant loosening within the trapezium have led to the development of a number of hemiarthroplasty designs. A pyrocarbon resurfacing hemiarthroplasty prosthesis for the base of the first metacarpal has been developed (Ascension Orthopedics, Austin, TX, USA) (Figure 61.8). At Wrightington, a review of the first 19 patients to undergo pyrocarbon hemiarthroplasty with a minimum follow-up of 1 year presented at the British Hand Society¹²⁰ indicated an improvement in pain scores but no change in function or grip strength. However, 4 of 19 joints subluxated, a finding observed

in other series.¹²¹ The authors conclude that the implant may have a role in the young patient who wishes to retain strength. More recently, a modular metal uncemented hemiarthroplasty with titanium plasma spray stem has been introduced. It is proposed that modularity will allow better soft tissue balancing and use of head sizes that better fit the anatomy. Furthermore, the authors suggest that the varus position of the head of the implant more closely replicates normal anatomy than other designs. Initial results from the originator indicate 94% implant survival at 72 months and high patient satisfaction.¹²²

Interposition arthroplasty at the base of the thumb with pyrocarbon implants has been studied using a number of forms including spheres, ellipsoids and tori or ‘doughnuts’ that are inserted by reaming the trapezium to create a cup. Despite high rates of patient-reported satisfaction, spherical prostheses have been reported to subside into the bone in almost all cases, causing pain, weakness and stiffness.^{123,124} Ellipsoid-shaped implants have also struggled to demonstrate benefits over trapeziectomy, with high rates of dislocation or subsidence.³⁴ The use of other materials has been no more successful. Artelon TMC spacer (Artimplant AB, Sweden) is a biocompatible degradable polyurethaneurea ‘T’-shaped device designed to stabilize the joint and interpose between the joint surfaces.¹²⁵ Exuberant granulomatous foreign body giant cell reactions have been demonstrated in relation to the use of this implant; these have resolved with implant removal.^{126–128}

Reported outcomes: metacarpophalangeal joint arthroplasty

The predominant cause of MCP joint destruction is rheumatoid arthritis. Consequently much of the literature concerning arthroplasty at this joint concerns this patient group. Silicone arthroplasty has been shown to produce reliable outcomes in the MCP joint in inflammatory conditions. In osteoarthritis there is a scarcity of evidence. A series of 15 silicone MCP joint replacements in 14 osteoarthritic patients at an average of 40 months reported good or excellent outcomes in 12 patients. One implant had been revised for fracture but of the remaining implants none were reported to show signs of fracture or joint subluxation or malalignment.¹²⁹

Osseointegrated titanium implants followed from the use of osseointegration in dental surgery. Titanium-stemmed implants have been shown to osseointegrate when implanted at the MCP and PIP joints. At the MCP joint early reports using this concept with a silicone spacer indicate a high rate of failure of the joint mechanism, although pain relief and high patient satisfaction have been reported.^{130,131}

The first unconstrained ‘anatomical’ implant was made from alumina ceramic with favourable outcomes, but the authors felt that the design could be improved by moving the centre of rotation more volarward.^{90,132–134} Other designs now use pyrocarbons and other composite materials. Pyrocarbon is a synthetic material with a high-strength graphite core coated with a pyrolytic carbon layer formed by heating a hydrocarbon

Figure 61.8 Pyrocarbon first carpometacarpal joint. Hemiarthroplasty.

gas to approximately 1300°C. Pyrocarbon was first used in mechanical heart valves, is inert and compatible with normal bone. It was initially thought that osseointegration would occur, but this has been shown not to be the case.¹³⁵ In 1999, Cook *et al.* reported their experience in 53 predominantly rheumatoid patients with 151 anatomical unconstrained MCP joint implants made from pyrocarbon.¹³⁶ The authors reported a revision rate of 12% with a 10-year survival rate of 81.4%. The short-term outcome of a pyrolytic carbon implant in patients with osteoarthritis has also been shown to be good.^{137,138} Medium-term follow-up at 2–4 years indicates that promising early results are maintained with high rates of patient satisfaction and low pain scores.¹³⁹ No problems of implant migration, fracture or dislocation were observed.

Harris and Dias have reported their results using an anatomical implant with cobalt–chrome on an UHMWPE bearing.¹⁴⁰ The proximal cobalt–chrome component is inserted into an UHMWPE press-fit sleeve that is itself inserted into the metacarpal with an interference fit. The authors followed up 13 joints for a mean of 5 years; there was one revision for infection, and evidence of loosening of two phalangeal and one metacarpal component.

MCP joint arthroplasty with either silicone or resurfacing implants appears to reliably relieve pain and maintain function. Subluxation or dislocations of the unconstrained components, loosening of the implants, implant fracture and joint stiffness have all been described.^{136,141}

Reported outcomes: proximal interphalangeal joint arthroplasty

As in other joints, constrained or semi-constrained implants have not performed well in the PIP joint. The LPM prosthesis, a semi-constrained ceramic-coated cobalt–chrome implant, was reported to undergo high rates of early failure.¹⁴² Silicone arthroplasty can reliably relieve pain in the short term, but complications of angular deviation have been observed in a series of patients with osteoarthritis in whom the implant was inserted through a lateral approach.¹⁴³ The risk is greatest in the radial digits due to lateral forces during pinch.

Anatomical replacement is less constrained. The first anatomical resurfacing PIP joint was developed by Linscheid using stemmed unconstrained implants with a bearing of UHMWPE on cobalt–chrome.¹⁴⁴ The stems were fixed with PMMA cement. Linscheid *et al.* reported the results of 66 of their implants in 47 patients, 56% of with primary osteoarthritis, 24% with post-traumatic arthritis and the remainder with inflammatory arthropathy, with a minimum follow-up of 1 year.¹¹³ Using their own criteria they reported 32 good, 19 fair and 15 poor outcomes. The outcomes were worst in digits with pre-existing deformity or extreme bone and/or soft tissue loss. A more recent cohort reported excellent long-term results in 18 of 20 patients with predominantly primary or post-traumatic osteoarthritis.¹⁴⁵ Importantly, Linscheid's group has shown that in the long term, pain scores remain low and there is no substantial change in

range of motion. They observed a higher failure rate for those implanted via a volar approach.¹⁴⁶

Moller *et al.* reported a series of 22 osseointegrated titanium PIP joint replacements with a silicone hinge between the stems.¹⁴⁷ They reported initial good outcomes with 41 of 44 stems showing osseointegration but high rates of silicone failure with deformity or fracture in 45% at a minimum follow-up of 12 months. They concluded that the silicone component would need further development.

The outcomes of uncemented anatomical pyrocarbon PIP joint arthroplasty have been reported in a number of studies.^{148–154} At Wrightington, we have undertaken the largest study to date of 97 joints in 72 patients, 60% of whom had primary osteoarthritis, with a minimum follow-up of 2 years. The results indicate good implant survival rates of 85% at 5 years. Although arthroplasty resulted in good relief of pain, there was no significant increase in the arc of motion of the digit from preoperatively. The main concern with the pyrocarbon implants is at the bone–implant interface. Osseointegration does not occur and, in many cases, a radiolucent line may be seen around the implant.¹⁴⁸ To date this worrisome lucency has not translated into large numbers of implant failures but it does give cause for concern. A comparative study of pyrocarbon arthroplasty against silicone arthroplasty showed equivalent outcome in all parameters except stability in the coronal plane, which was better in the pyrocarbon group.¹⁵¹ A prospective multicentre randomized trial of titanium on polyethylene, pyrocarbon and silicone implants reported equivalent significant reductions in pain scores but revision rates as high as 39% in the resurfacing implants, compared to only 11% in the silicone group at 3 years post implantation.

The PIPr (MatOrtho Ltd) has a mobile UHMWPE-bearing distal component articulating with a cobalt–chrome proximal component; both components have a hydroxyapatite-coated cobalt–chrome uncemented stem (Figure 61.9). The 1-year results with this prosthesis in 43 digits have been reported from Wrightington with favourable results; pain scores and range of

Figure 61.9 PIPr arthroplasty design.

movement improved although two revisions occurred at six months and 2 years and three patients developed a swan-neck deformity.¹⁵⁵ Ongoing analysis continues.

Taken together, the literature suggests that PIP joint arthroplasty using silicone or anatomical arthroplasty can result in high patient satisfaction and pain relief but that gains in arc of motion have been disappointing. Most series have used a dorsal approach and the disruption caused to the extensor mechanism may influence the outcome. Results of small series using a volar approach to the PIP joint have reported substantial improvements in the arc of motion that warrants further investigation, however reports of higher rates of failure using this approach cause concern.^{146,156}

As with all implants, infection is a major concern after PIP joint arthroplasty. From our own data we estimate the risk at approximately 1%. This is best treated by excision and secondary reconstruction with a silastic implant, or volar plate arthroplasty. With unconstrained implants, instability is a problem that is best avoided with careful soft tissue balance and accurate implant alignment at the primary procedure. Early dislocations may be addressed with closed reduction and splintage. If this management fails then revision to a hinged silicone implant is likely to provide a stable, pain-free joint. Implant loosening, a common problem with highly constrained arthroplasty, is also seen with unconstrained components. Revision with larger components and bone grafting may be successful, otherwise a silicone hinged implant can be used.

Reported outcomes: distal interphalangeal joint arthroplasty

At the DIP joint arthrodesis forms the mainstay of treatment of painful osteoarthritis. Small series of flexible silicone implant arthroplasty have been reported. These indicate durable results at an average of 5 years with good pain relief and mean motion of 33°.^{157–159}

CHAPTER 62

Wrist pathology

Owen L. Ala, T. Shane Johnson and L. Scott Levin

Department of Orthopaedic Surgery, Hospital of the University of Pennsylvania, Philadelphia, PA, USA

Physical exam of the wrist

For many wrist pathologies, a good physical exam is more helpful in determining the diagnosis than expensive imaging studies. However, it is imperative to have a thorough knowledge of wrist anatomy in order to correlate anatomical knowledge with specific pathologies. When performing a physical exam of the wrist it is helpful to approach the exam in a systematic way and compartmentalize the wrist based on anatomic regions. There are several physical exam manoeuvres and tests that can be performed to help in the diagnosis of specific wrist conditions. An anatomically based approach to wrist palpation will be presented followed by a discussion of common wrist problems that present to hand surgeons.

Radial-sided wrist pain

Palpation of the wrist should not be a neglected or generalized part of the exam. Palpation of the wrist should be very specific and correlate with anatomy. When examining the radial side of the wrist, pain on palpation along the tendons of the first dorsal compartment (abductor pollicis longus and extensor pollicis brevis) as they exit at the level of the radial styloid is indicative of de Quervain's tenosynovitis. A hypertrophied tendon sheath is also a common finding. Palpating just distal to the radial styloid in the anatomic snuff box can elicit pain from a scaphoid fracture. The distal pole of the scaphoid can also be palpated immediately volar to the snuff box at the base of the thenar eminence. Continuing the exam by palpating distal to the snuff box will bring the examiner to the scaphoid, trapezium and trapezoid (STT) joint and the carpometacarpal (CMC) joint. Palpation of this area can elicit pain from common arthritic pathologies such as CMC arthritis.

Ulnar-sided wrist pain

Ulnar-sided wrist exam examination should start with palpation of the ulnar head and ulnar styloid. Pain along the ulnar styloid can be indicative of triangular fibrocartilage complex

(TFCC) pain or a distal ulna fracture. Palpation of the soft spot on the ulnar side of the wrist just distal to the distal ulna will elicit pain from the TFCC and can indicate pathology in this area. Immediately dorsal to the ulnar soft spot is the extensor carpi ulnaris (ECU) tendon, which is a frequent site of ulnar-sided tendonopathies. Palpation of the ECU tendon and sixth dorsal compartment sheath, especially in ulnar deviation, will help in diagnosing ECU pathologies. Volar-sided palpation can elicit pain from a fractured pisiform or hook of the hamate, as well as piso-triquetral arthritis.

Central wrist pain

Palpation of the wrist more central or midline is often less specific but still very helpful. The wrist should be palpated along the dorsal aspect and examination for pain at the lunate or scapholunate interval can be indicative of scapholunate (SL) ligament tear or Kienböck's disease. Palpation just proximal to the carpal bone can elicit pain from the distal radioulnar (DRU) joint.

Kienböck's disease

Pest first described avascular necrosis of the lunate based on cadaveric dissections. Avascular necrosis of the lunate is named after the radiologist Robert Kienböck.¹ Although he is best remembered for his paper 'Concerning traumatic malacia of the lunate and its consequences', he published over 250 scientific papers, an eight-volume edition on radiology and was the first to develop a film dosimeter to measure exposure to radiation.² Despite Kienböck's disease being described over 100 years ago, the aetiology and natural history are not clearly understood.

Kienböck's disease presents in patients as wrist pain, usually located centrally over the dorsum of the wrist. The pain usually affects one wrist and is rarely bilateral. Varying degrees of pain are present, with many patients going years before they seek medical attention. Pain is usually present with wrist motion but

as the disease progresses, pain at rest is common. It is commonly seen in men 20–40 years of age.

Traditionally, it was thought that fractures of the lunate would lead to Kienböck's disease because of its poor blood supply, but there is no clear consensus on the relationship. Long-term follow-up studies have shown that that lunate fractures do not reliably develop avascular necrosis, even with an ulnar negative variance.³ Ulnar negative variance has been associated with Kienböck's disease, prompting many to point to this anatomical feature as a possible aetiology. Hulten's classic study in 1928 showed an association between ulnar negative variance and Kienböck's disease but more recent studies do not demonstrate a clear correlation.^{4,5}

Clinical evaluation

The clinical evaluation of the patient with Kienböck's disease starts with a thorough physical exam of the wrist. However, the exam findings for Kienböck's disease are usually not diagnostic because they are non-specific. Dorsal wrist pain, often with motion or activity, is the main physical exam finding. The differential diagnosis will include dorsal wrist ganglion, scapholunate ligament injuries, DRU joint pathology or ulnar impaction syndrome just to name a few.

Radiographic evaluation is followed by the physical exam. Kienböck's can be diagnosed by correlating the physical exam with radiographs, however imaging using MRI is often necessary for definitive diagnosis (Figure 62.1). Radiographs are evaluated

Figure 62.1 (a, b) Lateral and postero-anterior views of a wrist with sclerosis of the lunate and mild collapse of the lunate without general carpal collapse. Also note the ulnar positive variance. (c) MRI showing T1 with low signal intensity of the lunate and fracture line through the lunate. (d) Intraoperative X-ray showing capitatal shortening osteotomy and revascularization of the lunate using capsular-based vessels from the fourth extensor compartment as described by Sotereanos *et al.*¹³ (e, f) Three months postoperative radiographs showing revascularization of the lunate, no further collapse, and patient returning to pain-free wrist motion.

for sclerosis of the lunate and ulnar variance should be noted. The lack of lunate sclerosis does not rule out the disease. If radiographs are not diagnostic, then an MRI should be considered.

Kienböck's staging and treatment

Radiographs and MRI are used to stage Kienböck's disease. The staging system as presented by Lichtman and associates is the most popular and helps guide treatment and determine prognosis.^{6,7} The treatment of Kienböck's disease is based on the staging and will be discussed together.

Stage I

Symptoms of stage I Kienböck's disease are usually non-specific and mimic wrist sprains or synovitis. Radiographs are usually normal in stage I Kienböck's and represent a precollapse and early appearance of the disease. MRI will demonstrate low signal on T1 and T2 weighted images. It is important to recognize if there is low signal of the entire lunate. If there is only focalized low signal on T1 weighted images then other diagnoses, such as ulnar abutment, fractures, osteoid osteoma or enchondromas, become much more likely. If T2 weighted images show increased signal, this can be a sign of revascularization and MRI can be used to monitor resolution of disease.

Stage I disease is best treated non-operatively with a splint. Most people advocate for at least three months of splint use. Some authors advocate for night-time splinting; nevertheless, non-operative management is the mainstay of treatment.⁸

Stage II

Radiographs become diagnostic or at least suggestive of Kienböck's disease during stage II. One typically finds increased sclerosis of the lunate with possible fracture lines or early collapse. MRI continues to be diagnostic with the entire lunate showing low T1 and T2 signal intensity. Lunate height is maintained and symptoms usually mimic chronic wrist synovitis.

Stage IIIA

Stages II and IIIA are usually discussed together because the treatment options are the same. Stage IIIA Kienböck's disease demonstrates collapse of the lunate; however, there is maintenance of carpal height and no signs of arthritis. The anterior-posterior distance of the lunate is usually increased on the lateral radiograph. Sclerosis is present and MRI findings of low signal intensity on T1 and T2 weighted images remain consistent.

The treatment of stage II and stage IIIA disease should start with initiating supportive care and immobilization. A surgeon should not rush to surgery during this stage of treatment and a course of non-operative treatment should be initiated. The severity of the patient's symptoms should dictate whether to proceed with surgical treatment or continue with non-operative treatment. The surgical treatment options differ based on ulnar variance.

Stage II and IIIA with ulnar negative variance

When ulnar variance is noted to be negative, it is thought that increased pressure from the lunate fossa of the distal radius is the cause of the symptoms. Unloading and decreasing the pressure on the lunate through a radial shortening osteotomy is usually the treatment of choice. One study demonstrated 93% of patients had diminished pain after a radial shortening osteotomy.⁹ Ulnar lengthening osteotomy has been described for stage II and IIIA disease with ulnar negative variance but this is generally considered a more difficult procedure with higher complications. Ulnar lengthening requires bone grafting and healing at two osteotomy sites, both the proximal and distal ends.

Stage II and IIIA with ulnar positive or neutral variance

Revascularization procedures are most appropriate in stage II and IIIA with ulnar positive or neutral variance. A number of revascularization procedures have been described, including vascularized pedicle transfer from the distal radius, vascularized pisiform transfer, vascularized bone graft from the metacarpal and free vascularized grafts from the iliac crest or medial femoral condyle.¹⁰ The most popular vascularized pedicle transfer is from the distal radius and is the 4,5 extracompartmental artery.^{11,12} Sotereanos *et al.* have described a capsular-based vascularized bone graft (see Figure 62.1d) based on the fourth extensor compartment artery for the treatment of scaphoid avascular necrosis, which has been adapted for the treatment of stage II and IIIA Kienböck's disease because of its surgical simplicity.¹³ These procedures may be accompanied by joint levelling procedures such as capitate shortening, radius osteotomy or external fixation.

Stage IIIB

Stage IIIB is characterized by lunate collapse, rotation of the scaphoid and loss of carpal height. Revascularization procedures are usually not considered after lunate collapse and loss of carpal height because of the destruction of normal anatomic architectures. A good result from a revascularization procedure would not be expected. There is some controversy about the best way to treat stage IIIB disease and some authors have had good results with limited wrist arthrodesis, including scapho-capitate arthrodesis and scaphotrapezium-trapezoid arthrodesis. Although controversial, other authors have had good results with radial shortening osteotomies.¹⁴ Lunate excision with interposition arthroplasty or proximal row carpectomy are additional salvage procedures that have been described.

Stage IV

Stage IV is characterized by collapse of the lunate and degenerative changes in the radiocarpal and midcarpal joints. Joint levelling or revascularization procedures are not performed once degenerative changes appear. Many patients can be managed non-operatively with supportive care such as splints, anti-inflammatory medications and activity modification. In patients who have failed non-operative management, salvage procedures

can be considered such as limited or total wrist arthrodesis or proximal row carpectomy. For a proximal row carpectomy to reliably provide pain relief, the proximal capitate must be free from degenerative changes since it will eventually articulate with the lunate fossa of the distal radius.

De Quervain's tenosynovitis

De Quervain's tenosynovitis causes pain on the radial side of the wrist, centred over the first dorsal compartment. Active radial deviation of the wrist (such as a mother picking up a small child) or passive ulnar deviation causes severe pain over the tendons of the first dorsal compartment. The first dorsal compartment tendon sheath can be up to five times its normal size due to fibrous tissue deposition. De Quervain's tenosynovitis is a myxoid degeneration of the first dorsal compartment. Although non-steroidal anti-inflammatory medications are a first line treatment, it is not an acute inflammatory process. Often the tendon sheath can be easily palpated due to its enlarged size.

Intersection syndrome should be ruled out during the diagnosis of de Quervain's tenosynovitis. Intersection syndrome causes pain in a similar area but there are subtle differences. It is caused when pain, swelling and sometimes crepitus occur because the outcropping muscle bellies of the abductor pollicis longus and extensor pollicis brevis intersect with the long wrist extensors on the dorsum of the forearm.

Diagnosis of de Quervain's tenosynovitis is usually done with a patient history and physical exam. Imaging studies are usually not required. Pain over the first dorsal compartment on the radial aspect of the wrist, which is made worse with palpation, is the first physical exam findings. A thickened tendon sheath and pain with active radial deviation are also common findings. Finkelstein's manoeuvre (Figure 62.2) is the classic physical exam manoeuvre used to aid in the diagnosis.

Figure 62.2 Finkelstein's manoeuvre. Pain is generated on the radial aspect of the wrist over the first dorsal compartment when the patient clasps his or her thumb into the palm and the examiner pulls the wrist into ulnar deviation.

Initiation of non-surgical treatments such as watchful waiting, splinting, non-steroidal anti-inflammatory medication and steroid injections into the second dorsal compartment should be considered. Multiple studies have shown successful treatment with each of these non-surgical techniques. The authors recommend non-surgical treatment be initiated upon diagnosis. We recommend a removeable thumb spica splint and non-steroidal anti-inflammatory medications. Other non-operative modalities include rest, ice, activity modification, iontophoresis and corticosteroid injections. Cases that are refractory to non-surgical management should be considered for surgical release.

Surgical release of the first dorsal compartment is very successful and produces reliable, long-term pain relief. Open surgery through a small horizontal incision is the authors' preferred method of treatment. One study showed complete pain relief after surgical release in 19 of 20 patients.¹⁵ Branches of the radial sensory nerve are in or near the operative site and should be carefully identified and/or avoided. If a branch of the radial sensory nerve is cut during surgery, a painful neuroma can result. Endoscopic methods of treatment have also been described and are successful.

Scaphoid fractures

The scaphoid is most commonly injured by a fall on an outstretched hand, resulting in radial-sided wrist pain and, classically, snuff box tenderness. Scaphoid fractures represent 60% of all carpal bone fractures. Because of the distally based scaphoid blood supply, fractures are notoriously difficult to treat with a high incidence of delayed union, non-union and avascular necrosis. Eighty per cent of the scaphoid is covered in articular cartilage, which limits its blood supply. The majority of the blood supply to the scaphoid comes from the dorsal scaphoid branches of the radial artery, with a minority of the blood supply from the volar scaphoid branches. These vessels enter the scaphoid relatively distally, resulting in purely intraosseous perfusion of the proximal pole. The tenuous blood supply of the proximal pole explains the reported avascular necrosis that occurs in 13–50% of scaphoid fractures. These percentages increase for proximal pole fractures. Early diagnosis and treatment is important since scaphoid fractures that are left untreated have a higher incidence of non-union and malunion. Scaphoid non-union is difficult to treat and if left untreated will progress to carpal collapse and degenerative arthritis, specifically, scaphoid non-union advanced collapse (SNAC).

Diagnosis of scaphoid fractures can be surprisingly difficult. Diagnosis begins with a good history and physical exam. Patients typically have pain on the radial side of the wrist, specifically in the anatomic snuff box, decreased range of wrist motion, decreased grip strength, and pain with thumb motion. Adequate radiographs, including postero-anterior (PA), lateral, pronated oblique, supinated oblique and a PA with ulnar deviation (scaphoid view), are essential. However, X-rays often

show no evidence of fracture. When there are signs of scaphoid fracture on history and physical exam but no radiographic evidence, the traditional algorithm would be to cast the patient in a short arm thumb spica cast and repeat the X-rays in two weeks. After two weeks there is usually sufficient resorption at the fracture site to visualize a scaphoid fracture on radiographs. However, following this algorithm will overtreat and subject many patients who do not actually have a scaphoid fracture to two weeks of casting, which can be costly in terms of loss of work and productivity. Advanced imaging studies, such as MRI and CT scans, can help in the diagnosis and in the surgical decision making. MRI is the preferred test if the diagnosis of a scaphoid fracture is in question. The sensitivity and specificity of diagnosing a fracture is 90–100% with MRI. CT scans show bone structure better than MRI and are therefore better in determining displacement of a fracture. However, a CT scan should be used with caution in diagnosing an occult scaphoid fracture because there is a high rate of overdiagnosis with CT (false-positives), most likely due to normal vascular foramina appearing as a fracture. Therefore, a CT scan is better used in surgical decision making to determine if a fracture seen on radiographs is displaced or not. MRI is the better test for determining if a fracture is actually present.

Cast immobilization for 8–12 weeks can successfully treat most non-displaced or minimally displaced scaphoid fractures. There is no consensus on whether to use a short arm or long arm cast. A long arm cast will prohibit wrist rotation and will better immobilize the scaphoid. If treating a scaphoid fracture non-operatively, the authors recommend using a long arm cast for the first 4–6 weeks and then changing to a short arm cast for the duration of the treatment. The disadvantages to cast treatment are increased time to healing, frequent office visits, increased need for radiographs, potential for skin breakdown, and stiffness.

Although controversial, some authors have advocated immediate percutaneous internal fixation of minimally displaced and even non-displaced scaphoid fractures. The reasons behind the trend to immediate percutaneous fixation of these fractures are a decreased time to healing, faster return to sports or work, and a favourable economic analysis in terms of social life and return to work.^{16–20} There appear to be similar outcomes at 2 years of cast versus percutaneous treatment of non-displaced or minimally displaced scaphoid fractures.

Internal fixation is indicated in scaphoid fractures with displacement of at least 1 mm on any radiographic view. Scaphoid fractures with displacement have a much higher probability of progressing to a non-union with cast immobilization compared with internal fixation. The headless compression screw is the most accepted technique for fixation of scaphoid fractures. It has the advantage of being recessed below the articular surface of the scaphoid. The scaphoid is a curved bone, shaped much like a kidney bean, although there can be significant variability. The shape of the scaphoid makes screw fixation challenging; for the best results, the screw should be placed down the central

axis of the scaphoid. Breaching of the scaphoid with the screw during fixation should be avoided since it will lead to early degenerative arthritis. Healing rates of 95% have been reported with adequate screw fixation.

Scaphoid non-unions

Scaphoid non-unions develop in about 5% of scaphoid fractures and are usually the result of inadequate immobilization, displacement or delayed diagnosis. Scaphoid non-unions are difficult because of the tenuous blood supply of the proximal pole and resultant avascular necrosis, the tendency for the scaphoid to collapse into a 'humpback deformity', and the systematic progression to degenerative arthritis and SNAC.

Successful treatment of scaphoid non-unions without collapse, using open and percutaneous techniques has been described. Percutaneous fixation of scaphoid non-unions without collapse or displacement has been described with a cannulated compression screw.^{21,22} Even with resorption of bone at the fracture site, the union rates of percutaneous screw fixation have been as high as 100%. The Matti–Russe technique has traditionally been the treatment of choice for scaphoid non-unions without collapse.²³ This technique uses corticocancellous pieces of bone taken from the iliac crest and placed into the scaphoid after the fibrous tissue from the non-union has been removed. Modifications of the Matti–Russe technique have taken the graft from the distal radius instead of the iliac crest²⁴ or placed a corticocancellous graft with either screw or K-wire fixation. The Matti–Russe technique has been reported to provide union in up to 90% of patients. The majority of patients who did not achieve union were reported to have avascular necrosis of the proximal pole, and this technique is not generally recommended for patients with avascular necrosis.

Treatment of scaphoid non-unions with collapse ('humpback deformity') is more difficult since this requires a need for reduction of the deformity, replacement of the lost bone and stable fixation. Volar wedge fixation with a tricortico-cancellous bone graft taken from the iliac crest has been a successful way to correct a humpback deformity and replace lost bone.²⁵ This technique is usually augmented with screw fixation down the central axis of the scaphoid. Recently, there have been published reports of treating scaphoid non-unions with humpback deformity without structural bone graft and only placing cancellous bone graft. The reduction is performed open through a volar approach and assisted with K-wires, while a screw fixation provides a stable construct for healing. Bone graft is then harvested from the distal radius and packed around the screw to replace the bone lost from the collapse.²⁶ The good results reported with these techniques have not been duplicated when the proximal pole has gone onto avascular necrosis.

Treatment of scaphoid non-unions with avascular necrosis of the proximal pole have been most successfully treated with vascularized bone grafts. The most popular vascularized bone graft is the 1,2 intercompartmental suprapretinacular artery

(1,2 ICSRA) bone graft taken from the dorsal aspect of the distal radius.²⁷ The vascular anatomy of the 1,2 ICSRA is consistent, but very small. Recent reports have shown about a 75% union rate with use of the 1,2 ICSRA vascularized graft. A capsular-based vascularized bone graft has been described by Sotereanos *et al.* and based off the artery of the base of the fourth dorsal compartment.²⁸ This technique has been praised for its simplicity. However, both of these techniques provide only a small amount of bone for reconstructing a humpback deformity and the vascular pedicles are tenuous. Recently, a

free vascularized bone graft taken from the medial femoral condyle (Figure 62.3) and based off the descending geniculate artery has been described.²⁹ This graft has the advantage of replacing articular surface to the scaphoid. The free vascularized medial femoral condyle flap can be taken with or without articular cartilage, with or without a chimaeric skin paddle, and a relatively much larger piece of bone can be harvested. The vascular pedicle of the medial femoral condyle flap is sufficiently robust and is usually anastomosed end-to-side into the radial artery.

(c) Medial femoral condyle free flap bone with its associated vascular pedicle. (d) Medial femoral condyle free flap being harvested from the knee. (e) Medial femoral condyle free flap being inset into the scaphoid defect. (f) Radiograph showing scaphoid one month after treatment with a medial femoral condyle free flap and microvascular anastomosis end-to-side to radial artery.

Scapholunate dissociation

Injuries to the scapholunate joint are part of a broader category of pathology termed carpal instability dissociative (CID). CID is a dissociation between two bones of the same carpal row. Common injuries such as scapholunate dissociation, lunotriquetral dissociation, unstable scaphoid fractures, inflammatory arthritis or advanced Kienbock's disease can cause CID. Carpal instability non-dissociative (CIND) describes pathology between the bones of two separate carpal rows.

Scapholunate dissociation (SLD) is caused by an injury to the scapholunate ligament that connects the scaphoid and the lunate. It represents a wide spectrum of pathology, ranging from minor sprain of the scapholunate ligament to total perilunate dislocation. With complete SLD the lunate-triquetrum rotate into an extended position while the scaphoid assumes a flexed position as it rotates around the radioscapohcapitate ligament. This classic pathologic position of the scaphoid and lunate-triquetrum is termed dorsal intercalated segmental instability (DISI) and is best identified on a lateral radiograph with an increased scapholunate angle. The DISI deformity caused by SLD is in contrast to the resultant volar intercalated segmental instability (VISI) caused by luno-triquetral dissociation. SLD is part of a process of carpal destabilization that can lead to scapholunate advanced collapse (SLAC) and severe degenerative arthritis.

SLD is usually caused by a fall on a hyperextended and ulnar deviated hand. A low index of suspicion is needed for diagnosis since many of these injuries go undiagnosed because of the subtle physical exam and radiographic findings. Low-grade (predynamic) sprains to the scapholunate ligament may have no discrete physical exam or radiographic finding and are usually diagnosed on arthroscopy. Patients with acute or chronic SLD usually have pain localized at the scapholunate ligament when palpated over the dorsal wrist just distal to Lister's tubercle. Some patients will also have pain in the anatomic snuff box and over the scaphoid tubercle.

Scaphoid shift test is a dynamic test that aids in the diagnosis of complete scapholunate tears. The scaphoid shift test, or Watson test, produces abnormal scapholunate motion and pain when positive. The examiner places the thumb over the scaphoid tubercle (volar) and the other four fingers on the distal radius (dorsal) and pushes the scaphoid in a dorsal direction with the thumb. The examiner then moves the patient's wrist from ulnar deviation (scaphoid extended) to radial deviation (scaphoid flexed). If there is a tear in the scapholunate ligament with instability, the scaphoid will be unable to be flexed and will instead be subluxated from the dorsal aspect of the distal radius. When the pressure is released from the scaphoid, the scaphoid will reduce back into anatomic position with a classic 'clunking' sound. This test is helpful in diagnosis but one should be aware of the low specificity of the manoeuvre.

The scapholunate ballottement test is performed by holding the lunate firmly with thumb and index finger of one hand and

the scaphoid with the thumb and index of the other hand. The scaphoid and lunate are then shifted volar and palmar opposite to each other. An excessive amount of motion, pain and crepitus are signs of a positive result.

The classic radiographic sign of SLD is an increased distance between the scaphoid and the lunate. An increased scapholunate distance on radiographs has been called the 'Terry Thomas' sign (in reference to the English film comedian's space between his two front teeth). However, the normal three views of the wrist (PA, oblique, lateral) may not show an increased distance and as a result there is a high false-negative incidence. Special radiographic views have been described that center the X-ray beam tangentially to the scapholunate joint and therefore show the true extent of the scapholunate distance. The clinched fist view and the Moneim view (PA with 20° of hyperpronation)³⁰ are both helpful in better visualizing the scapholunate distance. A distance of 5 mm or more is diagnostic of SLD.

The lateral radiograph should be examined carefully for DISI. An increase in the scapholunate angle compared to the contralateral side or a unilateral scapholunate angle of 70° (normal range is 30–60°) usually indicates increased flexion or rotatory subluxation of the scaphoid. A DISI deformity is seen in advanced stages of SLD and may not be present in occult or predynamic SLD.

Often, advanced imaging is needed to confirm a suspected SLD. MRI is the advanced imaging of choice used by the authors. With newer 3 Tesla magnets, the sensitivity and specificity of detecting a SLD is 89% and 100%.³¹

Treatment

The treatment of SLD is based on the stage of the injury at the time of treatment. SLD is separated into six different stages which progress from occult scapholunate injury to SLAC. When determining the severity of the injury and subsequent treatment, there are five questions proposed by Garcia-Elias *et al.*³² that help the surgeon understand the pathology and provide a framework for treatment.

- 1 Is the dorsal scapholunate ligament intact?
- 2 Does the dorsal scapholunate ligament have enough tissue to repair?
- 3 Is the scaphoid posture normal?
- 4 Is any carpal malalignment reducible?
- 5 Is the cartilage on the radiocarpal and midcarpal surfaces normal?

Stage I SLD presents as an occult scapholunate injury with only a partial tear of the scapholunate ligament. The dorsal scapholunate ligament is usually intact. Many stage I SLD injuries are diagnosed late, but if they are diagnosed early they may benefit from non-operative treatment including casting, splinting, non-steroidal anti-inflammatory medications and therapy. Arthroscopic debridement and arthroscopic thermal shrinkage have also had reported success.³³ Also temporary scapholunate pinning has been advocated for treatment of occult tears.³⁴

Stage II SLD is characterized by dynamic instability, a complete tear of the scapholunate ligament and enough scapholunate tissue to repair. Patients typically have pain and instability under loading conditions. By definition, there is no fixed deformity. Patients are treated with open repair of the scapholunate ligament, which can be accomplished by a number of methods. Commonly, the scapholunate ligament tears off of the scaphoid and remains attached to the lunate. Direct repair can be done with suture using transosseous suture holes, bone tunnels or suture anchors. K-wires are helpful in reducing the scaphoid and lunate and temporary pinning or headless screw fixation of the scapholunate joint is often helpful.

Stage III SLD is characterized by a dynamic instability, complete tear and an irreparable scapholunate ligament. For a patient to be a candidate for the reconstructive surgeries required to address this problem, there must not be collapse of the carpal bones or degenerative changes. The modified Brunelli procedure has become a popular ligament reconstruction that has had some success,^{35,36} but the preservation of motion and the maintenance of alignment continue to be a problem. A technique called the reduction and association of the scaphoid and lunate (RASL) attempts to make a pseudarthrosis between the scaphoid and lunate.³⁷ There have been some positive short-term results, but no long-term results are available. Loosening of the screw and symptomatic hardware have been a problem with this technique.

The scaphoid will naturally fall into a flexed position, or a DISI deformity, when it is dissociated from the lunate. To counteract this flexion deformity of the scaphoid, a dorsal capsulodesis is performed. The traditional capsulodesis was performed by Nathan and Blatt³⁸ and is proximally based. There have been a number of modifications to the original Blatt technique,^{39,40} which theoretically will allow for more motion. A drawback of the Blatt dorsal capsulodesis is the common 20° loss of flexion.

Stage IV SLD is characterized by a complete tear of the scapholunate ligament, an irreparable ligament and a DISI deformity that is reducible. Rotatory subluxation with the scaphoid in flexion and the lunate in extension is the hallmark of stage IV. SLD with associated DISI deformity represents a severe acute injury, as seen in perilunate dislocation, or a chronic attritional process that has destroyed the secondary stabilizers of the scaphoid. If left untreated, these injuries will predictably progress to degenerative arthritis and SLAC. The progression to SLAC starts with degeneration of the radial styloid, progresses to the entire scaphoid fossa, and then begins to affect the midcarpal joint. However, the time course to SLAC is unpredictable and in many patients is very slow. Some patients will choose to be treated with splinting and activity modification instead of a ligament reconstruction which limits motion. Treatment of stage IV SLD is similar to stage III with the use of a modified Brunelli ligament reconstruction, RASL and/or dorsal capsulodesis.

Stage V SLD is characterized by a complete tear of the scapholunate ligament, an irreparable ligament and a fixed DISI

deformity. There have been a number of limited intercarpal fusions recommended for a symptomatic SLD with DISI deformity. However, few patients fall into this category since degenerative changes usually accompany symptomatic, fixed DISI deformities. There are limited trials or results that support the use of scaphoid-sparing intercarpal arthrodesis. Scapholunate arthrodesis has largely been abandoned because of the low fusion rate.

Stage VI SLD is represented by carpal collapse and degenerative arthritis. SLAC wrist is the term used to describe this deformity. Patients should first be given a trial of non-operative treatment consisting of activity modification, splinting, steroid injections and non-steroidal anti-inflammatory medications. If non-operative intervention fails, then surgery may be indicated. Radial styloidectomy, radioscapoid arthrodesis, scaphoid excision four-corner fusion and proximal row carpectomy have all been described for SLAC. If the midcarpal joint is involved in the arthritic process, then a proximal row carpectomy usually has poor results. Also if the lunate facet and midcarpal joint show degenerative changes, then a total wrist arthrodesis may be the best option for the patient.

Perilunate dislocation and fracture dislocation

Perilunate dislocations (PLDs) are a spectrum of injuries represented by the carpal bones dislocating around the lunate. These injuries start on the radial aspect of the wrist with a scapholunate ligament tear, then progress to the articulation between the lunate and the capitate. The spectrum of injury severity progresses with tearing of the lunotriquetral ligament, dislocation of the capitate from the lunate (usually the capitate migrates dorsally), then finally the lunate dislocates into the carpal canal and possibly rotates on its own axis. These injuries are often missed because they are rare and the X-ray findings are not often seen by general medical providers. PLD can be purely ligamentous as noted above, or can have associated fractures (usually the scaphoid). Lesser and greater arc injuries refer to PLDs that are purely ligamentous or associated with a fracture respectively.

Radiographic evaluation of a PLD starts with standard, high-quality images. A decrease in carpal height, disruption of Gilula's lines (Figure 62.4), increased distanced between carpal bones, and fractures of the carpal bones or distal radius may be seen on the PA radiograph. Ulnar migration of the carpus can also present with PLD since these injuries are such high energy and contain both intercarpal ligament and intracarpal ligament disruption (carpal instability complex). The lateral may show the capitate dislocated from the lunate or possibly the lunate dislocated volarly. MRI and CT scans are often helpful in diagnosing ligamentous injuries and the extent of carpal fractures, respectively.

Non-operative treatment of PLDs or fracture dislocations has been shown to have poor results and is not recommended.

Figure 62.4 Postero-anterior radiograph of a wrist showing the three Gilula's lines. The first line represents the smooth arc connecting the scaphoid, lunate and triquetrum of the proximal carpal row at the radiocarpal joint. The second line represents the smooth arc of the proximal carpal row at the midcarpal joint. The third line represents the smooth arc around the capitate and hamate of the distal carpal row. A break in any line may represent wrist pathology.

Urgent closed reduction to relieve pressure on the median nerve is the first line of treatment. The median nerve must be monitored for progressive symptoms of dysfunction. If closed reduction cannot be obtained, then open reduction in the operating room should be performed. Both dorsal and volar approaches have been described for treatment. The dorsal approach gives good access to the proximal carpal row and the midcarpal joint. The volar approach has the advantage of being able to decompress the carpal tunnel if needed and allows visualization with possible repair of the volar ligaments. Greater arc injuries with fractures of the scaphoid usually have an intact scapholunate ligament and a disruption of the lunotriquetral ligament. Open fixation of the scaphoid and repair of the lunotriquetral ligament has been shown to be a successful treatment strategy for these injuries.⁴¹ Whenever PLD are associated with fractures, most authors recommend fixation with headless compression or cannulated screws. K-wire stabilization

of ligamentous injuries are advocated by some, with or without augmentation by primary ligamentous repair. Intercarpal screws have been compared to K-wire stabilization of ligamentous injuries without significant difference in outcome, except for fewer pin site-related complications with intercarpal screws.

The outcome of PLD treated after a delay in diagnosis (around four weeks or more) is worse than that in those treated soon after injury. There is no surgical procedure that is recommended above another, but the surgical procedure chosen should provide adequate visualization, repair of ligamentous injuries and fixation of fractures. Primary repair of ligaments, suture anchor repair, K-wire stabilization or intercarpal screws are all accepted treatments of unstable ligamentous injuries.

Lunotriquetral dissociation

Lunotriquetral dissociation is an often missed tear of the ligament connecting the lunate and triquetrum. Lunotriquetral dissociation is usually caused by a fall backwards with an outstretched hand in supination and radial deviation. This position concentrates the force on the pisiform, which acts as a punch against the triquetrum. The resulting ulnar-sided wrist pain is often misdiagnosed as a TFCC tear. Lunotriquetral dissociation can also be part of a more severe perilunate dislocation injury.

Lunotriquetral dissociation is part of a category of wrist pathology called carpal instability dissociative (meaning dissociation between bones of the same carpal row) or CID. It follows a familiar pattern of wrist deformity, with the scaphoid and attached lunate rotating into flexion and the triquetrum rotating into extension. The deformity is called volar intercalated segmental instability (VISI). The lunate follows the scaphoid and rotates into flexion (opposite to DISI deformity).

Physical exam findings of lunotriquetral dissociation are often sensitive but not very specific. Pain in the ulnar side of the wrist can represent many different problems. Lunotriquetral ballottement and a triquetral shear test are often positive. Radiographic evaluation will often show a subtle disruption of Gilula's lines and a possible increased lunotriquetral distance. Dynamic radiographs with the wrist in ulnar and radial deviation can be helpful in showing the disruption between the lunate and triquetrum. At times the radiographs will be normal and MRI or arthroscopic evaluation of the ligamentous structures will show evidence of lunotriquetral ligament injury.

If non-operative treatment of an acute lunotriquetral dissociation is initiated, a long arm cast should be applied to inhibit wrist supination and pronation. Failure of non-operative management is not uncommon. The indications for surgical treatment of lunotriquetral dissociation are varied and not very clear. There are many ways to address lunotriquetral dissociation surgically, including arthroscopic debridement, ligament repair, capsulodesis, K-wire stabilization and arthrodesis. Lunotriquetral ligament injuries are often associated with other injuries that may need addressing at the time of surgery.

Figure 62.5 (a) Radiograph showing scapholunate widening. The patient had wrist pain, popping and decreased range of motion but chose to treat non-operatively. (b) Postero-anterior wrist X-ray 4 years later of the same patient. He now has severe pain even with rest. There are advanced degenerative changes at the radioscaphoid joint and significant degeneration at the capitulunate joint. The radiolunate articulation is spared. (c) A scaphoid excision and four-corner fusion was performed. The patient was able to return to work as a construction worker.

Scapholunate advanced collapse and scaphoid non-union advanced collapse

Scapholunate advanced collapse (SLAC) and SNAC are arthritic changes that take place in the wrist with a typical progression. They are both caused by trauma, but SLAC can also be caused by non-traumatic chronic changes of the wrist as seen in gout. Watson and Ballet demonstrated that wrist arthritis progressed in a predictable pattern.⁴² Stage I arthritic changes begin at the radial styloid and then progress to (stage II) the proximal radioscaphoid articulation. Arthritic changes next advance to the midcarpal joint between the capitate and the lunate (stage III). The lunate fossa rarely shows arthritic changes.

The diagnosis of SLAC and SNAC is made through history, physical exam and radiographs. The patient usually has a painful wrist with decreased range of motion. Radial-sided wrist pain predominates and dorsal wrist swelling is common. Bilateral radiographs are helpful for comparison. Staging the arthritic changes will help in determining treatment options.

Non-operative treatment will be beneficial for many patients. There are no studies delineating the natural history and many patients will have minimal symptoms for years. Symptomatic treatment with splints, non-steroidal anti-inflammatory medications and steroid injections is the first line of treatment. If a patient fails non-operative treatment and continues to have a painful, arthritic wrist, surgery is an option (Figure 62.5). Surgical options for SLAC and SNAC include partial wrist arthrodesis (scaphoid excision and four-corner fusion), complete wrist arthrodesis, proximal row carpectomy, denervation and radiostyloidectomy. SNAC can also be treated with excision of the distal scaphoid fragment. Traditional teaching states that a proximal row carpectomy should not be performed in patients with capitate arthritis. However, outcomes comparing scaphoid

excision four-corner fusion with proximal row carpectomy show similar results.^{43,44} Proximal row carpectomy has the added benefit of lower cost, no need for hardware, no need to wait for fusion and no extended postoperative immobilization. There has been some question about the lasting durability of proximal row carpectomy with younger patients (<35 years) and patients who are very active or manual labourers.^{45,46} Total wrist arthrodesis reliably relieves pain in the arthritic wrist but sacrifices wrist motion. Total wrist arthrodesis can be performed after a failed proximal row carpectomy or partial wrist fusion.

CHAPTER 63

Rheumatoid arthritis of the hand and wrist

Rebecca Ayers and Mark Pickford

Department of Plastic Surgery, Queen Victoria Hospital, East Grinstead, UK

Definition

Rheumatoid arthritis is a chronic inflammatory disease of synovial joints. It is characterized by a symmetrical polyarticular arthritis, typically affecting the wrist and small joints of the hand and feet. Inflammation progresses to joint destruction with pain, deformity and disability.

Non-articular manifestations include rheumatoid nodules, pulmonary fibrosis, renal amyloidosis, pericarditis, endocarditis, atherosclerosis, Felty's syndrome, keratoconjunctivitis sicca, haemolytic anaemia and generalized systemic symptoms such as malaise, anorexia, anaemia and weight loss. The course of rheumatoid arthritis is variable and unpredictable but premature mortality is well recognized.¹⁻³

The incidence of rheumatoid arthritis is generally quoted across European and North American literature as affecting 1% of the population. According to the 2009 National Institute of Health and Clinical Excellence (NICE) guidelines about 12 000 people are diagnosed with rheumatoid arthritis each year in the United Kingdom. Rheumatoid arthritis is two to four times more common in females than males, with a peak age of incidence in the seventh decade.⁴

Rheumatoid arthritis may have a significant social and economic impact on the people afflicted with this disease. According to NICE,⁴ approximately one third of people stop work within 2 years of diagnosis and total cost to the UK economy is £3.8 to £4.75 billion per year.

Diagnostic criteria

In 2010 the American College of Rheumatology (ACR) and the European League Against Rheumatism (EULAR)⁵ revised the classification schema for rheumatoid arthritis (Table 63.1). Diagnosis is confirmed by synovitis in at least one joint, not explained by another cause, and a total score of 6 or more (out of 10) in four domains: joint involvement, serology, acute phase reactants and duration of symptoms. A key aim was to

identify patients with rheumatoid arthritis early, especially those with persistent or erosive disease, and to commence early pharmaceutical intervention.⁶ Assessment may be repeated as symptoms progress.

The classification system is designed to identify new cases of rheumatoid arthritis but patients with erosions typical of rheumatoid arthritis on X-ray, or patients who historically fulfilled the criteria may, of course, still be diagnosed with rheumatoid arthritis.

Pathophysiology

The causes of rheumatoid arthritis are unknown and tremendously complex. Antigen-presenting cells (APCs) bind and present an as yet unknown arthritogenic antigen to T cells. The binding of co-stimulatory ligands, also on the APCs, such as CD80 and CD86, assist in activation of T cells. T cells, fibroblasts and macrophages secrete numerous proinflammatory cytokines, such as the interleukins IL-1 and IL-6 and tumour necrosis factor alpha (TNF- α). These recruit and activate neutrophils, lymphocytes, macrophages, synovial cells, fibroblasts and B cells. Inheritance of certain HLA-II loci may mediate antigen presentation, T-cell reactivity and likely other immune relationships.⁷

B cells differentiate into plasma cells that secrete antibodies and autoantibodies. This process is abetted by IL-6. Autoantibodies include those to immunoglobulin G (IgG) (rheumatoid factor, RF) and citrullinated peptides (anticitrullinated protein antibody, ACPA), among others. The autoantibodies form immune complexes that drive the secretion of proinflammatory cytokines, augmenting the inflammatory process. Activated B cells also act as APCs. In conjunction with cells of the innate and acquired immune system there are numerous other chemokines that guide and control this intricate process.⁸

The final stage in the pathogenesis is a swollen synovium full of macrophages, T cells, B cells, plasma cells and synovial fibroblasts. This synovial pannus then erodes cartilage, bone

Table 63.1 The 2010 American College of Rheumatology/European League Against Rheumatism classification criteria for rheumatoid arthritis

Patients with at least one joint with clinical synovitis, not explained by another disease	Score (out of 10)
A. Joint involvement	
1 large joint	0
2–10 large joints	1
1–3 small joints	2
4–10 small joints	3
>10 joints (at least one small joint)	5
B. Serology	
Negative RF and negative ACPA	0
Low positive RF or low positive ACPA	2
High positive RF or high positive ACPA	3
C. Acute phase reactants	
Normal CRP and normal ESR	0
Abnormal CRP or abnormal ESR	1
D. Duration of symptoms	
<6 weeks	0
≥6 weeks	1

RF, rheumatoid factor; ACPA, anti-citrullinated protein antibody; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate.

and supporting soft tissues, leading to joint destruction, deformity and pain. Synovial proliferation around tendons can cause tenosynovitis or tendon destruction and rupture. Joint destruction begins early and erosive changes may occur within months.

Rheumatoid nodules are typically cutaneous and contain a centre of fibrinoid necrosis surrounded by macrophages and fibroblasts and finally a cuff of connective tissue with lymphocytes and plasma cells. These nodules are typically found on areas of repeated mechanical stress or over bony prominences such as the olecranon, the calcaneum and the metacarpophalangeal (MCP) joints. Rheumatoid nodules are associated with more aggressive disease.

Due to a generalized dysfunction of the immune system rheumatoid arthritis patients have an increased susceptibility to infection.⁹

Management principles and operative options

Assessment and evaluation

A rheumatology referral should be made for any patient with a persistent and unexplained synovitis. This includes patients with normal inflammatory markers and those who are RF-negative. Referral should be expedited if the synovitis affects multiple joints, or if the duration of symptoms has been longer than three months. There is an urgency to diagnose rheumatoid arthritis; prompt treatment has been shown to reduce permanent joint damage.¹⁰

Rheumatoid arthritis should be managed by a multidisciplinary team, which may include a rheumatologist, occupational therapist, orthopaedic or plastic surgeon and other allied health professionals.

Box 63.1 Initial assessment of rheumatoid arthritis

- Clinical evaluation: joint synovitis and extra-articular manifestations
- Blood work: ESR, CRP, RF, ACPA, FBC, liver and renal biochemistry
- X-rays of hand and feet

Figure 63.1 Various rheumatoid deformities of the hand including a swan neck deformity of thumb, subluxation of the index MCP joint and generalized arthritic change throughout the hand and wrist. Note fusion of the DIP joint of the ring and the PIP joint of the little fingers.

General assessment

Assessment includes examination for joint synovitis and extra-articular manifestations (Box 63.1). Blood tests should include inflammatory markers such as erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP). Serology should include RF and ACPA, a positive ACPA being more specific for rheumatoid arthritis. Baseline full blood count (FBC), liver and renal biochemistry are useful for planning treatment. X-rays of hands (Figure 63.1) and feet are appraised for early bony erosions.

Radiological features

X-rays provide a record of the permanent damage of rheumatoid arthritis (Box 63.2). Changes include surface erosions, cystic changes, cortical thinning, osteoporosis and progressive joint narrowing through to frank ankylosis, subluxation and dislocation.

Box 63.2 Radiological features of rheumatoid arthritis

- Joint narrowing and destruction progressing to ankylosis
- Erosions
- Cortical thinning
- Osteoporosis
- Subluxation/dislocation
- Bony destruction (mutilans)

Box 63.3 Poor prognostic features on diagnosis of rheumatoid arthritis

- Positive RF or ACPA
- Early functional limitations
- Multiple swollen or tender joints
- Early bony erosions on X-ray
- Extra-articular manifestations
- High ESR or CRP

In mutilans arthropathy there is bony destruction, which may progress rapidly.

There are a number of radiological classification systems; the most well known are the Sharp and Larsen systems. They score radiographs of the hands, wrists and feet; the higher the score the more severe the bony destruction. The Sharp method scores bony erosions and joint space narrowing separately over 31 areas to give a score from 0 to 448. The Larsen method assesses 20 joints over the hands, wrists and feet, to give a score out of 100. The Larsen method is easier to utilize, but the Sharp method is more sensitive for detecting changes over time. The Sharp and Larsen assessments have significant correlation with each other¹¹ and with the extent of joint and cartilage destruction.¹²

MRI is increasingly used to detect pre-erosive synovitis, and early bone damage not seen on standard radiography. Fat-suppressed gadolinium-enhanced T1 weighted images will demonstrate pre-erosive synovitis, tenosynovitis and bony erosions. The presence of bone marrow oedema, seen on T2 weighted images, is also predictive of the development of bony erosions.¹³ Identification and treatment of subclinical synovitis and prevention of bony erosions are the aims of more aggressive medical management regimes.^{14,15}

Identifying patients with aggressive disease

One of the key goals of initial assessment is to identify those patients with signs that suggest an aggressive disease process (Box 63.3). These patients are monitored closely; a poor response to first-line medical treatment may warrant early use of biological therapies to gain early control of the disease.

Assessment of disease activity

People with newly diagnosed rheumatoid arthritis require regular assessment of disease activity until the disease is stable. Usually this consists of a monthly to tri-monthly review including CRP and a Disease Activity Score (DAS28). The DAS28 is a measure of disease activity in rheumatoid arthritis; an online

tool collates a clinical assessment of 28 specified joints, serum inflammatory markers and a visual analogue scale (0–10) of the patient's global function. A score greater than 5.1 indicates active disease and less than 3.2 indicates well-controlled disease. A score of less than 2.6 indicates remission. Alteration in the DAS28 can be used to assess response to treatment. Until the disease is well controlled, repeat radiography of the extremities is recommended every 6–12 months. Persistent erosive disease despite good symptom control may warrant a change in medication regime.¹⁶ Stable disease requires annual review.

Assessment of disability status and health status

Rheumatoid arthritis is a chronic illness and it is crucial to document both the disability and health status of each patient.

The most common measure of disability status is the Stanford Health Assessment Questionnaire Disability Index (HAQ-DI), which has eight categories covering dressing, arising, eating, walking, hygiene, reach, grip and activities. For each domain, a score of 0–1 represents mild to moderate disability, 1–2 moderate to severe disability and 2–3 severe to very severe disability.

Health status is frequently assessed via the Short Form 36 (SF-36). The SF-36 consists of eight sections covering vitality, physical functioning, bodily pain, general health, ability to perform social roles, ability to perform physical roles, ability to perform emotional roles, and mental health. Each of the eight sections are scored from 0–100, with 100 being normal health status.

Surgical options

The benefits of surgery include relief of pain, recovery of function and cosmetic improvement. Rheumatoid deformities are frequently multifactorial and they must be assessed within the context of the patient's rheumatoid pathology and global function. The decision to offer surgery requires evaluation of the surgical problem and functional limitations. There are general principles when creating a rheumatoid management plan; operate on the lower limb before the upper limb, operate proximally then distally, offer reliable procedures with the highest chance of success first. Souter presented his personal reflections on the relative merits of different rheumatoid hand procedures and felt the three most efficacious procedures were extensor synovectomy and excision of ulnar head, wrist stabilization and thumb MCP joint fusion.¹⁷ However critical analysis of the different surgical procedures is lacking across the literature. Randomized controlled trials comparing different surgical treatments are rare. There is also considerable discrepancy between the views of surgeons and rheumatologists so the benefits of managing rheumatoid patients within the confines of a multidisciplinary team are obvious.^{18,19}

Synovectomy and tenosynovectomy

Synovectomy is the excision of inflamed synovial tissue within a joint and tenosynovectomy implies removal of inflamed synovial tissue surrounding a tendon. The benefits and roles of

synovectomy and tenosynovectomy are quite different; refractory tenosynovitis benefits more clearly from surgical treatment.

Synovitis is increasingly managed by alteration of medications. Isolated synovitis may benefit from intra-articular steroid injection. Recalcitrant synovitis or incidental synovitis discovered during the course of a surgical procedure may be excised but there is no evidence that synovectomy alters disease course or reduces intra-articular cartilage destruction. It may provide temporary pain relief.^{20,21} Possible side effects include discomfort and postoperative stiffness.

Tenosynovitis may affect any tendon surrounded by synovium. Extensor tenosynovitis creates a swelling over the dorsum of the hand, extending beneath and restrained by the extensor retinaculum. The synovial pannus may cause tendon attrition and rupture. Extensor tenosynovectomy is recommended to prevent tendon rupture when synovitis persists for more than 3–6 months despite aggressive medical management. A dorsal longitudinal incision allows exposure of all extensor compartments. The extensor retinaculum is elevated from the sixth to second compartments, ulnar to radial; the tendons are examined for rupture and tenosynovectomy performed. The distal radioulnar (DRU) joint should be examined and treated (synovectomy/capsular repair/Darrach procedure) if required. The retinaculum may then be split in half transversely, with one half being placed beneath the tendons to provide protection from the DRU joint and the other used to reconstitute the extensor retinaculum and prevent bowstringing. Brumfield *et al.*²² reviewed 78 rheumatoid patients, with 102 dorsal wrist tenosynovectomies, intra-articular synovectomies and a Darrach (ulnar head) resection. With an average follow-up of 11 years pain was improved in 83% of wrists, with a 13° loss in wrist movement. Synovitis recurred in 16% of patients, subsequent tendon ruptures occurred in 5% of patients but radiologically the disease progressed unchecked. A total of 27 wrists required revision surgery including tendon transfers, partial and total wrist fusion and wrist arthroplasty.²²

There are three principal types of flexor tenosynovitis: isolated carpal tenosynovitis, palmodigital tenosynovitis and diffuse tenosynovitis. Synovial proliferation within the carpal tunnel may cause carpal tunnel syndrome. Wrist tenosynovectomy is performed through an extended carpal tunnel incision, preserving the palmar cutaneous branch of the median. Bony protrusions on the floor of the carpal tunnel should be smoothed.²³ Palmodigital tenosynovitis typically causes diffuse swelling, triggering and restriction of flexion, and may progress to rupture of flexor tendons due to erosive tenosynovitis. Again, if there is no improvement after three months of intensive medical treatment then tenosynovectomy is indicated. Palmar synovectomy requires broad exposure and may necessitate extension into the digits. Digital triggering may be improved by synovectomy, nodule excision and A1 pulley release. Flatt recommended release of the radial side of the A1 pulleys and cautioned against the release of multiple A1 pulleys, which may potentiate ulnar drift deformity. In this situation resection of the one slip of flexor digitorum superficialis (FDS) is preferred.²⁴

Wrist

The wrist is the major load-bearing joint of the hand and therefore pain or instability may cause significant impairment of upper limb function. Wrist involvement affects up to 50% of patients within 2 years of disease onset, increasing to 90% after 10 years;²⁵ wrist surgery is both common and beneficial to rheumatoid patients.

Pathogenesis of rheumatoid wrist disease

The wrist is inherently unstable and relies on an extensive collection of extrinsic and intrinsic ligaments to preserve stability between the forearm bones and carpus. Extrinsic ligaments extend from the radius and ulna to the carpus; palmar ligaments are stronger than dorsal ligaments. Intrinsic ligaments link the carpal bones only. The scapholunate and lunotriquetral ligaments secure the proximal carpal row and are key in maintaining the mechanics of force transmission through the wrist. Further stability is provided by the flexor and extensor retinaculi and the 23 extrinsic extensor and flexor tendons that surround the wrist. The triangular fibrocartilage (TFC) complex provides stability to the DRU joint. Normally 80% of load is transmitted through the capitate, scaphoid and lunate to the radius. Pathological weakening of ligaments distorts the biomechanics of the wrist, initially during loading and later at rest. Weakening of the important volar radiocarpal ligaments (radioscaphocapitate and radiolunotriquetral ligaments) contributes to ulnar translation and volar subluxation of the carpus. The ulna remains in its original position and becomes relatively prominent as the position of the carpus alters. This collection of signs is termed a caput ulnae deformity (Box 63.4). Bony destruction and intrinsic ligament failure, especially scapholunate ligament disintegration, leads to carpal dissociation and loss of carpal height. With ulnar translation of the carpus the metacarpals fall into radial deviation.

X-ray assessment of the rheumatoid wrist

Standard postero-anterior (PA) and lateral wrist X-rays should be assessed for features of rheumatoid arthritis and caput ulnae deformity. Two further aspects should be assessed: carpal height ratio and ulnar translation. The key features to document are:

- general features of rheumatoid arthritis (osteoporosis, erosion, diminished joint space);
- focal area of arthritis (radiocarpal joint, midcarpal joint);
- features of caput ulnae deformity;
- carpal height;

Box 63.4 Classic patterns of rheumatoid wrist deformity

- Caput ulnae deformity
- Ulnar translation and radial deviation of the carpus
- Palmar subluxation of carpus
- Supination of carpus
- Prominent ulnar head

- ulnar translation; and
- status of the DRU joint/ulnar head.

The carpal height ratio as described by McMurtry *et al.* is the distance from the third carpometacarpal (CMC) joint to the lunate fossa divided by the length of the third metacarpal. The average carpal height ratio is 0.53 (range 0.45–0.60).²⁶ Other methods of calculation are also available.

A rapid semi-quantitative measure of ulnar carpal translation can be made by assessing the position of the lunate relative to the radius; approximately 50% of the lunate should reside over the radius. A formal measure, described by Chamay and Della Santa, can be made by calculating the distance from the centre of the capitate head to the long axis of the ulna, divided by the length of the third metacarpal; the average is 0.3 (range 0.27–0.33).²⁷

Classifications of rheumatoid wrist disease

There have been several classification systems for rheumatoid arthritis of the wrist. The Larsen classification (1973) is a radiographic descriptive classification (Table 63.2).²⁸

The Wrightington classification (1989) is another radiographic classification system, designed to codify wrist pathology and guide treatment (Table 63.3). This scheme lacks the ability to anticipate the progression of wrist disease.²⁹

Simmen and Huber proposed an alternative classification system to try to predict the pattern of disease development (Table 63.4).³⁰ Identifying the broad progression of rheumatoid arthritis can be of assistance in planning surgical procedures, especially the type III patients who the authors felt should be followed closely and offered reliable stabilization of the wrist with the onset of ulnar translation or loss of carpal height.

Partial wrist arthrodesis

A partial wrist arthrodesis in rheumatoid arthritis may be performed for two reasons: isolated radiocarpal arthritis and ulnar translation. Options include radiolunate fusion and radioscapulolunate (RSL) fusion. The benefit of a partial arthrodesis is to preserve wrist movement at the midcarpal joint; most activities of daily living can be accomplished with a range of wrist movement from 5° flexion through 30° extension.³¹ Should it be necessary, subsequent conversion of partial arthrodesis to total arthrodesis is not technically difficult.³²

Chamay and Della Santa introduced radiolunate fusion in 1983 after it was observed that spontaneous ankylosis of the radiolunate joint prevented continued distortion of the wrist and preserved a reasonable range of movement.³³ Partial fusion may be combined with synovectomy and ulnar head resection. The radiolunate joint is denuded of remaining cartilage and the lunate is positioned in a neutral position of 10–15° flexion and secured with K-wires, screws, staples or plates. It is important to place the lunate in a neutral position to allow maximal extension of the wrist. Bone graft may or may not be used. Radiolunate fusion is one of the classic and reliable operations for rheumatoid wrist pathology; it provides pain relief and maintains wrist

Table 63.2 The Larsen classification for rheumatoid arthritis of the wrist

0	No changes
1	Soft tissue swelling, demineralization
2	Marginal erosions, radial deviation
3	Articular erosions. Joint space narrowing, mild radiocarpal instability
4a	Midcarpal ankylosis, major radiocarpal instability
4b	Radiocarpal ankylosis, stable
5a	Destruction of carpus, radiocarpal dislocation
5b	Destruction of carpus, complete ankylosis

Table 63.3 The Wrightington classification of rheumatoid wrist X-rays

Grade 1	Wrist architecture is preserved Peri-articular osteoporosis Early cyst formation Mild rotatory instability of scaphoid
Grade 2	Ulnar carpal translation Marked scaphoid flexion Radiolunate arthritis
Grade 3	Midcarpal arthritis Radioscaphoid arthritis Volar subluxation of the carpus on the radius
Grade 4	Significant loss of bone stock from distal radius

Table 63.4 Simmen's classification for rheumatoid arthritis of the wrist

Type I – Ankylosis	Spontaneous tendency to fuse Stable
Type II – Arthrosis	Articular loss and arthrosis (similar to osteoarthritis) Stable
Type III – Disintegration	Progressive destruction Loss of alignment Unstable

motion.³⁴ Linscheid *et al* reviewed 19 wrists, an average of 28 months postradiolunate fusion; the average wrist extension and flexion were 25° and 30°, respectively, and pain and grip strength were generally improved.³⁵ Progression of arthritis at the midcarpal joint may still occur; this may be due to alteration of carpal kinetics or disease progression.³⁶ Borisch and Haussmann retrospectively reviewed 91 wrists postradio-lunate fusion with a mean follow-up of 60 months. Radiolunate fusion was often accompanied by synovectomy, ulna head resection and division of the posterior interosseous nerve. Radiologically, ulnar translation was effectively reduced. Most patients were pain free and content with the overall result, despite disease progression in 37% of midcarpal joints. There was an 8% complication rate, comparable with other studies; this consisted mainly of problems with osteosynthesis, either displacement or malplacement of metalware or subsequent fractures. Of note the authors recommend that in wrists with a fixed carpal collapse, repositioning of the lunate and restoration of carpal height should not be attempted as this seemed to precipitate secondary arthrosis and cause midcarpal dislocation.³⁷

RSL arthrodesis is a less commonly performed operation, but may be appropriate for patients with extensive involvement of the radioscaphoid joint. Gordon and King reported the first RSL arthrodesis in 1961. Via a dorsal midline incision and through the fourth extensor compartment, the wrist joint is entered, preserving the dorsal wrist ligaments; the articular surfaces of the radius, scaphoid and lunate are denuded to cancellous bone and osteosynthesis performed with or without bone graft. RSL arthrodesis reduces pain and preserves some motion, however the incidence of serious complications is significant, including non-unions, subsequent scaphoid fractures and midcarpal arthritis,³⁸ probably a consequence of altered carpal kinematics. Distal scaphoid resection may improve postoperative wrist flexion-extension; McCombe *et al.* demonstrated an 86% increase in passive midcarpal motion in a cadaver model following distal scaphoid excision with RSL fusion.³⁹

Total wrist arthrodesis

Total wrist arthrodesis is a reliable option for patients with severe painful rheumatoid wrist destruction, flexion deformity secondary to extensor tendon rupture and as a salvage procedure following failed arthroplasty or partial wrist fusion. The radius, scaphoid, lunate, capitate and third CMC joint should be fused.⁴⁰ The suggested position of arthrodesis ranges from 0° to 30° extension, with or without a small amount of ulnar deviation. Reliable arthrodesis was established in the 1960s, when Hazewinkel *et al.* introduced wrist fusion with a Rush pin and bone graft⁴¹ and Clayton used a Steinmann pin.⁴² Mannerfelt *et al.* modified this with the addition of staples⁴³ and Benkeddache *et al.* used staples in isolation.⁴⁴ Internal fixation with an intramedullary nail through the third metacarpal is well known for being a fast and reliable method of fixation, especially in the presence of osteopenic bone; bone grafting is not essential.

In 1971 Meuli *et al.* introduced a nine-hole plate for wrist fusion;⁴⁵ Heim and Pfeffer used a 3.5 mm dynamic compression plate.⁴⁶ Currently a straight or precontoured limited contact dynamic compression plate, with 3.5 mm screws proximally and 2.7 mm screws distally is used. Plate fixation absolutely relies on decent bone stock, it is suitable for osteoarthritic wrists and seldom used in rheumatoid arthritis.

Solem *et al.* reviewed 42 wrist fusions, 34 for rheumatoid wrist disease, over a mean 10.5-year period.⁴⁷ There were 21 Mannerfelt fusions (Rush pin and staples) and 21 plate fusions. There were two non-unions in the Mannerfelt group. The mean position of the wrist following Mannerfelt and plate fusions was 0° and 8° of extension respectively ($p < 0.02$). There was no significant difference in key pinch, grip strength, pain in the wrist and patient satisfaction between the two methods of fusion, although scores in the plate fixation group were slightly better.⁴⁷

There is no clear consensus on the position of fusion in bilateral arthroplasty. Suggestions within the literature range from 10° extension of both wrists, neutral position both wrists

or 5–10° flexion of non-dominant wrist and a neutral position of dominant wrist.⁴⁸ Slight flexion does assist with some activities of daily living (e.g. perineal hygiene).

Total wrist arthroplasty

Total wrist arthroplasty (TWA) is an attractive option for rheumatoid patients with painful wrists, reasonable range of movement and well-preserved hand function. It is especially appealing in patients requiring surgery for bilateral wrist disease. Contraindications include an active rheumatoid arthritis flare, infections, high-demand patients, patients requiring the use of walking aids, poor hand function, poor bone stock or previous carpal resections and inadequate wrist control, especially poor wrist extension.⁴⁹ The surgeon should document the current disease activity, status of the skin and extensor tendons (especially extensor carpi radialis brevis), presence or absence of carpal tunnel syndrome and range of movement.

The first wrist replacement implant was designed by Swanson and consisted of a simple silicone spacer.⁵⁰ Despite similar implants being successful within the small joints of the hand, Swanson wrist replacements are no longer used due to a high rate of complications. Jolly *et al.* reviewed 23 Swanson wrist implants, an average of 72 months following surgery.⁵¹ Complications included implant fracture (58%), revision surgery (30%), radiographic changes consistent with particulate synovitis (30%) and prosthetic settling and bone resorption (75%).⁵¹

A number of wrist surface replacement arthroplasty implants have been introduced since Swanson's silicone spacer. The Menon prosthesis or Universal Wrist Implant was developed by Jay Menon in the 1980s. Titanium-stemmed prostheses are inserted into the radius and carpus, with a broad ellipsoid articulation between a contoured cobalt-chrome surface on the radial component and a polyethylene carpal component. Limited resection of the carpus and intercarpal fusion aids in prosthetic stability. Radial inclination and volar offset improve joint stability and wrist extension. The ulnar head may be retained or a Darrach procedure performed. The Universal-2™ Total Wrist Implant System is a later modification with reduced radial inclination and a porous coating to encourage osseous integration.⁵²

Kailash *et al.* reviewed 92 Universal-2 wrist replacements, 83 for rheumatoid wrist disease.⁵³ With a mean follow-up of 51 months, 91% of patients had satisfactory pain relief with 23° extension and 21° of flexion. Complications included joint stiffness (10%), wrist pain (9%) and superficial infection (2%). Almost 5% of patients required revision surgery and 3.5% needed salvage arthrodesis.⁵³ Salvage options for failed total wrist joint replacement include revision surgery or arthrodesis. Beer and Turner⁵⁴ followed 12 patients who underwent salvage arthrodesis after TWA using tricortical bone graft and an intramedullary Steinmann pin. Seven patients united and five had a painless pseudo-arthritis, with 17 complications in nine patients.⁵⁴

For patients with severe bilateral wrist involvement, wrist arthroplasty of the non-dominant wrist and fusion of the

Figure 63.2 (a) Antero-posterior view of wrist post Darrach procedure with marked degenerative change within carpus. (b) Lateral view of wrist demonstrating palmar subluxation of the carpus.

dominant wrist may confer a functional advantage. Vicar and Burton⁵⁵ noted that patients who had a wrist fusion on one side and a wrist arthroplasty on the other prefer the arthroplasty.

Distal radioulnar joint

The DRU joint is often affected early in rheumatoid arthritis. Caput ulnae syndrome is present in 25% of patients; the head of the ulna appears prominent due to carpal subluxation and supination plus DRU joint subluxation. Clinically this generates the piano key sign on examination: downward pressure on the head of the ulna temporarily relocates the ulnar head. DRU joint arthritis occurs in 31–75% of patients and causes pain on pronosupination and compression of the distal forearm.

Ulnar head prominence and associated tenosynovitis can cause tendon attrition and rupture (typically EDM is affected first). Surgical treatment requires synovectomy and either stabilization or excision of the ulnar head.

Ulnar head resection, as described by Darrach in 1912, has good results in the majority of low-demand rheumatoid patients (Figure 63.2). It is easily combined with other procedures on the dorsum of the wrist, such as synovectomy, partial or total wrist arthrodesis and TWA. The surgical approach is dorsal via the fifth compartment, preserving the ECU subsheath of the sixth

compartment. There is minimal bone resection, just proximal to the sigmoid notch; this preserves the attachments of the pronator quadratus, which acts as a dynamic stabilizer. There is no evidence that surgical stabilization of the stump with part of pronator quadratus muscle or flexor carpi ulnaris or extensor carpi ulnaris tendons improves results.⁵⁶ Ulnar carpal translation is not a complication of ulnar head resection.⁵⁷ Thirupathi *et al.* reported that 95% of patients had excellent pain relief.⁵⁸

Rasker *et al.* followed 40 patients with rheumatoid arthritis who had a Darrach procedure.⁵⁹ After 35 months, 38 patients had complete or almost complete resolution of pain. Functional use, supination, pronation and strength all improved.⁵⁹ It is clear this symptomatic benefit applies to rheumatoid patients rather than patients with posttraumatic DRU joint pathology. Fraser *et al.* reviewed patients following resection of the distal ulna for rheumatoid and posttraumatic conditions.⁶⁰ Although 83% of rheumatoid patients were pain free, only 36% of patients with posttraumatic DRU joint problems had similar benefit.⁶⁰

The Sauvé–Kapandji procedure involves DRU joint arthrodesis and segmental resection of the ulna.⁶¹ It is seldom indicated in rheumatoid arthritis. Via a dorsal incision, the DRU joint is exposed, cartilage removed and an arthrodesis is performed with compression screws or K-wires. The ulnar head is placed in

a position of neutral or slight ulnar negative variance. A narrow segment of ulna is removed just proximal to the arthrodesis site to create a psuedoarthrosis. Complications include radioulnar impingement, non-union, tendon rupture and union of the ulna.

Ulna head arthroplasty is a recent option for rheumatoid DRU joint pathology although it is mainly used in osteoarthritis; there are hemi or total ulnar head implants available. Currently it is mainly used as a salvage procedure for failed distal ulna resection or Sauvé–Kapandji procedures, but its indications may expand with time. The benefits of arthroplasty include improved stability of the forearm axis and prevention of impingement. The contraindications to ulna head arthroplasty include poor bone stock, infection, advanced joint destruction and significant instability of the DRU joint. The surgical approach is similar to that for a Darrach or Sauvé–Kapandji; there is careful preservation of the soft tissue stabilizers such as the DRU joint ligaments, ECU and dorsal capsule. A cutting guide marks the amount of ulna resection and after broaching the canal the implant is placed. Sometimes the sigmoid notch is deepened to facilitate stability of the DRU joint. The soft tissues are carefully repaired to provide support.⁶² Berger and Cooney used the Avanta U-Head prosthesis in 22 patients, including some with rheumatoid arthritis and followed them for 2 years.⁶³ Clinical results were good to excellent in 18 of 22 patients. Two patients were successfully revised after prosthetic loosening.⁶³

Digital extensor deficiency

Loss of digit extension is a common problem in rheumatoid arthritis and has a number of possible causes: extensor tendon rupture, posterior interosseous nerve (PIN) palsy, subluxation of extensor tendons or volar subluxation of metacarpal heads (Box 63.5).

Extensor tendon rupture always occurs at the wrist and is due to tendon attrition by proliferative synovium. Vaughan-Jackson first described sequential rupture of digital extensor tendons at the level of the DRU joint. Usually the extensor digiti minimi (EDM) tendon ruptures first, followed by other digital and wrist extensors. Surgery has a reparative and prophylactic role and involves tenosynovectomy and surgical treatment of the ulnar head/DRU joint plus tendon repair or transfer as required.

Due to gradual attrition and retraction of tendon ends, direct repair is usually not feasible. For isolated ruptures an end-to-side transfer or intercalated grafting are options. Multiple ruptures require intercalated grafts or tendon transfers of extensor indicis proprius (EIP) or adjacent EDC tendons (Table 63.5). If all the digital extensors are ruptured then an FDS transfer is required.⁶⁴ The FDS tendons to the third and fourth digits are transferred through the interosseous membrane or around the side of the radius and into the digital extensors.⁶⁵ Interposition tendon grafts can be used with reasonable results in recent ruptures;⁶⁶ excursion of greater than 2 cm of the proximal musculo-tendon unit is required for this to be a feasible option.⁶⁷ Results are always best in patients who maintain good wrist mobility.

Rupture of the extensor pollicis longus (EPL) tendon on Lister's tubercle is common, but the functional deficit depends

Box 63.5 Possible causes of loss of digital extension

- Extensor tendon rupture
- PIN palsy
- Subluxation of extensor tendons
- Volar subluxation of metacarpal heads

Table 63.5 Suggested extensor tendon transfers

Ruptured tendon	Transfer
EPL	EIP to EPL
EDM	Tenosynovectomy and treatment DRU joint
EDM & EDC 5	EIP to EDC 5 or EPL to EDC 5 or EDC 5 to EDC 4
EDM & EDC 4 & 5	EIP to EDM, EDC 4 to EDC 3
EDM & EDC 3–5	EIP to EDM & EDC 4, EDC3 to EDC 2
Multiple EDC, EDM & EIP	FDS 4 to EDM & EDC4, FDS 3 to EDC 2 & 3 & EIP
Thumb & all fingers	FDS 4 to EDC 3–5, FDS 3 to EPL & EIP

on the function of the extensor pollicis brevis (EPB) and the interphalangeal joint. Often EPB and the intrinsic thumb muscles are too weak to fully extend the MCP joint and this causes difficulties with opening the hand for grasp. The treatment of choice is EIP transfer, however with multiple extensor ruptures the EIP may be needed to reconstruct digital extension and so other options need to be considered. An interposition tendon graft may be used for fresh ruptures with sufficient excursion of the proximal musculo-tendon unit.⁶⁸ EPL to EPB transfer provides simultaneous extension of the interphalangeal and MCP joints and the functional limitations are minimal.⁶⁹

Extension of digits is achieved by combined action of the EDC tendons and sagittal bands; sagittal bands are crucial for maintaining the position of the extensor tendons over the metacarpal heads. Radial sagittal band attenuation or rupture causes rheumatoid digits to move into a position of ulnar drift. A zigzag deformity of the wrist and digits is common as rheumatoid arthritis progresses; the metacarpals fall into radial deviation and the digits into ulnar deviation.⁷⁰ Subluxation of extensor tendons between the heads of the metacarpals ultimately causes them to behave as MCP joint flexors.

Extensor tendon subluxation requires rebalancing of the extensor tendons. The extensor hood is opened to allow access to the joint and for synovectomy, the radial sagittal band is then imbricated to centralize the extensor tendon over the head of the metacarpal. A crossed intrinsic transfer may be performed; the tight ulnar lateral band is transferred to the adjacent radial lateral band or MCP joint collateral ligament.⁷¹

Flexor tendon rupture

Flexor tendon rupture is also due to synovial infiltration and attrition and may occur within the wrist, palm or digits. The Mannerfelt lesion is a rupture of the flexor pollicis longus

(FPL) tendon at the wrist and is frequently followed by ruptures of the long digital flexors.⁷² Surgical treatment involves an extended carpal tunnel exposure, synovectomy and debridement of bony prominences. The tendon ruptures are reconstructed on an individual basis and after consultation with the patient. An isolated rupture of the FPL may be treated by interphalangeal joint fusion, tendon graft or FDS transfer. FDP ruptures may be treated with distal interphalangeal (DIP) joint fusion, formal tendon reconstruction or side-to-side transfer. Isolated FDS ruptures may be left untreated and used as tendon grafts.⁷³

Ertel *et al.* reviewed 115 flexor tendon ruptures in 36 rheumatoid patients; 80% of ruptures occurred at the wrist, 17% within the digits and 3% within the palm.⁷⁴ At the wrist level 67% of ruptures were due to attrition on bony spurs and 34% were due to infiltrative tenosynovitis, whereas all ruptures within the palm and digits were due to infiltrative tenosynovitis. Although active motion was achieved in 88% of tendon reconstructions, the average motion was poor; average movement was 23° at the thumb interphalangeal joint and 55° at the digital PIP joints. Isolated ruptures within the palm or wrist had the best results. The authors highlighted the importance of early surgery, if only to debride tenosynovium and bony spurs that may cause further ruptures.⁷⁴

Rheumatoid digital joint replacements

The classic end-stage MCP joint deformity is one of flexion, ulnar deviation and subluxation or dislocation. Proliferative synovitis attenuates or destroys supporting capsuloligamentous structures around the joint. Proximal deformities, such as carpal translation and radial deviation of the metacarpals plus the relatively ulnar pull of long flexor and extensor tendons and the intrinsic musculature all contribute to the ulnar drift. The established surgical practice has been to offer MCP joint arthroplasty only when function is severely limited. Recently the benefits of pain relief and cosmetic improvement, as well as range of movement has altered the indications for MCP joint arthroplasty.⁷⁵ Indications include pain, a significant extensor lag, ulnar deviation or functional impairment, although some patients with advanced changes may remain pain free and function well. These patients may still consider surgery for cosmesis but should be warned that function may not be improved and grip strength may be weakened.⁷⁶ Correction of proximal wrist deformities and extensor tendon ruptures should be performed prior to arthroplasty.

Silicone interposition implants are still the preferred choice due to their intrinsic stability and durability. Swanson's implants encapsulate in scar like all implants; they are not fixed to bone, a fact that almost certainly contributes to their long-term survival.⁷⁷ Encapsulation may mean that implant failure does not necessitate revision of the arthroplasty but implant failure may be associated with increased ulnar drift and poorer outcome.⁷⁸ Pain relief is good but the subsequent range of motion, of about 40°, is not significantly changed. Improvement in extension allows the MCP joint to function

in a more useful arc and facilitates opening of the hand for grasp.⁷⁹ Complications include recurrence of deformity, implant failure, implant dislocation, osteolysis, instability, stiffness and silicone synovitis.⁸⁰

Rothwell *et al.* confirmed significant improvement in hand function following silicone arthroplasty; benefits were maintained for at least 3–4 years following surgery.⁸¹ Chung *et al.* prospectively followed 16 patients following Swanson MCP joint arthroplasty.⁷⁵ At 6 and 12 months functional measures such as grip and pinch strength were unchanged but significant improvements in subjective hand function, activities of daily living, pain, aesthetics and patient satisfaction were reported. Ulnar drift significantly improved too (mean 24°). The arc of motion (mean 46°) was unchanged. The initial benefits of arthroplasty diminish with time. Goldfarb and Stern assessed long-term follow-up of 208 silicone MCP joints arthroplasties over a mean of 14 years.⁷⁸ The mean arc of movement improved from 30° preoperatively to 46° postoperatively but this decreased to 36° at final follow-up. The MCP joints were placed in a better position for grip with improved extension lag; preoperative extension lag was 57°, postoperative extension lag was 11° but this decreased to 23° at final follow-up. Initial improvement in ulnar drift was not maintained. Implant fractures were reported in 63% of arthroplasties and were associated with increased ulnar drift. Only 27% of patients were pain free at the time of final follow-up. Different silicone implants may have different longevity and outcome measures. Sutter implants used a modified design and had a 45% failure rate by 3 years.⁸² Analysis demonstrated that the stress of flexion was concentrated, rather than distributed diffusely as with a Swanson implant, resulting in a high rate of implant failure at the central portion of the hinge.⁸³

A newer option is surface replacement arthroplasty. The indications for these implants are as above but their use is typically contraindicated by inadequate soft tissue stabilizers and poor bone stock.⁸⁴ Cook *et al.* followed 71 pyrolytic carbon unrestrained MCP joint arthroplasties for a mean of 11 years in 26 patients, 19 with rheumatoid arthritis.⁸⁵ The replacements were all used in patients with minimal deformity of the MCP joint. At follow-up, 94% of implants were in a reduced position, with an improved range of motion and 13–16° reduction in extensor lag. There was no change in ulnar deviation. The 10-year implant survival rate was 81%.⁸⁵ Pyrocarbon arthroplasty is a suitable and wear-resistant implant for mild MCP joint deformity in patients complaining of pain.

Flexible silicone implant arthroplasty can also be performed at the PIP joint. Ashworth *et al.* followed 99 Swanson PIP joint replacements. After an average 5.8 year follow-up 67% of patients were pain free. The average postoperative arc of motion was 29°, which was less than the preoperative arc of motion of 38°, and 19% of the implants required revision at 9 years.⁸⁶ Surface replacement arthroplasty for the PIP joint of rheumatoid patients is rare and typically contraindicated due to instability.^{87,88} Murray *et al.* reviewed 67 prostheses in 47 patients with a mean follow-up of 8.8 years.⁸⁹ Seventy-five per cent of patients

Figure 63.3 (a) Swan neck deformity of index finger. (b) Boutonnière deformity of the thumb.

had osteoarthritis and 25% rheumatoid arthritis. The average range of movement was 40°. There was a 15% failure rate by 15 years, and there were 22 complications requiring four PIP joint fusions and two amputations. The failure rate was not different in osteoarthritis and rheumatoid patients.⁸⁹ The alternative and reliable option is fusion of the PIP joint.

Rheumatoid digital deformities

The two classical digital deformities are boutonnière deformity and swan neck deformity (Figure 63.3). In established rheumatoid arthritis the approximate incidence of boutonnière deformity is 36% and swan neck deformity 14%.⁹⁰ Both conditions have PIP joint deformity due to rheumatoid synovitis but the mechanical aetiology is quite different. Deformities may be classified as fully correctable, partially correctable or fixed. Surgery for rheumatoid digital deformities usually occurs towards the end of the rheumatoid treatment sequence.

Boutonnière deformity is characterized by flexion of the PIP joint and hyperextension of the DIP joint. The primary pathology is synovitis of the PIP joint leading to attenuation or rupture of the central slip insertion, and with time, volar subluxation of the lateral bands; the latter then act to flex the PIP joint and hyperextend the DIP joint. Secondary contracture of the accessory collateral ligaments, transverse retinacular ligaments, oblique retinacular ligament and volar plate creates a fixed deformity. Although patients often dislike the appearance of boutonnière deformity, PIP joint flexion and grasp are not usually compromised.

Formal boutonnière deformity repair is often disappointing and surgeons should not swap a bent digit for a stiff and extended digit. A fully correctable boutonnière deformity usually has an extensor lag of less than 15° and is best treated with splintage. The PIP joint is held straight in the splint and flexion of the DIP joint is encouraged to allow lateral band glide. If the DIP joint cannot be flexed with the PIP joint in neutral then an extensor tenotomy (Fowler tenotomy) may be required; this divides the terminal extensor tendon over the mid portion of the middle phalanx, while preserving the oblique retinacular

ligament (ORL) to enable extension. A partly correctable boutonnière deformity usually has an extensor deficit of 30–40°. Splintage is used initially to convert the partly correctable deformity back to a flexible deformity; extensor tendon reconstruction may then be attempted.

There are a number of methods of extensor reconstruction available, including plication of the central slip and using a distally based FDS slip passed through the middle phalangeal base and woven into the extensor over the proximal phalanx.⁹¹ A fixed boutonnière deformity may require fusion in an improved position.⁹² If X-rays show PIP joint destruction, arthrodesis is usually recommended.⁹³ Kiefhaber and Strickland performed 21 reconstructions for rheumatoid boutonnière deformities. Tendon reconstructions included either reefing of the central slip, coaptation of the lateral bands, use of a free tendon graft, a Matev procedure or flexor digitorum sublimis transfer.⁹⁴ At a mean follow-up of 2 years the results of were variable and unpredictable; the mean final extensor deficit was 39° and the average loss of flexion was 12°.⁹⁵

Swan neck deformity is characterized by hyperextension of the PIP joint and flexion of the DIP joint. Although the hyperextension of the PIP joint is the most obvious clinical finding, the primary pathology may occur at the MCP, PIP or DIP joints. Determining which joint is responsible for the swan neck deformity guides treatment. Secondary contracture of intrinsic muscles may also contribute to the deformity. Swan neck deformity causes difficulty in initiating grasp and can prove a functional problem for patients.

Treatment of swan neck deformity depends on the joint pathology that initiates the deformity (Table 63.6). As with other rheumatoid conditions it is important to treat proximal deformities first. Correctable swan neck deformity requires treatment of the abnormal anatomy. Thus MCP joint dislocation or ulnar subluxation of tendons should be corrected and tight intrinsic muscles should be released. At the PIP joint a palmar restraint to prevent hyperextension may be achieved by either FDS tenodesis or a lateral band transfer. FDS tenodesis involves division of the radial slip of FDS proximal to the A1 pulley, which is then

Table 63.6 Summary treatment guide for swan neck deformity

	Fully correctable	Partially correctable	Fixed
MCP joint	Correction ulnar deviation Arthroplasty and/or Soft tissue correction	Soft tissue release and Arthroplasty and/or Intrinsic release	As for partially correctable
PIP joint	FDS tenodesis or Lateral band transfer	Soft tissue release and FDS tenodesis or Lateral band transfer	Arthrodesis or arthroplasty
DIP joint	Arthrodesis	Arthrodesis	Arthrodesis

secured to the proximal phalanx or to the A1 or A2 pulley,⁹⁶ keeping the PIP joint in 20° of flexion and preventing hyperextension. The other option is a lateral band transfer as described by Zancolli; the lateral band is mobilized from the midpoint of the proximal phalanx to the midpoint of the middle phalanx, the flexor sheath is opened between the A2 and A4 pulleys and the radial lateral band is translocated palmarward around a sling created between the FDS tendon slip and palmar plate.⁹⁷ Lateral band transfer has the benefit of correcting both PIP joint hyperextension and DIP flexion. Tonkin *et al.* performed lateral band transfer in 30 digits with swan neck deformity, the majority of patients having rheumatoid arthritis.⁹⁸ Mean preoperative hyperextension of 16° was corrected to a mean flexion contracture of 11°; all deformities were corrected with no recurrences or complications.⁹⁸ Deformities that are not passively correctable may imply contracture of soft tissues around the joint, which require release before surgical correction of the primary deformity may be performed. This typically involves release of the dorsally subluxed lateral bands off the central slip and dorsal capsulectomy or capsulotomy.⁹³ Absence of movement may indicate articular damage, which requires either arthrodesis or arthroplasty.

Rheumatoid thumb deformities

The thumb is commonly involved in rheumatoid arthritis; 60–80% of patients are affected.⁹⁹

Nalebuff developed a classification system for the rheumatoid thumb by identifying the joint primarily responsible for deformity (Table 63.7).^{100,101} In type I (boutonnière deformity) the primary pathology is synovitis at the MCP joint with attenuation of the EPB insertion and subluxation of the EPL ulnarly. Extensor force concentrates on the interphalangeal joint, causing hyperextension. It is the most common thumb deformity.¹⁰²

In type II thumbs, a boutonnière deformity is also present but originates due to pathology at the CMC joint. In a type III thumb (swan neck deformity) the problem originates with synovitis at the CMC joint, causing dorsal and radial subluxation of the metacarpal base, adduction of the first metacarpal, narrowing of the first web and reciprocal MCP joint hyperextension and interphalangeal joint flexion. Belt *et al.* evaluated X-rays over a 20-year period and found that 81% of rheumatoid

Table 63.7 Nalebuff classification of rheumatoid thumb deformity¹⁰⁰

I	Boutonnière deformity
II	Boutonnière deformity with CMC joint involvement
III	Swan deformity
IV	Gamekeeper's thumb
V	Swan neck deformity due to MCP joint involvement
VI	Arthritis mutilans

patients with greater than 4 mm CMC joint subluxation developed swan neck deformity of the thumb.¹⁰³

In a type IV thumb (gamekeeper deformity) attenuation of the ulnar collateral ligament creates lateral instability of the MCP joint. Type V deformity is a swan neck deformity due to volar plate laxity at the MCP joint with a normal CMC joint. Type VI deformity is arthritis mutilans with extensive bony resorption.¹⁰⁴

Although the Nalebuff classification provides a mechanical explanation for the zigzag deformities found in rheumatoid thumbs, it is the two concepts of boutonnière deformity and swan neck deformity that are of value to surgeons.

A boutonnière deformity classically requires treatment at the MCP joint and occasionally at the interphalangeal joint. Terrono *et al.* followed 53 rheumatoid patients with boutonnière deformities of the thumb over 7 years. The authors classified type I deformities into early, moderate and advanced to aid assessment and treatment. Early deformities had fully correctable MCP and interphalangeal joints; treatment was MCP joint synovectomy and EPL–EPB rerouting, as described by Nalebuff.¹⁰³ In moderate deformities the MCP joint was destroyed and fixed but the interphalangeal joint was correctable; surgical options were MCP joint arthroplasty or arthrodesis. Advanced deformities were fixed at both joints, which were radiologically destroyed and both joints required treatment; options included MCP joint arthroplasty or fusion and interphalangeal joint release or fusion. For moderate deformities MCP joint arthrodesis provided a high degree of satisfaction (4.7/5), and a pinch-strength of 6 pounds (2.7 kg); 13% had subsequent interphalangeal joint collapse. MCP joint arthroplasty patients experienced a lower satisfaction rate (4.1/5), and a 3.5 pound (1.6 kg) pinch-strength; 23% subsequently had interphalangeal joint collapse. In advanced cases 85% of interphalangeal joint releases failed. Combined MCP joint and interphalangeal joint fusion were recommended for high-demand patients and MCP joint arthroplasty and interphalangeal joint fusion for low-demand patients.

EPL rerouting can be performed with numerous variations. Nalebuff's original description divides the EPL just distal to the MCP joint and attaches it either into the dorsal capsule of the MCP joint or to the proximal phalanx, EPL then extends the MCP joint. The EPB is reattached to the EPL and extension of the interphalangeal joint is performed by the intrinsic muscles via the lateral bands.¹⁰⁴ Another option is EPB-plasty: the thinned or ruptured EPB is dissected free from the extensor hood and reattached to the proximal phalanx. The extensor hood is plicated over the tendon

repair.¹⁰⁵ Both procedures required immobilization of the MCP joint for 4–6 weeks postoperatively.

MCP joint arthroplasty is performed through a sinusoidal incision with capsulotomy between EPB and EPL. A minimal amount of bone is resected, preserving the collateral ligaments. The largest silicone implant that fits is inserted, capsular structures are repaired and the attenuated EPB and EPL are restored to their anatomical position.¹⁰⁶ Average range of movement is about 25°, with an improved flexion arc of 15–40°.¹⁰⁷ Complications include implant failure and instability. Arthroplasty is not suitable for high-demand patients or patients with gross instability around the MCP joint. Conversion to arthrodesis may require bone graft.

Arthrodesis of the MCP joint is a reliable procedure for disorders of the rheumatoid thumb, especially if CMC or interphalangeal joints are intact. The position of fusion is usually 15° flexion, 5° abduction and 20° pronation.¹⁰¹ Fusion rates range from 80 to 100%. Bone grafting may be required, particularly for arthritis mutilans.

Surgical treatment of swan neck deformity usually involves trapeziectomy to position the thumb better; ligament reconstruction and tendon interposition as described by Burton and Pellegrini¹⁰⁸ is optional. Persistent hyperextension of the MCP joint may warrant sesamoid arthrodesis¹⁰⁹ or fusion depending on X-ray appearances. Very occasionally, restriction of the first web may require deepening or release.¹¹⁰ Arthrodesis of the CMC joint is not recommended.

Fortunately, rheumatoid arthritis does not usually affect all three thumb joints to the same degree. Soft tissue procedures often do not provide long-term correction but may be performed cognizant that further surgery may be required. When more than one joint is affected it is best to preserve mobility in as many joints as possible: arthroplasty is preferable at the CMC joint, the MCP joint may have either arthroplasty or arthrodesis, depending on patient demand, and the interphalangeal joint is usually fused.¹¹¹

CHAPTER 64

Lesions of the hand

Richard D. Lawson, David A. Stewart and Michael A. Tonkin

Department of Hand Surgery & Peripheral Nerve Surgery, Sydney Medical School, University of Sydney, Royal North Shore Hospital, St Leonards, Australia

Introduction

Hand tumours represent a substantial proportion of the workload for hand surgeons. Most tumours are benign and arise from soft tissues. Ganglions, giant cell tumours of tendon sheath and inclusion dermoids make up the bulk of soft tissue lesions seen within the hand, whereas malignant tumours are much less common. Bone tumours are seen less often than soft tissue lesions; the vast majority are benign and of these enchondromas predominate. Primary malignant bone tumours are extremely rare within the hand. Metastases occur and most frequently involve the terminal phalanges.

Despite the relative rarity of malignant lesions, the surgeon must remain alert and keep the possibility of malignancy in mind whenever dealing with any hand tumour, as this diminishes the chance of missing or mistreating a malignancy. The principles of management of malignant tumours, including appropriate staging and biopsy, have been well described and must be conscientiously adhered to.

Approach

It is necessary to ask about the duration and progression of symptoms (slow-growing lesions are more likely to be benign, rapid growth implies a higher chance of malignancy), the presence of pain, particularly night pain, and response to medication (osteoid osteomas are said to respond readily to aspirin) and symptoms of neurological dysfunction. Systemic features such as unexplained weight loss and respiratory symptoms should always be sought.

Physical examination should include: site and size of the lesion (lesions greater than 5 cm in diameter are more suspicious for malignancy;¹ consistency; colour; an attempt to define the tissue level of the lesion (e.g. skin, subcutaneous tissues, deep to tendon); fixity to surrounding structures such as bone or tendon; range of motion of the adjacent joints (e.g. dorsal wrist ganglions often impair dorsiflexion); the presence of nerve or vascular dysfunction distal to the lesion; the presence of a

Tinel's sign on tapping upon the lesion; and an examination of draining lymph nodes (epitrochlear and axillary).

Investigation

Plain radiographs

A plain radiograph of the hand is the starting point for investigation of bone tumours. Considerable information about the biology and behaviour of the tumour can be obtained from the margin between bone and tumour and the reaction of periosteum.

If there is a very clear, distinct margin between the tumour and the bone this is described as 'a well defined zone of transition'. This implies a slow-growing, usually benign lesion where the host bone has time to respond to the lesion. This kind of margin is typically seen in enchondromas. If the margin is indistinct the lesion can be described as permeative and this implies a more rapidly growing and potentially sinister lesion.

A periosteal reaction is a worrisome feature and implies infection or an osteosarcoma. Speckling of the interior of the tumour, known as matrix calcification, implies a cartilaginous tumour.

CT scan

CT scans are helpful in assessing complex regions of the upper limb, particularly the carpal bones, where plain radiographs may be difficult to interpret. They can also be useful in searching for the nidus that characterizes an osteoid osteoma, and defining the relationship of the cortex of a tumour and the adjacent normal cortex, which is beneficial in distinguishing between an osteochondroma and less common surface lesions such as juxta-cortical chondromas and Nora's disease.

Ultrasound and MRI

Soft tissue tumours are best imaged with ultrasound, if a skilled technician and radiologist are available, and/or MRI. The principal use of an ultrasound is in distinguishing between solid and cystic lesions, especially in confirming the presence of a ganglion. Dynamic imaging is possible with ultrasound and the

capacity to evaluate blood flow is particularly helpful in the evaluation of glomus tumours.

An MRI provides excellent definition of soft tissue lesions and is useful in determining the anatomical location of the lesion and involvement of surrounding structures. It is mandatory in the setting of suspected malignancy. An MRI must be performed prior to a formal biopsy as the soft tissue planes will be disturbed by the surgical procedure and interpretation of the images will be adversely affected. It is good practice to notify the radiologist about any concerns regarding the potential for malignancy because an infusion of gadolinium will often be necessary; if this is not done initially the patient may need to be recalled for further imaging.

Blood tests

A full blood count and serum electrophoresis (EPG) should be performed when malignancy is suspected to assess for leukaemia and myeloma. Calcium, phosphate, urea, electrolytes and creatinine and liver function tests should also be checked in suspicious cases.

Biopsy

Many lesions of the hand are treated with excisional biopsy; for example suspected ganglions, giant cell tumours and small lipomas are usually definitively treated with excision through the reactive zone immediately surrounding the tumour. For lesions where there is a suspicion of malignancy an incisional biopsy is performed as the first stage of treatment, followed by definitive surgery when the tumour has been characterized.

The principles of incisional biopsy must be considered in all cases:

- Perform appropriate local imaging prior to surgery.
- Use a tourniquet and exsanguinate by prolonged elevation, rather than an Esmarch bandage as there is a theoretical risk of proximal seeding.
- Site the incision to allow inclusion in any subsequent definitive surgery.
- Use a longitudinal incision.
- Confine the incision to one compartment, avoid spreading with scissors and contamination of surrounding tissues.
- Obtain a substantial amount of material for analysis; include the periphery of the tumour as the centre of the tumour may contain only necrotic material.
- Infection must always be considered and swabs and specimens for microbiology should be taken as a routine.
- Employ exacting haemostasis and try to avoid use of a drain; if one is necessary it should exit in the line of the incision, close to the incision and ideally distal to the incision.

It is always prudent to approach the lesion with the question 'If this turns out to be malignant, will the current operation compromise any future operation?' Ideally, an incisional biopsy should be performed by the surgeon who will go on to definitively manage the lesion. It is good practice for the responsible

surgeon to physically convey the specimen to the pathologist to ensure that it does not go astray.

Soft tissue lesions

Skin

Epidermal inclusion cyst

These are common lesions, comprising approximately 10% of all hand tumours.² They tend to occur in the glabrous skin of the palm and fingers. A minor penetrating injury, which is usually not remembered by the patient, results in the implantation of some epidermal cells in the dermis, where they continue to produce keratin. The resulting collection of keratin within an epithelial lined cyst is a painless, smooth round tumour, not mobile relative to the skin but not fixed to underlying structures. Alternate theories of their origin have been proposed, including occlusion of pilosebaceous follicles or an arrest of keratinocyte migration.³ These cysts do not necessarily require treatment, but can interfere with function or grip, and can be complicated by infection. Treatment is by surgical excision, which should aim to remove the entire cyst wall, without penetrating the cyst, to reduce the chance of recurrence. If urgent incision and drainage is required for an infection, complete excision should not be attempted. A further procedure should be planned for at least six weeks after infection has settled.

Warts

Common warts are the most common neoplasm in the hand, and are caused by the human papilloma virus (HPV). They are generally self-limiting and will spontaneously regress within 2 years. Treatment to remove warts is best focused on stimulating immunity to HPV, with use of topical irritants such as salicylates. Cryotherapy can be used as first line but care should be exercised when underlying structures are at risk, for example the germinal matrix if the lesions are over the dorsum of the distal phalanx. On rare occasions, warts are resistant to non-surgical therapy and excision and grafting may be necessary. Recurrence at the margins of surgery is not unusual.

Actinic keratosis

Actinic or solar keratoses are pink, scaly macular lesions arising mainly on the sun-exposed dorsum of the hand. They have a modest risk of malignant transformation to squamous cell carcinoma (SCC), although this is difficult to quantify. They can be satisfactorily treated by curettage of the lesion, although recurrent lesions should be biopsied to exclude malignant transformation.

Squamous cell carcinoma

SCCs comprise approximately 75% of skin malignancies of the hand, and are the most common malignancy of the hand overall.⁴ They are more common in men, by a ratio of 4:1. There is an overall rate of metastasis of 3%, although SCC of the hand has higher rates of metastasis and recurrence. They present as

Figure 64.1 Squamous cell carcinoma on the dorsum of the hand.

pink or red nodules or plaques which can exhibit scale, ulceration or induration (Figure 64.1). Worrying features for both metastasis and local recurrence are ulceration, greater size of the lesion, lymphatic or perineural invasion. Keratoacanthoma can present as a similar lesion, clinically very difficult to distinguish from SCC. It can exhibit rapid growth and then spontaneous resolution, however prompt excision and histopathological examination is strongly recommended given the obvious risk of observing a potentially malignant lesion.

Treatment of SCC is by surgical excision. The lesion should be excised with one tissue plane below the tumour, and the appropriate margin depends on the size of the lesion. Tumours smaller than 2 cm in maximum diameter should be excised with a 5 mm margin, whereas larger tumours should have a 1 cm margin.⁵ Appropriate margins create defects that often need coverage with full-thickness skin grafts. Metastasis of SCC is by lymphatic spread and the antecubital fossa and axilla should always be examined for evidence of nodal spread. Where axillary lymph node metastases are confirmed, an axillary lymph node dissection should be performed.

Basal cell carcinoma

Basal cell carcinoma (BCC) occurs more commonly in sun-exposed areas, and is therefore prevalent on the dorsum of the hand. It occurs more commonly in men. Metastasis is extremely rare, and the treatment is by excision with clear margins. A 3 mm margin of excision is recommended for the more common nodular and superficial BCCs, although a 5 mm margin is necessary for morpheiform BCC where the margin is less distinct.⁵ Superficial BCC proven on biopsy can be treated with topical immunotherapy in the form of imiquimod, but the inconvenience of ulceration and dressings on the hand leads us to recommend excision in almost all cases.

Melanoma

Melanoma comprises approximately 3% of hand malignancies, and subungual melanoma is as common as the cutaneous variety. As with pigmented lesions elsewhere, suspicious lesions

Figure 64.2 Subungual melanoma with Hutchinson's sign.

should be biopsied promptly. Even where the index of suspicion is high, an excisional biopsy should have a small (2 mm) margin so as not to disrupt the lymphatic drainage of the area should sentinel node biopsy be necessary.

Subungual melanoma typically presents with longitudinal melanonychia, a band of brown/black in the nailbed as a result of melanin pigment deposition. Hutchinson's sign is the spread of pigmentation into the proximal nail fold and is an important though not pathognomonic sign of subungual melanoma (Figure 64.2). Subungual melanomas can mimic subungual haematomas, and unless there is a clear history of trauma and evidence of progression of the pigment with nail growth, the nail should be removed and the area biopsied.

Definitive management of melanoma is guided by histological analysis of the lesion. Melanoma *in situ* requires a 5 mm margin; tumours with a Breslow thickness of less than 1 mm should be excised with a 1 cm margin, those with a greater than 2 mm thickness require a 2 cm margin, and intermediate thickness melanoma should have a margin of at least 1 cm, with additional margins at the surgeon's discretion.⁶ Subungual melanoma cannot be given a Breslow thickness and treatment should be by amputation through the distal interphalangeal (DIP) joint.⁷

Use of sentinel lymph node biopsy (SLNB) varies widely. There is some controversy in the literature as to whether SLNB has a survival benefit either as a treatment itself or when it leads to regional lymph node clearance. It can yield useful prognostic information to patients as to their likelihood of metastasis and survival, and if done should be performed at the time of wide local excision.⁸

Other malignant skin lesions

Tumours of the eccrine sweat glands are rare, and consist of a variety of tumours including mucinous carcinoma, adenoid cystic carcinoma, porocarcinoma, malignant mixed tumour, cylindrocarcinoma and spiradenocarcinoma. They can be locally aggressive, and metastasis has been described, although its rate is difficult to estimate given the rarity of the conditions. Treatment is by surgical excision with a wide margin. Chemotherapy and radiotherapy have not been shown to be effective.

Merkel cell tumours are aggressive and carry a poor prognosis. They present as a painless, purple nodule of variable size. They arise from the Merkel cells of the basal layer of the epidermis. They are very radiosensitive and while neoadjuvant radiotherapy has not been shown to improve survival, it reduces the rate of local recurrence. Surgical treatment should be by excision with wide margins.

Fat

Lipoma

Lipomas are very common soft tissue tumours, although they are relatively rare in the hand. They are rarely symptomatic except when they grow sufficiently large to act as a space occupying lesion, for example in the carpal tunnel⁹ or Guyon's canal (Figure 64.3). Lipomas are typically soft, non-tender masses and can be multilobulated. The Bufalini sign is a relatively radiolucent area within the soft tissues on plain radiographs due to the transparency of the fatty tissue of the lipoma in relation to muscle. Preoperative imaging with MRI is recommended to delineate the extent of the tumour and also to confirm the absence of suspicious features of a soft tissue malignancy. There is typically a well-circumscribed mass with the features of normal fat on T1 and T2 images. Treatment is by surgery or observation. Complete excision, without requiring a margin of normal tissue, is generally curative. Malignant transformation is extraordinarily rare.

Figure 64.3 Large lipoma in the palm extending into Guyon's canal and causing ulnar nerve compression.

Lipoblastoma

Lipoblastomas are a distinct type of fatty tumour, most often occurring in children under 3 years old. They are composed of lobulated tissue with immature fat cells separated by fibrovascular septae and areas of myxoid matrix. Treatment is again by surgical excision.

Connective tissue

Ganglion cyst

This is the most common tumour of the hand and wrist. Ganglions are not true cysts, as there is no epithelial lining to the cavity. They are collections of mucin with a connective tissue wall, often with a stalk leading to a point of origin. Their pathogenesis is unclear, but may relate to mucinous degeneration of the capsule of a joint or the fibrous flexor sheath. There are four common sites of ganglion cysts in the hand: volar and dorsal wrist, DIP joint and the palm.^{10,11}

Ganglia tend to wax and wane in size (sharing this characteristic only with some vascular lesions), particularly in lesions around the palm, are soft to firm but compressible and may transilluminate.

Volar wrist ganglion cysts generally occur on the radial side and typically arise from the scaphotrapezium-trapezoid (STT) joint. They are often adherent to the adjacent radial artery, which is at risk during excision. It is not uncommon to mistake the radial artery for the stalk of the ganglion and the artery should be defined prior to excision. Dorsal wrist ganglia usually arise from the scapholunate ligament, and result in dorsal wrist pain, which is exacerbated by forced dorsiflexion as in pushing up from a table or performing pushups.

Ganglia over the dorsum of the DIP joint are conventionally called mucous cysts. They commonly arise in the context of DIP joint osteoarthritis, particularly with dorsal osteophytes. They can cause a pressure effect on the germinal matrix, leading to a characteristic concave deformity of the nail distal to the lesion. Palmar ganglion cysts occur over the metacarpophalangeal (MCP) joints and can arise from the volar capsule of the joint or the flexor sheath (Figure 64.4).

Figure 64.4 Ganglion of the flexor sheath.

As ganglion cysts frequently spontaneously resolve, and are essentially harmless masses, treatment is required only where they persist and cause discomfort or where the patient finds the lump unsightly. On rare occasions they can cause problems from a mass effect – for example a ganglion in Guyon's canal resulting in an ulnar nerve compression. Discharge of a mucous cyst through the nail fold or through breakdown of the skin over the cyst is a strong indication for surgery.

Treatment of ganglia is by complete excision of the lesion and excision and cautery of the point of origin. When designing incisions to approach ganglia, particularly those in atypical positions about the wrist, one must be aware that the stalk of origin may be long and lead some distance away from the palpable lesion. Sometimes a second incision is required to provide adequate access to the origin. Another important point is to avoid closure of the wrist capsule as this will only result in stiffness.

Figure 64.5 Mucous cyst with planned excision and local flap for closure.

Excision of dorsal osteophytes at the DIP joint and the joint capsule between the extensor tendon and the collateral ligaments can help reduce recurrence of mucous cysts. Occasionally the ganglion can result in overlying skin of poor quality, in which case a small local flap is required for skin closure (Figure 64.5). Recurrence rates are in the order of 10% with surgery. More conservative treatment options such as closed rupture or needle aspiration have higher recurrence rates and are not recommended, particularly as they may lead to septic arthritis of the DIP joint.

Giant cell tumour of tendon sheath

These are slow-growing firm lesions arising from the fibrous flexor sheath or joint. They are typically seen in the third to fifth decade of life, and present with a long history of a gradually enlarging, firm, non-compressible painless mass on the finger, commonly around the DIP joint. They do not transilluminate, which can differentiate them clinically from mucous cysts. They have no malignant potential, but can be locally aggressive, invading bone and tendon. Complete excision should be curative but is difficult particularly in extensive lesions, and recurrence is common, occurring in 20–50% of cases. A higher recurrence rate of giant cell tumour associated with downregulation of the *nm23-H1* gene has been reported¹² and immuno-histochemical analysis of nm23 expression within the tumour has been advocated for prognostic information. However this has been challenged in a more recent larger series.¹³ Incomplete excision is the greatest determinant of recurrence, and with a benign condition the need to avoid morbidity from radical excision of flexor tendons or annular pulleys makes it difficult to be confident of complete excision (Figure 64.6).

Figure 64.6 Giant cell tumour of flexor sheath before and after excision. Source: Prof. Christopher Coombs. Reproduced with permission.

Fibromas

Digital fibromas in adults present as painless firm masses, often in and around the fibrous flexor sheaths. They can be clinically difficult to differentiate from giant cell tumours. Treatment is by surgical excision. Infantile digital fibromas, or fibromas of Reye, are nodular proliferations more typically found on the dorsal or lateral aspect of the finger, occurring in the first 2 years of life (Figure 64.7). Many will spontaneously resolve, however recurrence is common after removal. It is therefore recommended to manage these conservatively and operate only in cases of functional impairment.

Juvenile aponeurotic fibromatosis is a condition of nodules in the palms (and soles) of young children. They can become calcified and be visible on plain X-ray imaging. These are benign lesions which are managed by excision in the case of masses causing a functional problem. Recurrence is common and excision with a margin of normal palmar aponeurosis is recommended.

Vessels

Historically the terminology used to describe vascular anomalies was confusing, with lesions grouped together inappropriately solely on their appearance. Mulliken and Glowaki¹⁴ proposed a classification based on the histological characteristics of the lesions which forms the basis of current terminology as adopted by the International Society for the Study of Vascular Anomalies (ISSVA).¹⁵ Vascular lesions can be broadly divided into tumours and malformations.

Haemangioma

This is a vascular tumour of infancy. It is not present at birth, and a reddish-purple mass develops at around 4–6 weeks. Deeper lesions appear blueish and superficial lesions red. They tend to grow rapidly in the first year and then undergo a long period of gradual involution, with 50% resolving at 5 years and 70% at 7 years. A variant exists which is present at birth, which will either rapidly involute in the first year (rapidly involuting congenital haemangioma or RICH), or can persist without

involuting at all (non-involuting congenital haemangioma or NICH). Haemangiomas on the hand can mostly be left to spontaneously involute. Indications for treatment are persistent ulceration, bleeding or infection. The basis of treatment of haemangiomas is now medical treatment with propranolol, although surgical excision – when able to be performed simply with minimal scarring and primary closure – may be more straightforward and still has a role.

Pyogenic granuloma (lobular capillary haemangioma)

The terminology of this non-pyogenic, non-granulomatous lesion has become so ingrained that it is unlikely to change. They are friable, pedunculated lesions with a shiny surface (Figure 64.8). They commonly arise at the site of minor trauma, where they grow rapidly and bleed easily. They tend not to resolve spontaneously and should be excised, although multiple treatments with silver nitrate have also been shown to achieve resolution in some cases. Tissue should always be sent for histological analysis as pyogenic granulomas can be mimicked by malignancies such as amelanotic melanoma.

Glomus tumours

The glomus body is a neurovascular structure involved in temperature regulation. Glomus tumours arise from the glomus body and present as blue/red lumps, usually in the fingertips, or as a hard-to-see subungual mass which can cause nail discoloration and ridging. They are more common in women, and often exhibit cold intolerance, severe paroxysmal pain and exquisite tenderness. Love's sign is point tenderness elicited by systematic palpation with a paperclip or similar; Hildreth's test involves inflating a tourniquet – eradication of the pain under tourniquet is highly suggestive of a glomus tumour. A plain X-ray may show a small lytic area in the distal phalanx, and ultrasound and/or MRI can be useful if the diagnosis is still in doubt. Because glomus tumours are multicentric in up to 30% of cases we usually obtain an ultrasound or MRI prior to surgery.

Treatment is by surgical excision. In subungual glomus tumours the nail plate is removed, and the nail fold is reflected

Figure 64.7 Infantile fibromatosis.

Figure 64.8 Pyogenic granuloma.

with the aid of bilateral incisions. A longitudinal incision is made in the germinal matrix to expose the tumour, which is excised to periosteum. Meticulous closure of the germinal matrix is essential to reduce the chance of ridging of the nail.

Malformations

Vascular malformations can be classified by their flow characteristics (into high-flow and low-flow lesions) and subclassified by their histology.

Slow-flow malformations

These can be classified as capillary, lymphatic, venous or combined malformations. They are present at birth but often not obvious. They can become manifest in the first few years of life and will grow commensurately with the patient. In addition to problems specific to their subtype, morbidity in slow-flow lesions of the hand can also be from the bulk and weight of the lesion impairing function, and from a mass effect of the lesion causing peripheral nerve compression.

Capillary malformations exhibit a red discoloration of the skin due to small vessels within the dermis. They are rarely the cause of any functional problem, although very large capillary malformations can lead to overgrowth phenomena in the affected limb. They can simply be observed for growth disturbance and for the possibility of a larger vessel anomaly. The cutaneous discoloration can be addressed with pulsed dye laser therapy.

Venous malformations can vary greatly in size, and often are not limited by tissue planes. They are soft and diffuse, and will decompress with pressure or elevation. Pain is a common feature relating to intralésional thrombus formation. Compression garments can give symptomatic relief by alleviating the heaviness associated with distension of the lesion. Low-dose aspirin in conjunction with compression is useful in preventing intralésional thrombosis. Sclerotherapy can also help to reduce the size of the malformation.

Lymphatic malformations can also vary in size and are sometimes characterized by excessive swelling of the extremity. They do not decompress with elevation, and are frequently complicated by recurrent episodes of infection. Compression and sclerotherapy is also useful for lymphatic malformations.

Surgery for slow-flow lesions is reserved for when conservative measures have failed, and where there is functional impairment, compression neuropathy or other problems due to a mass effect of the lesion. Excision should be staged where the lesions affect multiple anatomical areas.

Fast-flow malformations

These lesions are arterial or arteriovenous malformations. They are warm, occasionally painful lesions that are difficult to decompress. There is often a palpable pulse or thrill. In extremity arteriovenous malformations there can be signs and symptoms of distal ischaemia with shunting through arteriovenous fistulas, and where extensive the patients can exhibit signs of high-output congestive heart failure. There can also be a mass effect

causing peripheral nerve compression. Although the malformation is present at birth, a third of lesions will not be evident until after the age of 10 years.

There is a hormonal influence on the progression of both fast-flow and slow-flow lesions, with around a third to a half of females experiencing an exacerbation in puberty, pregnancy or with use of the contraceptive pill. There is a much smaller rate of progression in puberty in males.

Upper limb fast-flow malformations have been classified into types A, B and C.¹⁶ Type A fast-flow lesions are either single or multiple arteriovenous fistulas, aneurysms or ectasias of the arterial circulation. Type B are arteriovenous anomalies with macro- or micro-fistulas localized to a single axial artery of the limb, hand or digit. Type C malformations are diffuse arteriovenous anomalies with arteriovenous fistulas involving all tissues of the limb. They expand into previously uninvolved areas and often exhibit a distal vascular steal phenomenon.

Doppler ultrasound is useful to differentiate between fast-flow and slow-flow malformations, and MRI is used to identify the extent and exact position of the lesion. Fast-flow lesions can be helped with compression therapy. Arterial embolization can be useful, although failure to eradicate the lesion may lead to more rapid enlargement stimulated by the resulting relative ischaemia.

Where conservative measures do not alleviate symptoms or where there is recurrent bleeding or ulceration, surgical excision or debulking is indicated. It is of critical importance to maintain meticulous haemostasis during the resection, and keep the debulking of large lesions within a well-defined anatomical area. The excision of types B and C fast-flow malformations is aided by preoperative embolization. Type C malformations have a grave prognosis, with the majority of patients eventually having an amputation.

Nerves

Nerve tumours account for about 12% of all benign and 8% of all malignant soft tissue neoplasms.^{17,18} They comprise only 5% of upper extremity tumours in adults and 2% in children.^{19–22} Most are benign. These include pseudotumours such as neuromas, and true tumours, most of which arise from the peripheral nerve sheath and are designated as peripheral nerve sheath tumours (PNSTs). Neurilemmomas (schwannomas) and neurofibromas are most common. The granular cell tumour, neurothekeoma and nerve sheath myxoma may be found in the hand and upper limb less commonly. The perineurioma arises from the perineurium. Other nerve-associated tumours include the fibrolipoma and peripheral nerve sheath ganglion which derive from non-specific neural or peripheral tissue.

Malignant PNSTs arise *de novo* or from malignant degeneration in a benign tumour, and are often associated with neurofibromatosis type 1 (NF1).

Neurilemmoma

These benign PNSTs are the most common of the nerve tumour group, most often in patients of 30–60 years of age, with men and women equally affected.^{23–25} Common sites include the

(a)

(b)

Figure 64.9 (a, b) Neurilemmoma.

brachial plexus and the peripheral nerves of the upper limb. Occasionally there is no apparent nerve association but most are found tethered in the longitudinal axis of the limb in the line of a peripheral nerve. They are usually solitary with non-aggressive features, including slow growth and small size. However, multiple schwannomas may occur, occasionally in association with NF1.¹⁸

Schwannomas are fusiform, eccentrically sited in nerve trunks with apparent entry and exit of small nerve fibres at each end. Pain and neurological symptoms and signs of neurological deficit are unusual, even when the lesions are palpable. In some cases there is a sensory deficit and a positive Tinel's sign.²⁶

The schwannoma and the affected nerve lie within a true capsule: the epineurium. In most instances, at surgery, they can be enucleated from within the epineurium with no nerve deficit unless surrounding nerve fibres are injured at the time of removal (Figures 64.9). Large schwannomas that have been present for a longer time commonly undergo degenerative changes, including cyst formation, calcification, haemorrhage and fibrosis. These are referred to as 'ancient schwannomas'.^{18,27} These do not shell out easily at surgery and damage to nerve fibres is a greater risk.

The histological hallmark of schwannomas is identification of Antoni A and Antoni B regions. The former occur in hypercellular areas with elongated spindle cells with nuclear palisading forming occasional Verocay bodies. Antoni B regions are hypocellular and less organized, containing more myxoid loosely arranged tissue with high water content. The cells stain strongly for S-100 and moderately for Leu-7.²⁶⁻²⁸

Malignant degeneration of a true schwannoma is extremely rare.¹⁸

Neurofibroma

Neurofibroma is a benign PNST of Schwann cell origin, although perineural cells and fibroblasts are also present. It is differentiated from a neurilemmoma in that the tumour mass and the nerve fascicles are intertwined²⁸ (Figure 64.10). Clinical symptoms and signs are as for neurilemmoma.^{19,20,29} Three types are recognized: localized, diffuse and plexiform.^{26,28} Most are of the localized

Figure 64.10 Neurofibroma.

variety and usually affect superficial cutaneous nerves, although larger nerves in deep-seated regions may be involved. They are more likely to be multiple and deep-seated when in conjunction with NF1. Diffuse neurofibromas occur in the young, mainly in the head and neck. Plexiform neurofibromas are pathognomonic of NF1 and usually involve a long segment of a major nerve trunk extending into the nerve branches. These may be associated with massive and deforming enlargement of an extremity. The estimated prevalence of malignant transformation varies from 2 to 29%, with a sudden increase in size of a previously stable neurofibroma and the presence of pain and neurological defects leading to suspicion of malignant change.^{17,18,28}

A localized solitary neurofibroma is composed of interlacing fascicles; they do not contain Antoni A and B regions and myxoid areas and degenerative regions are not as prominent as they are in schwannoma. They stain less strongly for S-100 protein and Leu-7 than do schwannomas.^{17,18,28}

Granular cell tumour

Between 10 and 20% of these are found in the upper extremity, appearing as small, non-tender, subcutaneous nodules; 10–25% are multifocal. They may be found in association with a nerve trunk, a digital nerve or with no nerve association. They may or

may not be intimately associated with nerve fascicles. They stain moderately for S-100 and Leu-7, suggesting that their origin is the Schwann cell.^{28,30–34} Malignant change is reported as being less than 3%.^{30,35} Following biopsy, a granular cell tumour may be excised or not. However, malignant change is rare and resection may result in neurological deficit requiring reconstruction.

Perineurioma

The soft tissue perineurioma has been recently recognized as a distinct benign peripheral nerve tumour, arising from perineural cells.³⁶ There are two types, usually presenting in young adults. In both the cells do not stain for S-100 and Leu-7 proteins but they do stain for epithelial membrane antigen (EMA).³⁷ The soft tissue perineuriomas arise as slow-growing painless nodules in the trunk or extremities, often without a clear association with a nerve. Some report that tumours of perineural origin with malignant change may arise from benign soft tissue perineuromas, but this is not proven.^{38,39}

The intraneural perineurioma (localized hypertrophic neuropathy) is a benign neoplasm composed of perineural cells surrounding nerve fibres and is restricted to the boundaries of peripheral nerves. A motor deficit of nerve function is common, often with only mild sensory involvement. It occurs most commonly in the sciatic nerve but presents equally in upper and lower limbs. In approximately 17% of cases more than one nerve is involved.⁴⁰ These tumours are static or slowly progressive. Malignant degeneration has not been reported. Treatment may be indicated for a nerve deficit. Resection may be difficult because of the length of nerve involved. Nerve grafting, nerve transfers, tendon transfers or joint stabilizations may be considered following resection.

Fibrolipoma

This is an uncommon tumour-like lipomatous process involving peripheral nerves and their branches in which increased fatty tissue is interspersed among thick nerve bundles.^{18,41,42} Males and females are equally affected with presentation typical before 30 years of age, often at birth or early childhood. The median nerve is most commonly affected. Clinical symptoms are associated with slow growth of the soft tissue tumour, often in association with symptoms of a compression neuropathy. In 27–60% of cases the nerve lesion is associated with macrodactyly – macrodystrophica fibrolipomatosis – often involving the index and middle fingers.¹⁸ Multiple digits may be affected. The precise relationship between the fibrolipomatosis and the macrodactyly has not been established.

The affected nerve is diffusely enlarged. Currently the tumour is designated as a fibrolipomatosis of a nerve rather than arising from neural tissue.⁴¹ Those with a fibrolipomatosis hamartoma of nerve, most often the median nerve, may respond to a limited soft tissue excision and carpal tunnel release as appropriate. Recurrence of symptoms may occur.

Other benign nerve tumours

Neurothekeoma and nerve sheath myxoma both present as isolated, small dermal lesions in young adults. They may arise, at least in part, from the Schwann or perineural cell. They do not undergo malignant degeneration and excisional biopsy is usually curative.^{43–49}

Another neuromuscular hamartoma (the benign triton tumour) is exceedingly rare but may involve the brachial plexus or the sciatic nerve and other large nerve trunks of infants and young children. They are a multilobed proliferation of mature skeletal muscle and neural elements.²⁸

A Pacinian neuroma is a proliferation of Pacinian corpuscles, often presenting as a painful nodule on the digit.²⁸

A nerve sheath ganglion may arise from within the epineurium or from adjacent joints, such as the tibiofibular joint. A compression neuropathy may result.^{18,28}

Malignant peripheral nerve sheath tumours

These account for 5–10% of all soft tissue sarcomas, usually affecting adults aged 20–50 years, with an equal sex distribution. Twenty per cent occur in the upper extremities.⁵⁰ They constitute approximately 3% of all malignant tumours of the hand.^{51,52} These lesions are associated with NF1 in 25–70% of cases and most commonly involve major nerve trunks.¹⁸ The incidence of malignant PNST in patients with NF1 has been reported as 2–5%, although a recent longitudinal study suggests a lifetime risk as high as 13%, particularly for plexiform neurofibromas.^{51,52} Malignant change from a benign schwannoma or a solitary neurofibroma is rare. Malignant change can occur secondary to previous radiation therapy.

These are high-grade sarcomas. Presentation is with pain, increasing size of the tumour and neurological symptoms of motor weakness and sensory deficits. Regrettably the symptoms such as pain, weakness and numbness may occur late.

The tumour spreads along the affected nerve with thickening of epineurium and perineurium proximal and distal to the mass (Figure 64.11). The tumour cells are arranged in fascicles and areas of haemorrhage and necrosis are frequent.

Metastasis is through haematogenous spread, although perineural extension and lymphatic spread also occur.^{53–56}

Malignant peripheral nerve sheath tumours are reactive for S-100 protein in 50% of cases. Perineural cell differentiation may sometimes be seen and this could confer a better prognosis.

Investigations

The modalities of ultrasonography and MRI are particularly helpful in the characterization of nerve tumours and may assist in indicating the possibility of malignancy.²⁶ These may demonstrate: that the tumour is in the region of a major nerve; there may be evidence of tubular entry and exit of nerve, easier to detect in lesions affecting large deep nerves; fusiform shape of the tumour; a split-fat sign indicative of a ring of fat often present about neurogenic neoplasms; atrophic muscle changes with increased fat content or increased size of muscle, best seen on

Figure 64.11 (a, b) Neurosarcoma of the peroneal nerve.

T1 weighted MR images but also can be evaluated with a finding of increased echogenicity of muscle on ultrasound; and the presence of target sign and fascicular appearance – the former corresponds to fibrous tissue in the centre of the nerve with myxoid tissue peripherally, the latter represents multiple small ring-like structures corresponding to fascicular bundles.

In schwannomas, the mass is more likely to be eccentric and separable from the nerve, whereas in neurofibromas the two structures are indistinguishable. The target sign is more characteristic of neurofibroma and the fascicular sign is perhaps more commonly associated with schwannomas. Schwannomas are more frequently associated with central necrosis, cyst formation and calcification, particularly in long-standing schwannomas (ancient schwannoma). Central enhancement after gadolinium administration has been reported more frequently with neurofibromas.

Malignant tumours may demonstrate heterogeneous MRI signals with less well-defined margins; target and fascicular signs are rare; the enhancement pattern is predominantly peripheral and heterogeneous; a duplex ultrasound may exhibit sarcoma type anarchic hypervascularisation rather than the peripheral hypervascular changes of a benign tumour. Scintigraphic gallium 67 citrate imaging reveals a significant uptake and the positron emission tomography (PET) scan is positive.

It should however be emphasized that MRI differentiation between benign and malignant tumours, and among benign tumours such as schwannoma and neurofibroma, is not a reliable diagnostic tool. Formal biopsy remains the only reliable method of diagnosis.

Management

Surgical decision making and surgical technique must adhere to the principles of tumour surgery described in the introduction. The macroscopic appearance of a schwannoma is usually diagnostic and, in most instances, the tumour may be peeled from the nerve fibres with minimal or no neural damage and no subsequent deficit. This is not so for the ancient schwannoma,

when nerve fibres may be intimately involved with cystic areas which insinuate between and involve fascicles. Even when dissecting a typical schwannoma there may be an entering fascicle or exiting fascicle which is sacrificed, but usually with no discernible postoperative deficit. If the tumour does not dissect easily from the nerve, the surgeon must consider whether this might be a neurofibroma or a malignant lesion. A frozen section biopsy assists in making the diagnosis. Resection of a neurofibroma may leave some nerve deficit or amount to a debulking procedure with tumour remaining. If there is doubt about malignancy then a formal biopsy alone is appropriate. Subsequently, if the diagnosis is confirmed as a neurofibroma, the surgeon will discuss with the patient the advantages and disadvantages of further surgery, the possibility of nerve resection and grafting, and the possible consequences of leaving the tumour *in situ* without proceeding to secondary surgery.

If malignant, then a wide excision, preferably compartmental, is appropriate. However, spread along the nerve is possible and there may be multiple lesions. Limb-sparing surgery is most commonly advised. Compartmental excision is difficult in the hand but more applicable to the forearm. Vital vessels should be retained or reconstructed. Nerves may be reconstructed in a secondary manner with grafting or nerve transfers. Tendon transfers and joint stabilizations may be appropriate. Limb amputation may be necessary.

Local recurrence and metastasis are common. Radiotherapy may be helpful in controlling local disease. No chemotherapeutic regime has proven to be effective.^{50,53,57} Metastasis is by the way of haematogenous spread although perineural extension and embolization of lymphatics may also occur.²⁸ Those patients with neurofibromatosis and tumour size greater than 5 cm have a poorer prognosis. Ducatman *et al.* reported a median survival of 3 years from the time of diagnosis, with a 23% survival rate at 10 years.⁵³

Soft tissue sarcomas

Approximately 5% of soft tissue sarcomas occur in the hand. The commonest histological subtypes are epithelioid sarcoma, synovial sarcoma and malignant fibrous histiocytoma. Rhabdomyosarcoma

is a more common sarcoma in children. Patients typically present with a history of a rapidly enlarging painless mass in the hand.

When dealing with a suspicious soft tissue mass, tissue diagnosis is essential prior to definitive management. The principles of biopsy of soft tissue malignancies outlined above should be adhered to in obtaining tissue for histopathology. Patients should have MRI prior to biopsy, and if sarcoma is confirmed, it should be staged with imaging of the chest and possibly with PET scanning to identify metastases.

The traditional treatment of amputation for soft tissue hand sarcomas has given way to limb-sparing or hand-sparing surgery in many cases. The standard of care is now wide en-bloc excision with clear margins, followed by soft tissue reconstruction and postoperative radiotherapy and chemotherapy determined by the histological subtype. This approach has equivalent survival figures to amputation.⁵⁸ The histological grade of the tumour is the greatest determinant of survival, and guides the surgical and adjuvant management. Salvage of vital structures is a secondary goal to adequate resection of the tumour.

The goal of treatment is complete removal of the tumour with a surrounding cuff of normal tissue. Excision with a margin of 2–3 cm of normal tissue has been advocated. Radical excision with these margins in the hand will often necessitate extensive soft tissue reconstruction if any function is to be salvaged, and often a two-team approach with resecting and reconstructing teams will be useful. Functional outcomes are generally dependent on the amount of native tissue left behind, but even double ray amputations can leave a hand that is of superior function to a prosthesis.⁵⁹

Epithelioid sarcomas are epithelial tumours with a necrotic central area. They are most common in young adults, and are unusual in that they frequently exhibit lymphatic metastasis. Examination of the regional lymph node basins is therefore mandatory, and SLNB has been advocated. Synovial sarcoma is also most commonly a condition of young adults. The tumours are of epithelial and spindle cells. It usually presents with a soft tissue mass close to joints or bursae. There is some benefit to neoadjuvant chemotherapy in reducing the bulk of the tumours and increasing the feasibility of limb salvage. Rhabdomyosarcomas are mainly seen in children and adolescents. Preoperative and postoperative chemotherapy form part of the treatment protocol to reduce local recurrence and increase survival.

Bone tumours

Benign bone tumours

Enchondroma

Enchondromas are common, comprising up to 90% of all bone tumours within the hand. The proximal phalanges and metacarpals are most often affected. More than 50% of all enchondromas are located within the long bones of the hand.

These tumours frequently present as a pathological fracture. They can also manifest as a progressive, usually painless swelling, or as incidental findings on plain radiographs.

On plain radiographs matrix calcification suggests a tumour of cartilage. The calcification tends to lie in the centre of the lesion. There is a well-defined zone of transition. The cortical bone can be thinned and may appear to be scalloped from within. The lesion lies centrally within the metaphysis.

Treatment is with observation if the lesion is small and asymptomatic; if causing problems the tumour can be curetted from the bone, preferably via a midlateral incision. It is prudent to obtain radiographs intraoperatively to confirm that the curette has probed the limits of the tumour cavity in all directions. Bone graft is not necessary in most cases,⁶⁰ but judgement is used if the cortex is excessively thinned and the bone appears particularly fragile.

In the event of trauma the fracture is treated on its merits and once healed residual tumour can be observed or removed. Bone graft and internal fixation may be necessary when treating the fracture. Whenever graft is obtained, it should be via fresh instruments to avoid contaminating the graft site.

When the curetted specimen is sent to the laboratory, particularly in the setting of trauma it is necessary to provide an adequate history to the pathologist as it can be difficult to distinguish between an enchondroma and a low-grade chondrosarcoma (in the setting of elective curettage and no fracture) and between an enchondroma and an osteosarcoma (in the posttraumatic setting when osteoid is being produced). Following removal of the lesion some authorities recommend surveillance X-rays postoperatively.¹

Malignant change in a solitary enchondroma has been described but is very rare.

Multiple enchondroma

Ollier's disease

The name of Louis Ollier (1830–1900), a French surgeon, is attached to an acquired developmental abnormality characterized by multiple enchondromas involving multiple bones, and which can involve any or all of the epiphysis, metaphysis or diaphysis (Figure 64.12).

These lesions are of note for their propensity to cause significant growth disturbance, shortening of the bones and joint disruption, and for their higher potential for malignant change. The propensity for malignant change is less for the hand than for more central lesions. As for solitary enchondromas, growth usually ceases with skeletal maturity.

Maffucci's syndrome

Angelo Maffucci (1847–1903), an Italian pathologist, described a syndrome characterized by multiple enchondromas and haemangiomas. It has an even higher rate of malignant transformation than Ollier's syndrome and can be associated with very marked growth disturbance. Chondrosarcomas and malignant vascular tumours may both occur; furthermore these patients are prone to tumours of other systems including the thyroid, breast, pancreas and liver, leading to some authorities estimating an overall rate of malignancy approaching 100%.⁶¹

Figure 64.12 Multiple enchondromas.

In both syndromes treatment is targeted at lesions causing functional problems; it is usually not possible or sensible to attempt to remove all lesions. Children with these syndromes may need to endure many operations over the years. A high index of suspicion for malignant change must be maintained.

Osteochondroma (also known as cartilage capped exostosis)

An osteochondroma is a relatively common bone tumour characterized by a pedunculated or sessile outgrowth from the bone which has both cortex and cancellous bone in continuity with the normal bone, and which is covered by a cartilaginous cap, which in turn is covered by a fibrous band.⁶² It is caused by a defect in the perichondral ring of the physis; the physal cartilage slips to an aberrant position and there continues to grow. Being produced by the physis, growth should stop with skeletal maturity.

Most cases present by the late teens and lesions are more commonly seen in males. Around 5% of all osteochondromas are seen in the hand.

Radiographs demonstrate the characteristics of cortical and medullary continuity. Pedunculated lesions are usually directed

towards the diaphysis of the bone. Because radiographs do not show the cartilaginous cap, which can be 2–3 cm in thickness,⁶² the usual tumour is significantly larger clinically than on X-ray. MRI scans demonstrate the cartilaginous caps well and are of use when planning surgery in anatomically complex regions such as around the brachial plexus.

These lesions usually present as long-standing masses, which slowly enlarge. They can cause pain by direct pressure upon the skin or by impinging on adjacent nerves or tendons. A bursa may develop over a prominent osteochondroma.

Transformation to a chondrosarcoma is rare but has been described and is heralded by continued growth after skeletal maturity has been reached.

Treatment consists of excision of the lesion through the base of the stalk, and is usually reserved for symptomatic lesions.

Multiple hereditary exostosis (diaphyseal aclasis, osteochondromatosis)

This is an autosomal dominant inherited condition characterized by multiple lesions, usually picked up within the first years of life. The chief points of interest in this condition are that malignant change is seen at a much higher rate than in solitary osteochondromas, and that deformities of the forearm are common because of growth disturbance and/or pressure from lesions within this complex two-bone system.

Giant cell tumours

Giant cell tumours make up around 20% of benign bone tumours, are usually seen in the third to fourth decades and are slightly more common in women (bony tumours as a whole are more common in men).

In the upper limb giant cell tumours predominantly affect the distal radius, which is the third most common site for a giant cell tumour after the distal femur and proximal tibia. It is very rare in the carpus or phalanges. Multicentric giant cell tumours are uncommon but do occur more frequently with the small bones of the hand (10% versus 1% for long bones).

The lesions are benign but local recurrence is common. They usually present with pain and swelling, and occasionally with pathological fracture. Distant metastasis is possible but seen in less than 10%.⁶³ Late sarcomatous degeneration has occurred but most cases have been exposed to radiotherapy prior to malignant change.

On plain radiographs the appearance is characteristic; the lesion involves the epiphysis, extends to subchondral bone and has a well-defined but non-sclerotic zone of transition. Matrix calcification is not seen. More aggressive tumours may expand and penetrate the bone to involve the soft tissues. CT scans may aid in the evaluation of tumours of the carpus or metacarpus (Figure 64.13).

The main differential diagnosis is of chondroblastoma, a benign cartilage tumour which also involves the epiphysis. This tumour occurs in younger patients prior to closure of the physes, and may display matrix calcification on plain X-rays. It is also much less common in the radius than a giant cell tumour.

Figure 64.13 Giant cell tumour distal radius.

Other differential diagnoses include aneurysmal bone cyst, osteomyelitis and brown tumours of hyperparathyroidism.

Giant cell tumours are staged according to Campanacci's scheme.⁶⁴ Grade I lesions have a cortex that may be thinned but is not deformed. Grade II lesions have an expanded cortex. Grade III lesions have a poorly defined border and can extend into the soft tissues.

In the radius, wide intralesional excision is preferred for grade I and II lesions. The margin is then extended with an adjuvant therapy such as bone cement, liquid nitrogen or phenol. Without adjuvant therapy recurrence is almost inevitable. Grade III lesions are treated with en-bloc excision and reconstitution with anatomically specific allograft or free vascularized fibula grafting. Carpal and tubular hand bones are best treated with resection if possible, as the rates of recurrence are higher for the small bones of the hand – around 20% when adjuvant therapy is used.⁶⁵ Recurrent giant cell tumour is thought to have a higher malignant potential.

Aneurysmal bone cyst

Aneurysmal bone cysts are benign expansile lytic lesions seen in younger patients and typically involving the metacarpals. Radiographs show cortical thinning and expansion and MRI scans show pathognomonic fluid levels within the lesion. The main differential diagnosis is giant cell tumour, and the treatment is similar, with intralesional curettage and adjuvant therapy to extend margins using liquid nitrogen or bone cement;

for larger lesions and/or those extending into soft tissue resection and reconstruction is necessary.

Osteoid osteoma

Osteoid osteomas, described by Jaffe in 1935, are benign tumours composed of central calcified osteoid surrounded by a vascularized stroma and then a sclerotic periphery of reactive bone. Prostaglandins are secreted by the tumour. Tumours with the same pathology more than 2 cm in diameter are known as osteoblastomas.

Hand tumours represent 10% of all osteoid osteomas. The tumours typically occur in the second or third decade and are twice as common in males.

Pain is a characteristic and prominent feature of osteoid osteoma and is said to be worse at night, and be very responsive to aspirin, although Marcuzzi found that only just under half his patients had pain relief from aspirin.⁶⁶ Osteoid osteomas are often implicated as a cause of unexplained or chronic pain (as are glomus tumours). They can result in significant enlargement of the affected bone and lie in the differential diagnosis of macrodactyly.

They may occur in any of the bones of the hand with a slight predilection for the phalanges. The classic radiological appearance is of cortical thickening perhaps with a central lytic area, containing a small central nidus of bone, but initial radiographs are often unremarkable.⁶⁶ The lesions are often better seen on a CT scan, and three-phase bone scan is particularly sensitive for the tumour (Figure 64.14).

Treatment can be with prolonged aspirin use, but it may take several years for the lesion to burn out and surgical treatment is usually preferred. Radiofrequency ablation is used in other parts of the body but heats up the surrounding structures and may be less suitable for the hand with its closely packed vital structures. Surgical removal with or without grafting using a burr down technique is preferred in the hand and is highly successful.⁶⁶

Malignant bone tumours

These are very rare; chondrosarcomas are seen most often, whereas osteosarcomas and Ewing's tumours are extremely uncommon in the hand. Bone sarcomas present with pain, swelling, pathological fractures and, in the case of Ewing's sarcoma, systemic symptoms. Adequate staging, both local and systemic, is critical in developing a management strategy, and treatment must involve a musculoskeletal oncology service.

Chondrosarcoma

These are the most common malignant bone tumours in the hand. Chondrosarcomas can arise *de novo* or from malignant change of a solitary enchondroma (very rare) or less uncommonly from the enchondromas of Ollier's or Maffucci's syndromes.

Hand chondrosarcomas make up 2% of all chondrosarcomas.⁶² They occur in an older age group with most patients in the sixth or later decade. This tumour usually involves the proximal phalanges and metacarpals.

The lesions are typically slow growing and expansile, and have areas of matrix calcification and lysis. The cortex may be

Figure 64.14 Osteoid osteoma with sclerosis of proximal phalanx and nidus indicated by long arrow.

disrupted and there may be an associated soft tissue mass (Figure 64.15).

Treatment is by wide excision. Chondromas are typically not radio- or chemo-sensitive, and metastasis is late; if it occurs, the lungs are most often affected.

Osteosarcoma

These lesions are even rarer than chondrosarcomas. They tend to occur in an older age group than osteosarcomas elsewhere in the body and present with a rapidly enlarging painful mass.

Plain radiographs may show areas of lysis and/or bony destruction associated with periosteal new bone formation.

Treatment is with radical excision usually combined with chemotherapy. Some oncologists use neoadjuvant therapy, beginning chemotherapy after the incisional biopsy but prior to definitive treatment in order to shrink the tumour, diminish the reactive zone around the tumour and to allow assessment of the tumour response to chemotherapy.

Ewing's sarcoma

Ewing's sarcoma presents in younger patients than chondro- or osteosarcoma. The metacarpals and phalanges are most commonly involved. Radiographs demonstrate a destructive, expansile lesion, often with a soft tissue extension that is confirmed on MRI. The presentation often resembles an infection, with rapidly increasing swelling, pain and systemic features, and misdiagnosis as osteomyelitis is possible. Treatment involves incisional biopsy, then neoadjuvant chemotherapy in conjunction with wide resection.

(a)

(b)

Figure 64.15 (a) Chondrosarcoma arising from distal radius. (b) Excision of distal radius and creation of one-bone forearm.

Metastatic disease

Metastasis to the hand is rare. It typically involves the terminal phalanges. The most common malignancy metastasizing to the hand arises from the lung. Hand metastasis occurs late in the disease and the prognosis is dismal, with average life expectancy of nine months post diagnosis.

The goal of management is symptom control, and amputation through healthy tissue proximal to the lesion is usual.

CHAPTER 65

Facial anatomy and ageing

Chin-Ho Wong¹ and Bryan C. Mendelson²

¹W. Aesthetic Plastic Surgery, Mt Elizabeth Novena Specialist Center, Singapore

²The Centre for Facial Plastic Surgery, Toorak, Victoria, Australia

Introduction

Fundamental to safety when operating in the face is a firm grounding in the principles on which the facial soft tissue layers are constructed. This is also important because the pathogenesis of facial ageing is explained on an anatomical basis, particularly the variations in the onset and outcome of ageing seen in different individuals. This is most important in addressing the overriding concern of the course of the facial nerve branches. An anatomical approach to surgical rejuvenation of the face provides the way to obtaining a 'natural' result that is lasting and with minimal morbidity.

Regions of the face

The traditional approach to assessing the face is to consider the face in thirds (upper, middle and lower thirds). Although useful, this approach limits conceptualization as it is not based on the function of the face. From a functional perspective, the face has an anterior aspect and a lateral aspect. The anterior face is highly evolved for communication and facial expression. In contrast, the lateral face predominantly covers the structures of mastication. A vertical line descending from the lateral orbital rim is the approximate division between the anterior and lateral zones of the face. Internally, a series of facial retaining ligaments are strategically located along this line to demarcate the anterior from the lateral face (Figure 65.1). The mimetic muscles of the face are located in the superficial fascia of the anterior face, mostly around the eyes and the mouth. This highly mobile area of the face is designed to allow fine movement and is prone to develop laxity with ageing. In contrast, the lateral face is relatively immobile as it overlies the structures to do with mastication, the temporalis, masseter, the parotid gland and its duct, all located deep to the deep fascia. The only superficial muscle in the lateral face is the platysma in the lower third, which extends to the level of the oral commissure.

Importantly, the soft tissues of the anterior face are subdivided into two parts: that which overlies the skeleton and the

larger part that comprises the highly specialized sphincters overlying the bony cavities.^{1,2} Where the soft tissues overlie the orbital and oral cavities, they are modified as there is no deep fascial layer for support. Accordingly, support does not come from within the space immediately below, but from the rim of the cavities. The transitions between these areas, although not seen in youth, become increasingly evident with ageing.

Surgical anatomy of the face, superficial musculoaponeurotic system, facial spaces and retaining ligaments

The five concentric layers of the face are:^{1,2} (1) skin; (2) subcutaneous tissue; (3) musculoaponeurotic layer; (4) areola tissue; and (5) deep fascia. This five-layered arrangement is most clearly seen in the scalp and forehead due to expansion of the soft tissues as a result of evolutionary expansion of the underlying cranial vault necessary to accommodate the highly developed frontal lobe in humans. It is an excellent place to study the principles of the layered anatomy (Figure 65.2). Layer 4 (the loose areolar tissue) is the layer that allows the superficial fascia (defined as the composite flap of layers 1 through 3) to glide over the deep fascia (layer 5). The simplified anatomy over the scalp gives the basic prototype of layer 4.³ There are no structures crossing this plane, which is essentially an avascular potential space. At the boundaries of the scalp along the superior temporal line and across the supraorbital rim, the scalp and the forehead are firmly anchored by ligamentous attachments. Vital structures such as nerves and vessels are always located in close proximity to the retaining ligaments. In the face proper, although the principles of construction remain the same, there is considerably greater complexity. This is due to the compaction resulting from the absence of forward projection of the midface, as occurs in other species, and the predominance of the orbital and oral cavities that limit the availability of a bony platform for attachment of ligaments and muscles. To secure this five layers to the facial skeleton, an elaborate system of retaining ligaments

Figure 65.1 Regions of the face: The mobile anterior face is functionally adapted for facial expressions and is separated from the relatively fixed lateral face (shaded) which overlies masticatory structures. A vertical line of retaining ligaments (red) separates the anterior and lateral face. These ligaments are, from above: temporal, lateral orbital, zygomatic, masseteric and mandibular ligaments. In the anterior face, the midcheek is split obliquely into two separate functional parts by the midcheek groove (dotted line) related to two cavities: the periorbital part above (blue) and the perioral part below (yellow).

bind the dermis to the skeleton, the components of this system pass through all layers (Figures 65.3 and 65.4).⁴⁻⁶

Layer 1 – skin

The epidermis is a cell-rich layer composed mainly of differentiating keratinocytes and a smaller number of pigment-producing melanocytes and antigen-presenting Langerhans cells. A rich vascular plexus is an important component of the dermis. The thickness of the dermis relates to its function and tends to be inversely proportionate to its mobility. The dermis is thinnest in the eyelids and thickest over the forehead and the nasal tip. The thinner the dermis, the more susceptible it is to qualitative deterioration ageing changes.

Layer 2 – subcutaneous tissue

The subcutaneous layer has two components: the subcutaneous fat, which provides volume, and the fibrous retinacular cutis that binds the dermis to the underlying superficial musculoaponeurotic system (SMAS) of the face.²² Of note, the retinacular cutis is the name given to that portion of the retaining ligament that passes through the subcutaneous tissues. The amount, proportion and arrangement of each component vary in different

Figure 65.2 The face is constructed in five basic layers. This five-layered construct is most evident in the scalp but also exists in the rest of the face, with significant modification and compaction for functional adaptation. Layer 4 is the most significantly modified layer, with alternating facial soft tissue spaces and retaining ligaments. Facial nerve branches also transition from deep to superficial in association with the retaining ligaments through layer 4.

regions of the face. In the scalp, the subcutaneous layer has uniform thickness and consistency of fixation to the overlying dermis. In contrast, in the face proper, the subcutaneous layer has significant variation in thickness and attachments. In specialized areas such as the eyelids and lips, this layer is significantly compacted such that fat may appear non-existent. In other areas, such as the nasolabial segment, it is very thick.⁴ In areas with thick subcutaneous tissue, the retinacular cutis lengthens significantly, predisposing its fibres to weakening and distension with ageing.

Within the subcutaneous tissue, the overall attachment to the overlying dermis is stronger and denser than the attachment to the underlying SMAS.²² This is a result of the tree-like arrangement of the retinacular cutis fibres (see Figure 65.3), with fewer but thicker fibres deep as it rises through the SMAS that progressively divide into multiple fine microligaments as they reach the dermis. This explains why it is easier to perform subcutaneous dissection in the deeper subcutaneous level (just on the surface of the underlying SMAS) than more superficially nearer the dermis, as there are fewer retinacular cutis fibres and the

Figure 65.3 The retaining ligaments of the face can be likened to a tree. The ligaments attach the soft tissues to the facial skeleton or deep muscle fascia, passing through all five layers of the soft tissues. It fans out in a series of branches and inserts into the dermis. At different levels of dissection, it is given different names, such as the retinacular cutis in the subcutaneous layer and ligaments in the sub-SMAS level.

Figure 65.4 Three morphological forms of retaining ligaments of the face.

subcutaneous fat here does not attach directly to the outer surface of the underlying SMAS.

Furthermore, the retinacular cutis fibres are not uniform across the face, but vary in orientation and density according to the anatomy of the underlying deeper structures. As will be apparent when the anatomy of the underlying layer 4 is described, at the location of the retaining ligaments, the vertically orientated

Figure 65.5 The density and strength of the retinacular cutis fibres in the subcutaneous layer vary in different areas of the face. Where they overlie the retaining ligaments, the fibres are denser and orientated more vertically. In these areas, sharp release is usually necessary to raise a subcutaneous flap. In contrast, in areas overlying a space, the fibres are less dense and orientated more horizontally. Here it is relatively easy to elevate a subcutaneous facelift flap.

retinacular cutis fibres are the most dense and are the most effective in supporting for the overlying soft tissues and, in so doing, form boundaries that compartmentalize the subcutaneous fat. These areas, such as the so-called *McGregor's patch* over the body of the zygoma, often require sharp release to mobilize. In between these retaining ligaments in layer 4 are located the soft tissue spaces of the face that facilitate the mobility of the superficial fascia over the deep fascia. Where the subcutaneous fat overlies a space, the retinacular fibres are less dense and orientated more horizontally, as a result of which, the tissues tend to separate with relative ease, often with just simple blunt finger dissection (Figure 65.5). This variation in the density and orientation of the retinacular cutis fibres in the subcutaneous fat is the anatomical basis for the compartmentalization of the subcutaneous fat into discrete compartments, only recently described.⁷

Layer 3 – musculoaponeurotic layer

The muscles of facial expression are unique and fundamentally different from skeletal muscles beneath the deep fascia because they are situated within the superficial fascia and they move the

soft tissues of which they are a part. All muscles of facial expression have either all or the majority of their course within layer 3 and they are predominantly located over and around the orbital and oral cavities. In the prototype scalp, the occipital-frontalis moves the overlying soft tissue of the forehead, while its under-surface glides over the subgaleal aponeurotic space (layer 4). Layer 3 is continuous over the entire face, although for descriptive purposes, different names are given to certain parts according to the superficial muscle within. It is called the galea over the scalp, the temporoparietal (superficial temporal) fascia over the temple, the orbicularis fascia in the periorbital region, the SMAS over the mid and lower face and platysma in the neck.⁸

Within layer 3, the facial muscles themselves have a layered configuration, with the broad, flat muscles forming the superficial layer that covers the anterior aspect of the face. The frontalis covers the upper, orbicularis oculi the middle and the platysma the lower thirds, respectively. The muscles of this layer have minimal direct attachment to the bone, stabilized to the skeleton at their periphery indirectly by the vertically orientated retaining ligaments as noted earlier. The frontalis is fixed along the superior temporal line by the superior temporal septum, the orbicularis oculi laterally by the lateral orbital thickening and the main zygomatic ligament at its inferolateral border and the platysma at its upper border by the lower masseteric ligament. The deeper muscles in layer 3 provide greater functional control of the sphincters over the bony cavities. For the upper third, these are the corrugators and procerus and around the oral cavity, the elevators (zygomaticus major and minor, levator labii superioris, levator angularis oris) and levator angul oris and the depressors (depressor angularis oris, depressor labii inferioris) around the oral sphincter and the mentalis.

Layer 4

Layer 4 is the plane in which dissection is performed in sub-SMAS facelifts. It is an area of significant complexity and contains the following structures: (1) soft tissue spaces, (2) retaining ligaments, (3) deep layers of the intrinsic muscles passing from their bone attachment to their more superficial soft tissue origin, and (4) facial nerve branches, passing from deep to superficial. Functionally, a series of soft tissue spaces exist in layer 4 to allow independent movement of the periorbital and perioral muscle of facial expressions over the deep fascia responsible for mastication directly beneath the muscles of facial expression. The retaining ligaments of the face are strategically placed within and reinforce the boundaries between the soft tissue spaces (Figure 65.6).¹

In the lateral face, immediately in front of the ear, extending 25–30 mm forward of the ear cartilage to the posterior border of the platysma, is a diffuse area of ligamentous attachment, described by Furnas as the platysma auricular fascia (PAF). As no facial expression occurs here, the dermis, subcutaneous tissue, SMAS and the underlying parotid capsule (layers 1–5) are bound together as an area of diffuse retaining ligament. Layer 4 is reduced to a layer of fusion here, without a soft tissue

space. In contrast, in the anterior face where there is considerable movement over and around the bony cavities, the ligaments are significantly compacted and arranged around the edges of the bony cavities. These boundaries provide the last position where there is underlying deep fascia for the mobile shutters of the lids and lips to be supported. Importantly for the surgeon, the retaining ligaments also act as transition points for the facial nerve branches to pass from deep to superficial on their way to innervate their target muscles.

Soft tissue spaces of the face are in two forms: (1) those overlying bony cavities, such as the preseptal space of the eyelid over the orbit and the vestibule of the oral cavity, under the lips and the lower nasolabial segment of the cheek and (2) those overlying bone, where the spaces allow the overlying superficial fascia to glide freely over the underlying bone.

Layer 5

The deep fascia, the deepest soft tissue layer of the face, is formed by the periosteum where it overlies bone. Over the lateral face, where the muscles of mastication (temporalis and masseter) overlie the bone, the deep fascia is instead the fascial covering of the muscles, the deep temporal fascia and masseteric fascia above and below the zygomatic arch, respectively. The parotid fascia is also part of the deep fascia. The investing deep cervical fascia is the corresponding layer in the neck where it covers the supraomohyoid muscles and splits to form the submandibular space that contains the submandibular gland. The deep fascia, although thin, is tough and unyielding and gives attachment to the retaining ligaments of the face. In the mobile shutters over the bony cavities,

Figure 65.6 Topographical anatomy of layer 4 over the lateral face. Spaces (blue), ligaments (red) and the areas of important anatomy (stippled). The largest area of ligamentous attachment, the platysma-auricular fascia (PAF), dominates the posterior part of level 4 at the least mobile part of the face. The lateral face transitions into the anterior face at the vertical line of retaining ligaments. Immediately above and below the arch of the zygoma are the triangular-shaped areas that contain the important anatomy proceeding from the lateral into the anterior face.

the deep fascia is absent, being replaced by a mobile lining derived from the cavities, that of the conjunctiva or oral mucosa.

Anatomy over the cavities in the skeleton

The general pattern of the five-layered anatomy is modified where the orbital, oral and nasal cavities are present over the anterior face (Figure 65.7). Only the outer three-layer composite continues into the soft tissue overlying the cavities. The SMAS layer within this composite includes the sphincteric orbicularis muscles that extend to the free edge of the soft tissue aperture of the eyelids and lips. The retaining ligaments, which are such a key feature of the five-layered anatomy, are not present over the cavities. There are thus anatomical and functional transitions from the relative stability over fixed areas to the high mobility of the soft tissue shutters over the cavities. In order to support this composite, the retaining ligaments are condensed and compacted along the bony orbital rim (Figure 65.8). This is the anatomical basis for the periorbital ligament around the orbit, of which the lower lid part is the orbicularis-retaining ligament, which stabilizes the orbicularis oculi to the orbital rim periosteum. Around the oral cavity, the ligaments arise from the

platform of the body of the zygoma, from the deep fascia over the masseter and from the body of the zygoma.⁹

The deeper component of the eyelid and lips are derived from the origin of the cavity and are not an extension of the facial soft tissues. In the eyelid, the deeper lid muscles with their related aponeurosis (levator and capsulopalpebral fasciae) and fat are retained by the fascial system of the septum orbitale. The free edges of the upper and lower eyelids obtain their ligamentous support from the tarsal plates, with their canthal tendon attachments to the medial and lateral orbital rims. In the pretarsal area, the superficial and deep lid structures, the anterior and posterior lamellae, merge. But in between, the orbital rim and the pretarsal area of the lower lid the, lamellae remain quite separate (i.e. the preseptal orbicularis does not have an attachment to the septum orbitale). This is the anatomical basis for the surgically significant preseptal space of the lower lid. In the upper lids, there is not an equivalent space as the submuscular fat pad over the superior orbital rim continues on the outer surface of the septum orbitale where it is adherent to the overlying fascia on the underside of the orbicularis almost down to where the levator crosses into the orbicularis.

The extent of the vestibule of the oral cavity, covering the maxilla and the mandible, has a major impact on the susceptibility to ageing of the overlying soft tissue. The skeleton underlying the space is unavailable to provide ligamentous attachment for support of the soft tissues that cover this large area. The extreme mobility of the lip and adjacent part of the cheek renders it susceptible to ageing changes and the indication for a lower facelift is largely to correct ageing changes in this unsupported tissue.

Figure 65.7 The anatomy over the skeleton and over bony cavities, showing the relationship of the soft tissue spaces to bony cavity spaces.

Figure 65.8 The system of retaining ligaments situated around the bony cavities stabilizes the soft tissue over the cavities.

Facial spaces

A large part of the sub-SMAS layer 4 consists of soft tissue 'spaces'. These spaces have defined boundaries that are strategically reinforced by retaining ligaments. Significantly, these areas are by definition anatomically 'safe spaces' to dissect, as no structures cross within and all branches of the facial nerve are outside these spaces. As the roof of each space is the least supported part, they are more prone to developing laxity here with ageing, compared to their ligament-reinforced boundaries. This differential laxity accounts for much of the characteristic changes that occur with ageing. Once a space has been surgically defined to its boundaries, the retaining ligaments in the boundary can then be precisely released under direct vision to achieve the desired mobilization, while preserving the vital structures closely associated with the ligaments. A brief description of surgically significant facial soft tissue spaces is given below.

Upper temporal space

The upper temporal space separates the temporoparietal fascia from the deep temporal fascia and is separated from the forehead by the superior temporal septum (STS) along the superior temporal line (Figure 65.9).³ Antero-inferiorly, the upper space is separated from a lower triangular temporal area that contains important anatomy, by the inferior temporal septum (ITS). These septi merge at the triangular-shaped zone of adhesion called the temporal (orbital) ligament. The upper temporal space provides safe surgical access to the lateral brow and upper midcheek. The space can be readily opened by blunt dissection to its boundaries. Once identified, the boundaries are then released by precise sharp dissection. The STS can be released sharply, taking care only to preserve the lateral (deep) branch of the supraorbital nerve, which runs parallel to the septum about 0.5 cm medial to it. The ITS provides a marker to the important anatomy here as the temporal branches of the facial nerve are located parallel to and immediately inferior to this septum. To release the ITS, the ceiling of the space is gently lifted off the deep temporal fascia floor, which three-dimensionalizes the septum in preparation for gentle release at the level of the floor, bearing in mind the frontal branches are located on the underside of the temporoparietal fascia in the ceiling, under the roof of the lower temporal area. Once released, the sentinel vein comes into view. The sentinel vein is not a good landmark for locating the temporal branches as they course cephalad to the vein, between it and the ITS, where they travel in a layer of fat suspended on the underside of the temporoparietal fascia.

Prezygomatic space

This triangular-shaped space overlies the body of the zygoma, its floor covering the origins of the zygomatic muscles. The space allows the independent displacement of the obicularis oculi (pars orbitale) in its roof from the zygomatic muscles

Figure 65.9 The upper temporal space and the retaining ligaments of the temple. The boundaries of the space are the superior temporal septum (STS) and the inferior temporal septum (ITS), which are extensions of the temporal ligament adhesion (TLA). No structures cross the temporal space. The TLA continues medially as the supraorbital ligamentous adhesion (SLA). Inferior to the temporal space is the triangular-shaped area of important anatomy (stippled). Crossing Level 4 in this area are the medial and lateral branches of the zygomatic temporal nerve (ZTN) and the sentinel vein. The temporal branches of the facial nerve (TFN) course on the underside of the temporoparietal fascia over the area immediately inferior to the ITS. The periorbital septum (PS, green) is on the orbital rim at the boundary of the orbital cavity. The lateral orbital thickening (LOT) and the lateral row thickening (LBT) are parts of the periorbital septum.

under the floor. Contraction of the overlying orbicularis elevates the prezygomatic soft tissues, which results in zygomatic smile lines (below the crows feet) (Figure 65.10).^{10,11} With ageing laxity the roof of the space rests at a lower level. As a result, there is a now a greater amplitude of movement on orbicularis contraction, exaggerating the zygomatic lines with ageing. This ageing of the prezygomatic space, with bulging over its roof accentuated by its well-supported boundaries, is the anatomical basis for the clinical entity variously described as malar mounds, bags or malar crescent. These deformities indicate the presence of significant laxity and the treatment is directed to tightening the laxity of the roof.

Premaxillary space

This quadrangular-shaped space (medial to the prezygomatic space) overlies the maxilla. Its floor is formed by the levator labii superioris. The space allows the independent displacement of the obicularis oculi in its roof from the lip elevators under the floor. Figure 65.11 details the anatomical relations of the premaxillary space.¹² This space is clinically significant in that laxity over its roof contributes to the deepening of the nasolabial fold with ageing.

Figure 65.10 The prezygomatic space overlies the body of the zygoma. The origin of the zygomatic muscles extends under the floor. The roof is formed by the orbicularis oculi line by the SOOF (suborbicularis oculi fat). The upper ligamentous border formed by the orbicularis-retaining ligament is not as strong as the zygomatic ligament-reinforced lower border.

Lower premasseter space

This space overlies the lower half of the masseter and is analogous to the temporal space in that it overlies the deep fascia of a muscle of mastication (Figure 65.12).¹³ This gliding soft tissue plane allows opening of the jaw without restriction and avoids excessive distortion of the overlying soft tissues. The roof of this space is formed by the platysma. The lower premasseter space has profound clinical significance as it is the anatomical basis for the development of jowls with ageing. Laxity in the roof of the space, particularly where it has a weakened attachment to the anterior masseter by the masseteric ligaments and its inferior boundary where there is no ligament, manifests as the labiomandibular fold and jowl, respectively. The relatively stable fixation at the anterior-inferior corner of the premasseter space provided by the mandibular ligament accounts for the dimple that is commonly seen separating the labiomandibular fold above and the jowl below.

Middle premasseter space

The middle premasseter space is a rectangular space cephalad to the lower premasseter space (Figure 65.13).¹⁴ Its floor is formed by the masseteric facial and its roof by the SMAS. Its an important

Figure 65.11 The anatomy and key relations of the premaxillary space. LLS, levator labii superioris; ION, infraorbital nerve, TTL, tear trough ligament, ORL, orbicularis-retaining ligament.

facial soft tissue space in sub-SMAS facelift in that it is an anatomically safe area to dissect, with facial nerve branches located in its superior and inferior boundaries. The parotid gland and the duct are closely associated with the upper boundary of the middle premasseter space.

Buccal space

This is one of the deep facial spaces, being like the submandibular space (which contains the submandibular gland), deep to the deep fascia (layer 5). The buccal space is located in the anterior face, medial to the anterior border of the masseter above the level of the oral commissure in youth. The space and its contents, the buccal fat, facilitates movement of the overlying nasolabial segment of the midcheek as well as buffering this area from excessive motion from jaw movement. Ageing and attrition of the boundaries, particularly of the masseteric ligaments inferiorly result in the platysma being less firmly bound to the masseter. This allows the space to enlarge and also allows the buccal fat to prolapse inferiorly, below the level of the commissure into the lower face. As the buccal fat comes to overlie the anterior border of the lower masseter it results in increased prominence of the labiomandibular fold and jowl.

Figure 65.12 The rhomboid-shaped premasseter space overlies the lower half of the masseter. The roof of the space is formed by the platysma. The posterior border is defined by the anterior edge of the strong PAF and the anterior border is reinforced by the masseteric ligaments near the anterior edge of the masseter. The inferior boundary is mesenteric-like and does not contain any ligament. Weakness of attachment of the platysma roof at the inferior boundary leads to the formation of the jowl directly behind the strong mandibular ligament. The buccal space containing the buccal fat is anterior to the upper masseteric ligaments. All facial nerve branches course around and outside the space. The surgically important mandibular branch, after leaving the fixed PAF, courses under the inferior boundary of the space then rises onto the highly mobile outer surface of the mesenteric inferior border before reaching the mandibular ligament.

Figure 65.13 The middle premasseter space is located within the concavity of the parotid overlying the anterior masseter, above the lower space. The upper and lower buccal trunks of the facial nerve course outside the space within the upper and lower boundaries of the space. The masseteric process of the buccal fat pad is the only content and is variable.

Retaining ligaments of the face

To illustrate key concepts that retaining ligaments function to bind all five layers of the facial soft tissues together and that they are the anatomical basis for cutaneous grooves (seen between areas of laxity/bulges), let us examine the midcheek. The tear trough/orbicularis-retaining ligament complex is the key retaining ligament of the upper midcheek.¹⁵ It is located and closely follows the edges of the orbital rim. This retaining ligament system separates bony cavity (the orbital cavity) above from the bony platform (that of the midcheek skeleton) below, functioning to stabilize and secure the soft tissues of the lower eyelid before it transitions from the relative stability over the bone to the mobile area over the orbital cavity.

The *tear trough ligament* is a true osteocutaneous ligament originating from the maxilla and inserting into the dermis of the tear trough, passing through and binding all five soft tissue layers together.¹⁵ As previously shown, this is the retaining ligament that is the anatomical basis for the tear trough deformity (Figure 65.14). Laterally, the tear trough ligament continues as the orbicularis-retaining ligament. The orbicularis-retaining ligament has previously been demonstrated to be the anatomical cause of the palpebromalar groove. The continuity of the tear trough ligament with the orbicularis-retaining ligament then explains the observation that with more advance ageing, the tear trough becomes continuous with the palpebromalar groove, forming a prominent cutaneous groove sometimes called a prominent 'lid-cheek junction'. This demonstrates the key role facial soft tissue-retaining ligaments play in the cutaneous grooves seen with ageing.

Facial nerve branches

The danger zone for facial nerve injury has been well described in the literature, but is of limited value to the surgeon due to the two-dimensional perspective that gives the expected course of the nerve relative to surface landmarks.^{16,17} Confidence when approaching the nerve surgically comes from an understanding of the three-dimensional course of the nerve relative to the layered anatomy as described above and visually identifying the nerves in relation to defined landmarks (Figure 65.15).¹⁸ The facial nerve branches exit the parotid gland and remain deep to layer 5 in the lateral face. As they approach the anterior face, the branches traverse layer 4 to reach the underside of mimetic muscles of the face. It is at these transition points across layer 4 that the nerves are at greatest risk of injury. The transitions occur at predictable locations, in close association with retaining ligaments that provide stability and protection for the nerves. The surgical release of these ligaments to gain the needed mobility should be performed with extreme care on account of the proximity of the nerves.

The surface marking of the temporal branch of the facial nerve is along the Pitanguy line, from a point 0.5 cm below the

Figure 65.14 The tear trough ligament (TTL), the anatomical basis for the tear trough deformity. ORL, orbicularis-retaining ligament; OO, orbicularis oculi; PZs, prezygomatic space; LLS, levator labii superioris; Zmj, zygomaticus major; Zmi, zygomaticus minor.

tragus to a point 1.5 cm lateral to the supraorbital rim.¹⁹ It is traditional teaching that once the temporal branch exits the parotid, it immediately runs superficially from the deep fascia and comes to lie just deep to the SMAS as it crosses the arch of the zygoma.^{20,21} Because of its superficial location, surgical transection of the SMAS here, so-called high SMAS transection (i.e. at or above the arch) has been generally discouraged. It is now apparent that the nerve is deeper than was previously thought as it crosses the zygomatic arch. A histological study confirmed that the temporal branches are in transition from where they exit the parotid below the zygomatic arch, to where they enter the underside of the temporoparietal fascia some 2 cm above the arch.²² They course in a tissue layer (layer 4), just deep to the temporoparietal fascia (layer 3) and immediately superficial to the periosteum and above that, the temporalis fascia (layer 5), all along protected by a fascial, fatty layer, which is an upward

Figure 65.15 The relationship between facial nerve branches, spaces and retaining ligaments. The nerves stay deep to and outside the spaces at all times in the lateral face. In the boundary between the lateral and anterior face, the facial nerve branches transition from under layer 5 to enter layer 3, always in close association with the retaining ligaments of the face.

prolongation of the parotid-masseteric fascia and named the parotid-temporal fascia. In another study, the temporal branch was noted to transition to under the temporoparietal fascia (layer 3) at a distance of 1.5–3 cm above the zygomatic arch. The temporal branch would have transitioned to the underside of the temporoparietal fascia before the nerve crosses the sentinel vein more cephalically. Thus, once the sentinel vein is visualized from the temporal incision, the temporal branches would be located in the roof of the upper temporal space, in the wafer-like layer under the temporoparietal fascia.

The zygomatic branch exits the parotid gland deep to the deep fascia just below the zygoma and cephalad to the parotid duct. It travels horizontally on the masseter with the transverse facial artery. At approximately the origin of the zygomaticus major muscle, strong retaining ligaments (zygomatic ligaments) arise from the body of the zygoma. Here, the zygomatic nerve transition to the underside of the muscle it innervates. The zygomatic branch runs under zygomaticus major and minor and supplies them from the deep aspect in close association with the zygomatic ligaments. At the lateral border of zygomaticus major, a branch is usually given off to supply the orbicularis oculi, entering the muscle at its inferolateral corner. Careful dissection by vertical spreading of the scissors is crucial to avoid damaging this branch here.

The upper buccal trunk exits the parotid, about in line with, but superficial to the parotid duct and continues deep to the investing masseter fascia, close to but outside the upper boundary of the middle premasseter space. Approaching the anterior edge of the masseter, this branch leaves the floor under the masseter fascia in close association with upper key masseteric ligament. The lower buccal trunk leaves the parotid lower down, at about the level of the earlobe and remains under the

masseter fascia close to the lower boundary of the middle pre-masseter space. Similarly, upon approaching the anterior edge of the masseter, the lower buccal trunk transitions from deep to gain the underside of the SMAS in close association with the lower key masseteric ligament. After the nerves reach level 3, the zygomatic, upper and lower buccal trunks and mandibular branch connect with each other before continuing their course to innervate the mimetic muscles. This accounts for the overlap in muscles innervated by these nerves.

The temporal and mandibular branches are the most significant in terms of surgical risks because of the lack of cross-innervation of their target muscle. The marginal mandibular nerve is at risk where it is fixed by its close association with the retaining ligaments. Early in its course, around the angle of the mandible, this is within the PAF, and then well anteriorly by the mandibular ligament. Over most of its course, the mandibular branch is mobile, being in relation to the inferior boundary of the pre-masseter space. It is not necessary to dissect in the vicinity of the nerve because of the inherent mobility of the platysma where it overlies the jaw and submandibular area. The mobility of the nerve as it travels within the inferior membranous boundary of the lower pre-masseter space accounts for the reported variability of the location of this part of its course (occasionally below the mandible).^{23,24}

Ageing changes of the face

The youthful face has the general appearance of high rounded fullness, whereas the ageing process is characterized by a look of depletion and sagging, suggestive of tiredness. Changes with ageing occur at every level of the facial anatomy, starting with the facial skeleton. Current understanding of the ageing process remains largely empirical, given that it is based on the effectiveness of treatments designed to satisfy the requests of patients for a younger appearance. Historically, stretching of loose facial skin (traditional facelift), removal of apparent tissue excess (traditional blepharoplasty), tightening the dermis and evening the complexion (early phenol peels and CO₂ laser resurfacing) and, in recent years, soft tissue volume augmentation (lipofilling and soft tissue fillers) have all had a positive impact on rejuvenating appearance. The success of each is attributed to having reversed a cause of facial ageing. Yet, when each of these modalities is continued as the sole treatment, to further reverse the ageing appearance, the results tend to be bizarre, leading to the conclusion that multimodal therapy is required to further reverse, what must be, multiple components of the ageing process.

An understanding of the changes that occur in the layered anatomy forms the basis for logical treatment. Changes of the skin are readily observable and changes in the skeleton affecting layer 5 can also be observed radiologically. Because the changes within the superficial fascia (layers 2 and 3) are not directly measurable, empiricism has remained prevalent. A correlation

of the surface anatomy changes of ageing with the anatomy of layers 2, 3 and 4 indicates that bulging occurs over the roof of soft tissue spaces, which stand out in contrast to the absence of bulging of the adjacent cutaneous grooves. The grooves reflect the restriction imposed by the dermal insertions of the retaining ligaments at the boundaries of the spaces. The degree to which the bulging reflects true elongation from primary tissue degeneration and laxity and how much it is 'apparent' laxity secondary to loss of volume (skeletal and soft tissue) remains unanswered.

Skin

Skin ageing is influenced by genetics, environmental exposure, hormonal changes and metabolic processes. With ageing, the supple skin of youth becomes thinned and flattened, with loss of elasticity and architectural regularity.²⁵ Atrophy of the extracellular matrix is reflected by the decreased number of fibroblasts and decreased levels of collagen (especially types I and III) and elastin in the dermis. Although chronological skin ageing and photo-ageing can be readily distinguished and considered separate entities, both share important molecular features, that of altered signal transduction that promote matrix metalloproteinase (MMP) expression, decreased procollagen synthesis and connective tissue damage. Oxidative stress is considered of primary importance in driving the ageing process, resulting in increased hydrogen peroxide and other reactive oxygen species (ROS) and decreased antioxidant enzymes. These changes result in gene and protein structure alterations. Other environmental factors, notably smoking, accelerates skin ageing by between 10 and 20 years. Increased collagenase and decreased skin circulation have been suggested as possible mechanisms. The muscles of facial expression flex the skin in a specific pattern. As the underlying collagen weakens and the skin thins, the dermis loses its capacity to resist the constant force of the muscles and these lines become etched in the skin, ultimately even at rest.

Subcutaneous tissue

The fibrous and fat components in the subcutaneous tissue are not uniform but arranged in discrete compartments. Over specific sites, due to its prominence, the subcutaneous fat has been given specific names such as the malar fat pad and nasolabial fat. The boundary of these subcutaneous compartments corresponds to the location of the retaining ligaments, which pass superficially to insert into the dermis. In youth, transition between compartments is smooth and non-discernible. With ageing, a series of concavities and convexities develop, which separate these compartments. These changes have been attributed to a number of causes, including fat descent, selective atrophy and hypertrophy and attenuation of the retaining ligaments that causes the fat compartments to become malpositioned. It is apparent now, however, that fat descends minimally with ageing. As noted, the subcutaneous fat is not a confluent layer that can descend with ageing.

Distinct compartmentalization by the retaining ligaments holds the fat in its relative positions.

Muscle ageing

Skeletal muscles, in general, have been noted to atrophy up to 50% with age. This may be applicable to the muscle of mastication, such as the temporalis and masseter (compounded by the decreased demand and deterioration of the dentition with ageing), although no specific study on the effect of ageing on these muscles has been done to date. The mimetic muscles of the face, in contrast to skeletal muscles, may not undergo the same degree of degeneration with ageing because of their constant use with facial expression. The orbicularis oculi has been noted to remain histologically unchanged with no loss of muscle fibres, adherence to surrounding tissues or ptosis with ageing. The upper lip elevators, zygomaticus major and levator labii superioris were also noted to remained unchanged with ageing, based on MRI of their length, thickness and volume. In contrast, the upper lip orbicularis atrophies with ageing, with decreased muscle thickness, smaller muscle fascicles and increase in surrounding epimysium.

Facial spaces and retaining ligaments

The multilinked fibrous system attenuates with ageing, with decreasing strength of the ligaments and increasing laxity. The spaces expand with ageing as well, to a greater extent than the laxity that develops in the ligaments within their boundaries,

resulting in bulges between areas of relative fixations.¹³ Accordingly, the spaces dissect easily in older patients, and the boundaries widen as the ligaments weaken. In young people, the spaces are more potential than real and do not open quite so easily with blunt dissection (Figure 65.16).

Bone changes

The facial skeleton changes dramatically with ageing (Figure 65.17) and this has a profound impact on the appearance of the face with ageing (Figure 65.18).²⁶ At birth, the facial skeleton is underdeveloped and rudimentary. This explains why infants and toddlers often transiently have distinct midcheek segments (despite excellent tissue quality), which disappear as they grow older with the expansion of the midcheek skeleton. Peak skeletal projection is probably attained in early adulthood. Thereafter, although certain areas continue to expand, selective areas of the facial skeleton undergo significant resorption. Areas with strong predisposition to resorption include the superomedial and inferolateral aspects of the orbital rim, the midface skeleton, particularly that part contributed by the maxilla, including the pyriform area of the nose and also the prejowl area of the mandible. The resultant deficiencies in the skeletal foundation have a significant effect on the overlying soft tissues. In the midcheek in particular, retrusion of the maxilla causes increased prominence of the tear trough and the nasolabial folds. The retrusion of the facial skeleton causes the origin of the multilinked fibrous retaining ligaments to be displaced

Figure 65.16 In youth, the spaces are tight and more potential than real. The retaining ligaments are stout and the transition between spaces and spaces are not discernible. With ageing, spaces expand to a greater extent than the laxity that develops in ligaments within their boundaries, resulting in bulges between areas of relative fixations. These spaces open with relative ease with blunt dissection.

Figure 65.17 Arrows indicate the areas of the craniofacial skeleton that are susceptible to resorption with ageing.

posteriorly. This pulls the skin inwards, exaggerating the concavity between the areas of relative convexity that develop with ageing. Retrusion of the midcheek with loss of projection gives the visual impression of tissue descent with ageing. Some patients have a congenitally weak or inadequate skeletal structure. In such cases, the skeleton may be the primary cause of the manifestations of premature ageing. Accordingly, patients who suffer premature facial ageing, a weakness of the relevant part of the underlying skeleton is immediately suspect and should be addressed in order to obtain better aesthetic results.

Regional changes observed with the ageing face

Temple and forehead

The skin of the temple differs from that of the forehead, being thinner and less firmly supported to the underlying layers. The loose attachment reflects the underlying temporal space, which is extensive, and the nature of the surrounding temporal ligaments that are septal like and do not continue through the thin, loose subcutaneous layer 2 over the temple to fix to the dermis as do facial ligaments elsewhere. This explains why deep layer procedures in the temple are not as effective in toning the overlying skin as they are, for example, in the cheek.

Figure 65.18 The darker areas denote areas of greatest bone loss. Note how the stigmata of ageing as manifested by the facial soft tissues correspond to the areas of weakened skeletal support due to bone loss.

Corrugator muscle contraction is associated with the emotional states of grief and sadness. The transverse head of corrugator supercilii moves the eyebrow medially and produce vertical glabella lines. The oblique head of the corrugator, the depressor supercilii and the medial fibres of the obicularis oculi act in concert to depress the medial brow and produce oblique glabella frown lines. The procerus, also a brow depressor, causes transverse nasal skin lines. Laterally, the action of the lateral fibres of the obicularis oculi with the transverse head of the corrugator supercilii promotes lateral brow ptosis. The ptosis of the lateral brow together and to a lesser extent the laxity of the skin with ageing produces a pseudoexcess of the upper eyelid skin. Frontalis muscle hypertonicity from lateral brow skin hooding and its reaction to the action of antagonistic muscles (corrugator supercilii, obicularis oculi and procerus) results in the development of transverse forehead skin lines.

The medial brow, in contrast, seldom descends with ageing and in fact may rise. The mechanism responsible for this includes the chronic activation of the frontalis muscle. This may

either be to elevate the brow/eyelid complex associated with clinical or subclinical levator system weakness or to relieve visual field obstruction due to excess lateral upper eyelid skin. Anatomically, the frontalis muscle ends at approximately the temporal fusion line (STS). Lateral to this, there is no upward vector to counteract the downward pull of brow depressors and gravity on the lateral brow. This may explain why descent preferentially occurs at the lateral brow.

The midcheek

The midcheek is the anterior part of the midface. It is triangular in shape and bounded superiorly by the pretarsal part of the lower eyelid, medially by the side of the nose and the nasolabial groove below, and laterally around the lateral cheek where the arch of the zygoma meets the body. A smooth rounded midcheek is a powerful image of youth and gives a certain freshness to the face. With ageing, the three midcheek segments become clearly discernible, as they become separated by the three cutaneous grooves of the midcheek: the nasojugal, palpebromalar and midcheek grooves. This 'segmentation' of the midcheek has a profound impact on appearance and is responsible for giving the 'tired' look we associate with ageing.

The soft tissues of the midcheek are structurally composed of three segments or 'modules', with each overlying a specific part of the midcheek skeleton (Figure 65.19). The lid–cheek

segment overlies the prominence of the inferior orbital rim, the malar segment overlies the body of the zygoma and the nasolabial segment overlies the anterior surface of the maxilla. The skeletal foundation of the midcheek borders the three bony cavities of the anterior face, the orbital, nasal and oral cavities. Because of the many spaces and limited bony support available, the midcheek has some intrinsic structural weaknesses. Three factors make the midcheek susceptible to ageing changes. These are (1) the wedge shape of the soft tissues of the midcheek, which are thin above and thicker below, (2) the natural posterior incline of the midcheek skeleton from the relative prominence of the infraorbital rim and (3) the significant retrusion as a result of resorption of the maxilla with ageing. This is not uniform, as the maxilla recedes more medially and inferiorly. With early ageing, the retrusion of the maxilla, along with a slight descent of the wedge-shaped cheek soft tissue results in an appreciable reduction of volume of the upper cheek. The result is that the small amount of orbital fat over the prominent edge of the infraorbital rim, (originally concealed by the volume of the upper cheek), now becomes revealed, especially the underside of the lid fat bulge over the middle part. The visual impression is of a 'lengthened' lower lid. At the same time, the increased thickness of the soft tissue mass over the lower cheek tends to conceal the degree of maxillary resorption and gives the profound visual impression that the soft tissue mass has descended into the lower part of the midcheek.²⁷

Of the three segments of the midcheek, the lower lid segment changes the most dynamically with ageing. It has two distinct grooves across its surface that varies in their expression during the ageing process, often coexisting. The upper is the infratarsal groove at the junction of the pretarsal and preseptal parts of the eyelid. It defines the lower boundary of the pretarsal bulge. The pretarsal bulge in youth is the visual separation of the lid above and the cheek below. This so-called 'high lid–cheek junction' is located well above the infraorbital rim and is a characteristic of youth. The infratarsal groove location does not change with ageing, although its contour usually fades. The lower groove is the lid–cheek junction that relates to the lower edge of the pre-septal part of the lid. It is not usually present in youth and appears with ageing and then progressively deepens and descends slightly over time. Its shape when it first appears is a gentle C contour but as it 'descends', particularly in its central portion, its shape changes to a progressively more angulated V shape with the medial side being formed by the developing nasojugal groove and the lateral side by the palpebromalar groove. The centre of the V, the lowest and deepest part has the nasojugal groove continuing down the cheek as the midcheek groove that separates the cheek into the malar and nasolabial segments.

The reason why this contour demarcation changes while the skin itself does not descend is explained by difference in the tissue layers. In level 4, the orbicularis-retaining ligament is not rigid where it is over the centre of the inferior orbital rim, so

Figure 65.19 The midcheek has three segments, the lid–cheek segment (blue) and the malar segment (green) are within the periorbital part and are adjacent to the nasolabial segment (yellow) in the perioral part, which overlies the vestibule of the oral cavity. The three grooves define the boundaries of the three segments and interconnect like the italic letter Y. The palpebromalar groove (1) overlies the inferomedial orbital rim and the nasojugal groove (2) overlies the inferolateral orbital rim, then continues into the midcheek groove (3).

distension results in relative sliding between it and layer 3, the orbicularis oculi. As the lid–cheek junction becomes more prominent, it visually takes over from the infratarsal groove and becomes the new separation between the lower eyelid and the cheek. This is the basis for the commonly used but inaccurate phrase ‘lengthening of the lid cheek junction with ageing’ which is in fact the result of a visual shift from the prominence of the infratarsal groove in youth to the lid–cheek junction with age. Correction of the ageing of the lid–cheek segment of the mid-cheek, the visibly descended contour of the lid–cheek junction and long lower lid has gained the colloquial name of ‘blending the lid cheek junction’.

Lower face

The jowl and the labiomandibular fold in the lower face are not present in youth and develop with ageing. With the description of the concept of soft tissue spaces of the face, and specifically the premaseter space, the mechanism for the formation of the jowl can now be understood on an anatomical basis. With the onset of ageing, laxity develops in the roof of the premaseter space associated with attenuation of the anterior and inferior boundaries. The major retaining ligaments (the key masseteric and mandibular) in contrast remain relatively strong and at these locations the superficial fascia remains firmly fixed to the underlying deep fascia. Distension of the weaker masseteric ligaments at the anterior border of the lower premaseter space (below the key masseteric ligament) and inferior displacement of the buccal fat (within the buccal space) is the anatomical basis for the development of the labiomandibular fold. The mandibular ligament demarcates the transition from the labiomandibular fold above and the jowl below. The jowl develops as a result of distension of the roof of the lower premaseter space with resultant descent of the tissues below the body of the mandible. The more prominent the jowl, the more apparent will be the cutaneous tethering provided by the mandibular ligament. Accordingly, the anatomical solution to correcting these ageing changes is to reduce the inferiorly displaced buccal fat and to tighten the roof of the premaseter space.

Considerations for correcting ageing changes of the face based on the anatomy of the ageing face

Dissection planes

The subcutaneous plane of dissection (level 2) is the most commonly used plane for facelifts, either in isolation or more commonly with some form of SMAS management from the superficial aspect (Figure 65.20). A distinction should be drawn between subcutaneous dissection over the lateral face from that over the anterior face. This plane of dissection is perceived to be ‘safe’ as dissection remains superficial to the facial nerve branches at all times and is the main appeal of level 2 dissection. The subcutaneous dissection can be

performed either in the superficial subcutaneous or deep subcutaneous level. In the former, there is more density of the reticular cutis fibres as the multilinked ligaments branch out before inserting into the dermis. In the latter on the outer surface of the SMAS, there are fewer fibres, which tend to be thicker and stronger. The deep subcutaneous layer is not uniform in its tenacity: some areas, such as over the facial spaces, are inherently easier to dissect, whereas others that overlie the ligament are more adherent and require sharp release. For example, over the malar eminence at MrGregor’s patch, where the zygomatic ligaments are located, sharp release is often needed, as is required over the mandibular ligament. In contrast, in the lower face over the premaseter space, the subcutaneous layer separates quite readily, requiring only blunt finger dissection.

Sub-SMAS dissection (level 4)

In the scalp, this is the preferred tissue plane for dissection as the scalp readily separates from the underlying periosteum (level 5) through the avascular areolar tissue with ease and inherent safety. Bruising and swelling is kept to a minimum because of this anatomy. In the face proper, although the anatomical principles remain the same, level 4 is potentially the most risky plane to dissect because of the facial nerve branches which transition through this level, from level 5, to supply the facial muscles in level 3. However, it should be noted that similar to the situation in the scalp where raising the flap at level 4 gives a robust and structurally integrated composite flap that can be effectively tightened, sub-SMAS dissection in the face has the same advantages and potential benefits. Dissection can be performed safely in level 4 by applying the understanding of the three-dimensional anatomy of the face described earlier; the key being the facial spaces, which provide safe access through this layer. Because these spaces are ‘predissected’, access is quick, atraumatic and easy. An example of this is the lower premaseter space. Subcutaneous dissection is performed to approximately 30 mm anterior to the tragus through the zone of fixation, the PAF, where the SMAS is fused to the deep fascia including the parotid capsule. Because the objective of the surgery is to correct laxity in the mobile anterior face, the level of dissection used in the lateral face is of secondary importance.

A further benefit of leaving the PAF intact is that it is strong and can be used for suture fixation.²⁸ Once dissection has proceeded beyond the PAF (indicated by the posterior border of the platysma), the SMAS should then be incised to gain direct access into the lower premaseter space. The space can then be opened by gentle blunt dissection only, to define the boundaries of the space. The premaseter space below and the prezygomatic space above form a series of spaces in the anterior face (Figure 65.21). The boundaries of the spaces, reinforced by retaining ligaments, are where the important anatomy is located. These need to be precisely released to eliminate their tethering effect on the soft tissues, which is more difficult in younger patients as the

Figure 65.20 Alternative levels for dissection and redraping in facelifts. Dissection can be performed through any one of three alternative layers, namely subcutaneous (level 2), sub-SMAS (level 4) and subperiosteal for the upper two thirds of the face.

Figure 65.21 Using the facial spaces for safe and anatomical access to sub-SMAS dissection in facelifts.

ligaments are denser and stronger. Clear visualization, optimized by lifting the opened adjacent facial spaces, is beneficial. When blunt scissors are used with gentle vertical spreading of the blades the surrounding fat and areolar tissue separate to reveal the ligaments and the facial nerve branches in relation to them. With further lifting, the ligaments become more certainly

defined as they tighten further, at which time they can be safely released, while the nerves, being obliquely orientated, dislodge out of the way, unaffected by the controlled stretching.

The sub-SMAS spaces can be used to safely and atraumatically access various part of the face, the deep temporal space to the lateral brow, the preseptal space to the lower eyelid, and the prezygomatic space to the midcheek.

Level 5

Subperiosteal 'lifts' have the appeal of safety as far as the facial nerve risk is concerned as they are superficial and the remote nerves never cross this plane. However, there are inherent limitations to subperiosteal lifts. The accumulated ageing changes across all five layers are elevated as part of the subperiosteal lift. Overcorrection is required to effect the desired changes of soft tissue shape and skin tone, to compensate for the 'lift-lag' phenomenon, which is proportional to the soft tissue thickness and laxity. Accordingly, subperiosteal lifts work best in areas where the layers are more compacted as the lift-lag is minimized. An example of this is in the brow where subperiosteal lifts are popular and effective. Where the layers are thicker, such as the nasolabial segment of the midcheek, the lift-lag phenomenon significantly limits the improvement that can be achieved.

Because of the unyielding nature of the periosteum, extensive undermining beyond the target area is needed or alternatively a 'periosteal release' immediately beyond the area that requires lifting to isolate the area to a limited island of periosteum.

Placement of sutures

Although adequate surgical release is needed for mobility, it is the surgical fixation that achieves the desired effect by holding the mobilized soft tissue in its new position.²⁹ The strength and tenacity of the superficial fascia is not uniform. The areas where the retaining ligaments are located have an inherent ligamentous reinforcement, making them ideal for suture placement. It is also the location in which traction gives the most natural appearance, as these are the natural suspension sites of the face. Accordingly, the suture fixation should be placed where the retaining ligaments are located. Where fixation sutures are placed in the anterior face in sub-SMAS surgery, they function as replacements for the retaining ligaments that have weakened or have been divided in order to mobilize the composite flap. Accordingly, the replacement sutures should replicate the quality of support provided by the original ligaments as the 'mobile' spaces remain. In this respect braided permanent sutures are advantageous as they stimulate collagen and elastic deposition within the suture similar to a ligament. The PAF, a diffuse ligamentous area on the lateral face, provides an ideal area both anatomically and physically to fix the facelift flap, due to its inherent strength.

Summary

This chapter has been structured to assist the reader to develop a conceptual understanding of facial anatomy and how it changes with ageing. It is the framework that unifies the detailed anatomical information now available in the literature. Once understood, this knowledge will serve as the anatomical foundation for the logical and sound selection of surgical techniques for rejuvenation of the ageing face.

Non-operative facial rejuvenation

Jean Carruthers¹ and Alastair Carruthers²

¹Department of Ophthalmology and Visual Sciences, University of British Columbia, Vancouver, BC, Canada

²Department of Dermatology and Skin Science, University of British Columbia, Vancouver, BC, Canada

Introduction

In the ageing face, atrophy of subcutaneous tissues and changes to bony landmarks allow unsupported skin to fall into wrinkles and folds, and surface irregularities – such as coarse textural changes and alterations in pigmentation – to emerge. Traditionally, facial rejuvenation focused on invasive procedures, such as ablative laser resurfacing or cosmetic surgery, that were associated with considerable periods of recovery, patient discomfort and potential complications. A rise in demand for minimally invasive procedures with appreciable results and fewer side effects over the last two decades has led to a surge in popularity of ‘lunch-time’ treatments, from botulinum toxin (BoNT) and a plethora of injectable fillers, to a growing number of non-ablative light- or energy-based modalities intended to rejuvenate the skin. Used alone or in combination, these non-invasive therapies form the basis of an individualized approach to the modern ageing face.

Botulinum toxin

Botulinum toxin (BoNT) derives from *Clostridium botulinum*, the bacterium identified as the causative agent of botulism (from contaminated blood sausages) in nineteenth-century Germany. The symptoms of botulism include disturbances in vision, speech, and swallowing, with asphyxia and death sometimes occurring 18–36 h after ingestion.¹ The most potent serotype of *C. botulinum* – BoNT type A (BoNT-A) – was originally isolated, purified, concentrated and crystallized for use as a potential biological weapon in 1946, but the idea was abandoned when it became apparent that large doses were required to produce fatal results.²

Clinical experimentation with BoNT-A began in the late 1960s and early 1970s, when Dr Alan Scott (Smith-Kettlewell Eye Research Foundation, San Francisco, California, USA) used a second lot of BoNT-A to non-surgically align the eyes of primates with strabismus and published his findings in

1973.³ He followed his initial encouraging results with a landmark paper in 1980 demonstrating that intramuscular injections of BoNT-A could correct gaze misalignment in humans.⁴ By 1989, BoNT-A had been approved by the US Food and Drug Administration (FDA) for the non-surgical correction of strabismus, blepharospasm, hemifacial spasm and Meige’s syndrome in adults, and clinical use had widened to include the treatment of cervical dystonia and spasmodic torticollis.⁵ In 1992, Carruthers and Carruthers published the first report of the cosmetic use of BoNT-A for the treatment of glabellar frown lines.⁶ Other reports soon followed,^{7,8} along with the first double-blind, placebo-controlled study for the treatment of hyperkinetic facial lines.⁹

Mechanism of action and clinical effect

All serotypes block neuromuscular motor transmission by binding to receptor sites on motor nerve terminals. The light chain of BoNT-A cleaves to a 25 kDa synaptosomal associated protein (SNAP-25), whereas the light chain of BoNT type B cleaves to vesicle-associated membrane protein (VAMP or synaptobrevin).⁵ BoNT inhibits the release of acetylcholine and other neurotransmitters, including substance-P, glutamate and calcitonin-gene related peptide. When injected intramuscularly at therapeutic doses, BoNT produces temporary chemical denervation of the muscle, resulting in a localized reduction of muscle activity. The paralytic effect of the toxin is dose-related, with initial effects occurring within 2–3 days and peaking approximately 1–2 weeks after treatment. Effects generally last around three months; repeated injections can extend the clinical effect for up to 12 months.

Formulations

To date, the FDA has approved three distinct formulations of BoNT-A for both therapeutic and cosmetic purposes, and one formulation of BoNT-B for therapeutic use only. The original formulation of BoNT-A, onabotulinumtoxinA (BOTOX®/BOTOX Cosmetic®/Vistabel®/Vistabex®; Allergan, Inc., Irvine, CA, USA), has been joined by abobotulinumtoxinA (Dysport®;

Ipsen Ltd, UK/Medicis, Scottsdale, AZ, USA; and Azzalure® in 15 European countries; Galderma, France) and icobotulinumtoxinA (Xeomin®/NT-201; Merz Pharmaceuticals, Frankfurt, Germany). Only one formulation of BoNT-B – rimabotulinumtoxinB (Myobloc®/NeuroBloc®; Solstice Neurosciences Inc./Eisai Co., Ltd) – is available in North America. All products differ in terms of diffusion, potency and clinical effect. Likewise, clinical doses vary according to product and are not interchangeable.

Cosmetic use of BoNT-A

In 2002, after numerous open-label studies involving more than 800 subjects, and two large, double-blind, placebo-controlled randomized clinical trials, the FDA approved BoNT-A for the non-surgical reduction of glabellar furrows.¹⁰ Since then, off-label use of the toxin has exploded to include any number of hyperkinetic lines or deep grooves and folds in the face, neck and chest caused or exacerbated by repetitive muscular activity, with a high level of efficacy and patient satisfaction.^{11,12} Moreover, BoNT-A is often used to lift and shape the brow,¹³ widen the eyes,¹⁴ correct facial asymmetry¹⁵ and to reduce muscle thickness of the jaw in patients with masseteric hypertrophy.¹⁶

BoNT-A works particularly well in combination with other rejuvenating procedures, such as soft tissue augmentation and laser, light- or energy-based therapies, where it has been shown to prolong and enhance aesthetic results, especially for the treatment of deeper, more static rhytides and folds. In subjects who require surgical intervention, BoNT-A can be used during and after surgery to prolong surgical results and aid in wound healing; pre- and posttreatment injections stabilize the musculature surrounding the incision while the procedures heal, resulting in improved cosmesis of the scars.¹⁷

Adverse effects and complications

Most side effects of BoNT-A are injection-related and transient, such as swelling, bruising and pain. Complications occur when the toxin diffuses into non-targeted or glandular tissue surrounding the site of injection, due to overenthusiastic doses, inappropriate injection sites or poor technique.¹⁸ In the upper face, adverse events translate into a drooping eyelid or brow (ptosis), watery, dry or crossed eyes, and eyebrows that can appear askew or asymmetrical. Lower face complications impact muscle function, resulting in a flaccid cheek, lopsided smile, incompetent mouth, the inability to whistle, dysphagia and neck weakness. However, when used appropriately by experienced injectors, cosmetic doses of BoNT-A are well tolerated and safe, and over 20 years of clinical use has demonstrated a strong record of safety.¹⁹ Serious adverse events are rare and more likely to occur with the much higher doses used for therapeutic indications, particularly in individuals who may have underlying medical conditions that increase the risk of complications.²⁰

Fillers

While BoNT-A is first-line treatment for dynamic rhytides, deeper lines and folds require volume replacement for adequate correction. The volumizing effect of the first filler – autologous fat – was studied in 1893 when it was harvested and inserted into the face of a 20-year-old man to reconstruct a deeply retracted scar.²¹ Nearly a century later, autologous fat grafting was considered, by some, to be the ideal filling agent, allowing for soft tissue augmentation without any risk of allergy.²² However, although several grafting procedures were performed with variable success, results were often unpredictable and largely dependent on the method of harvesting, type of fat used and injector experience. The procedures themselves were complicated, with only a 25–30% rate of persistence when injected into areas of the face,²³ and rife with adverse effects that included donor site morbidity, calcification of the injected fat and unpredictable reabsorption.²⁴ By the 1980s, interest in using autologous fat had begun to wane, particularly after the introduction of the first ‘modern’ filling agent for human use: bovine collagen.

The most abundant protein in skin, human and animal-based collagen was first injected into volunteers in the late 1970s.²³ Bovine collagen was the first soft tissue augmenting agent approved in the United States,²⁵ but was characterized by a short duration of effect and required skin testing prior to injection. Human-derived collagen – developed to reduce the risk of antigenicity and hypersensitivity reactions – no longer required skin testing but did not last any longer than bovine collagen.²³ This lack of duration, particularly around areas of great animation, was collagen’s greatest disadvantage and was no doubt responsible for its gradual decline in use and eventual disappearance from the market when newer, more durable products arrived on the scene.

The development of synthetic fillers marked a new page in the history of facial rejuvenation. It was now possible to inject into different layers of the skin, and this discovery opened the door for three-dimensional volume replacement to achieve optimal aesthetic results, shifting from the treatment of lines and wrinkles to address the issue of subcutaneous atrophy and fat loss. Filling agents today generally fall under two categories: non-biodegradable and biodegradable.

Non-biodegradable filling agents

Ideal for individuals who desire permanent facial augmentation, non-biodegradable fillers can yield excellent results when used by skilled clinicians. However, because they are not readily broken down or absorbed by the body, they are associated with a higher risk of complications that can be more difficult to resolve.

Liquid injectable silicone

Liquid injectable silicone – purified polydimethylsiloxane – has been approved by the FDA only for intraocular use as a prolonged retinal tamponade during vitreoretinal surgery but has been used for subdermal volume restoration since 1997, when the US Modernization Act allowed physicians to use approved

medical devices and products for off-label indications.²⁶ Silicone oil induces neocollagenesis through fibroplasia in addition to direct volume restoration, but its use has been plagued by controversy thanks to associated complications, including migration and granulomatous reactions that may occur from weeks to decades after injection and can be severely debilitating.^{27,28} However, complications are often the result of improper technique, injection of large volumes and the use of industrial-grade products – frequently adulterated – injected by unlicensed or unskilled practitioners.^{29–31} Use of medical-grade, pure liquid injectable silicone and proper injection protocol – microdroplet serial puncture technique administered at monthly intervals to allow for product stabilization through adequate collagen deposition – can produce exceptional, permanent results,^{32,33} and liquid injectable silicone has been particularly beneficial over the long term in the treatment of HIV-associated facial lipoatrophy,^{33–36} acne scarring, and lip augmentation.^{37–40}

Polymethylmethacrylate

Approved by the FDA in 2006 for the correction of nasolabial folds, polymethylmethacrylate (PMMA; ArteFill®; Suneva Medical Inc., San Diego, CA, USA) is a third-generation filler comprising 20% PMMA microspheres (32–40 µm diameter) and 80% bovine collagen. After implantation, the carrier solution dissipates within 1–3 months, leaving behind the non-resorbable microspheres that induce fibroplasia and become encapsulated by collagen. Because of the animal component, skin testing is required prior to implantation. PMMA is used to treat well-defined, deeper folds and rhytides, as well as facial wasting and cheek depressions.^{41,42} Multiple treatments with small amounts of material are usually required to achieve optimal results and avoid overcorrection. Like silicone oil, the use of PMMA is controversial due to the history of side effects noted with first- and second-generation products (Arteplast® and Artecoll®, respectively),⁴² particularly nodules and beading in more mobile areas, hypertrophic scarring, ridges and granulomatous reactions that were reported to occur up to 6 years after implantation.^{43–48} Although severe complications are not as common with third-generation product,⁴⁹ PMMA is associated with a steep learning curve in terms of patient selection and injection technique and schedule, and should not be attempted by the inexperienced clinician.

Biodegradable fillers

Biodegradable filling agents require regular treatments to maintain the desired results but are less likely to provoke a severe complication and, in some cases, are entirely reversible.

Calcium hydroxylapatite

Calcium hydroxylapatite (CaHA) microspheres (Radiesse®; Merz Aesthetics, Inc., San Mateo, CA, USA) comprise biocompatible, smooth CaHA spherical particles (25–45 µm) that are identical in composition to bone material and suspended in an aqueous

carboxymethylcellulose gel carrier. The microspheres induce histiocytic and fibroblastic response, stimulating the production of collagen around the implant, while the gel carrier is absorbed. CaHA lasts for a year or more before the microspheres are broken down into calcium and phosphate ions and excreted.^{50,51} CaHA is used for its approved indications – the treatment of nasolabial folds and HIV-related facial lipoatrophy – as well as off-label for contouring and cheek augmentation, and to fill marionette lines and depressed scars, with a high level of patient satisfaction and results lasting up to 18 months.^{50–59} Although CaHA has a favourable long-term safety profile,⁶⁰ nodules and foreign body reactions have been reported,^{51–53,56,58,61} including one case of nodule formation from a distant injection site.⁶²

Poly-L-lactic acid

The FDA approved poly-L-lactic acid (PLLA; Sculptra®; Dermik Laboratories/sanofi-aventis, Bridgewater, NJ, USA), a biocompatible and biodegradable synthetic polymer from the alpha-hydroxy-acid (AHA) family, for the treatment of HIV-related lipoatrophy and moderate-to-deep rhytides in 2004 and 2009, respectively. When injected into the skin, PLLA stimulates fibroblasts to produce collagen, resulting in a gradual increase in dermal volume. The particles are eventually metabolized to lactic acid monomers that are further broken down by the body.⁶³ A number of studies have demonstrated the aesthetic efficacy of PLLA in the treatment of facial lipoatrophy,^{64–67} acne scars,^{68,69} and to fill deep rhytides and folds in the face.^{70–73}

Long-term trials have demonstrated the safety and tolerability of PLLA when used appropriately.^{74,75} Most side effects are due to the injection procedure, with complications sometimes attributed to poor injection technique,⁷⁶ although late-onset papules and nodules have been reported,^{71,73,77} as have cases of delayed granulomas.^{78–80} PLLA must be diluted 2–24 h prior to injection with sterile preserved water to allow adequate time for polymer hydration, and patients require a series of three injections over several months. These requirements, combined with an initial misunderstanding of proper injection protocol, have limited wider use of PLLA.²³

Hyaluronic acids

By far the most popular biodegradable filling agents are hyaluronic acid (HA) derivatives. An abundant key structural component of the skin and one of the chief components of the extracellular matrix, HA is a long, hydrophilic, cross-linked glycosaminoglycan that acts as a scaffold for collagen and elastin and contributes to cell proliferation and migration, as well as tissue repair.⁸¹ The HA molecule is stabilized through cross-linking with hydroxyl groups – allowing them to resist digestion by hyaluronidase – and it is the degree and type of cross-linking that determines longevity of the various HA products on the market. Although a large number of HA fillers are available for soft tissue augmentation (Table 66.1), they are all unique in terms of concentration of HA, cross-linking, particle size and manufacturing processes.

Table 66.1 Hyaluronic acid derivatives in clinical use in North America

Trade names	HA concentration (mg/mL)
Restylane®	20
Restylane® Fine Lines	
Perlane®	
Juvéderm®	24
Juvéderm® Ultra	
Juvéderm® Ultra Plus	
Juvéderm® Voluma®	20
Prévelle Silk®	5.5
Hydrelle®	28
Hylaform®	5.5
Hylaform® Plus	
Puragen®	20
Puragen® Plus	
Belotero®	22.5

When injected into the skin, HA combines with the body's own HA and binds to water, increasing skin turgor, elasticity and volume for a period of 4–12 months, depending on the product used. Most formulations are approved for the correction of moderate-to-severe facial rhytides, such as the nasolabial folds, but are also used off-label for volume replacement in the cheeks and elsewhere.⁸² The choice of product and viscosity depends on the depth of the defect and injector preference. The literature is replete with studies confirming the efficacy, safety and tolerability of HA fillers for the treatment of fine lines, deeper rhytides and folds, lip augmentation and facial contouring.^{82–84}

Side effects are generally mild and transient and include bruising and oedema. More serious adverse events are sometimes related to technique, such as the bluish Tyndall effect caused by injections placed too superficially.⁸⁵ Localized hypersensitivity reactions have been reported, particularly in products with higher amounts of protein.⁸⁶ More troublesome complications are rare but include granulomatous reactions^{87–89} and vascular ischaemic complications.^{90–94}

However, cross-linked HA is the only filler that can be fully reversed via the use of intracutaneous hyaluronidase, a soluble protein enzyme that breaks down and hydrolyses HA. Reports demonstrate that injection with hyaluronidase works within 24–48 h to relieve patient discomfort due to product misplacement or unwanted adverse effects.^{92,95–97}

Complications of biodegradable and non-biodegradable fillers

The most common adverse events for all filling agents are local injection site reactions and include transient pain on injection and intermittent bruising, oedema and erythema.⁸³ More serious complications can be classified as occurring early (up to 1 year after treatment) or delayed (1 year or more after implantation). Early complications usually result from poor injection technique and inappropriate placement of the filler, leading to palpable or visible implants, nodules and beading, changes to the texture and colour of the skin, and hypertrophic scarring.⁹⁷ Injections around

the mouth or in other areas of excessive movement or expression often cause lumpiness and migration of the implant. Hypersensitivity is rare but can occur with all fillers containing synthetic material; reactions range from persistent itching, burning and oedema, to granulomatous foreign body reactions. Vascular compromise leading to necrosis in the glabella or nasolabial folds – either by compression, injury or obstruction of the blood vessel – and retinal embolism after intravascular are rare but severe complications requiring immediate recognition and management.⁹⁸ Late-onset adverse events, such as excess fullness, persistent nodules, granulomatous or inflammatory reactions, chronic infections and filler migration, are almost always associated with non-biodegradable fillers, may be quiescent for over a year, and are often difficult to treat. Some complications can never be adequately reversed, particularly in the case of permanent filling particles; overcorrection, asymmetry and contour or textural irregularities require removal of the implant and may lead to scarring or other noticeable effects on the skin.⁹⁹

Cutaneous remodelling

Damage to the epidermis and dermis, which form a protective barrier against the environment, immediately initiates the tissue-repair cascade, in which inflammatory mediators induce fibroblasts to generate new collagen and elastin, ultimately leading to re-epithelialization and remodelling of the skin.

Microdermabrasion

Microdermabrasion is a simple and safe office procedure in which the skin surface is abraded with aluminium oxide crystals or other abrasive substances and removed with a hand-held vacuum device.¹⁰⁰ Aluminium oxide is the most commonly used abrasive, though less-effective crystals (sodium chloride, sodium bicarbonate and magnesium oxide) are also available.¹⁰¹ Crystal-free procedures involve diamond-tipped devices that are easier to use, neater and cause less pain.¹⁰² Depth of the treatment will depend on the rate and flow of the abrasive material, the amount of pressure applied with the hand-held device, and the number of passes over the skin. As with other cutaneous resurfacing techniques, surface trauma initiates the healing process, in which fibroblasts rush to produce new collagen, leading to smooth skin that looks fresh and robust. Weekly treatments can improve the appearance of fine lines, skin texture, pore size and acne scars, as well as postinflammatory pigmentation,¹⁰³ though posttreatment biopsies have shown no statistically significant improvement in rhytides.^{104,105}

Mild oedema and erythema are common immediately following treatment but usually subside within 48 h. Tiger stripes may appear on fair or sensitive skin. Adverse events are uncommon but include pain, burning, bruising (particularly around the lips), bleeding, infection and hyperpigmentation.¹⁰⁶ Uneven handling of the device can blemish the skin, and treatment that is too deep can permanently discolour the skin.¹⁰⁷

Chemical peels

A mainstay in the cosmetic clinician's armamentarium, chemical peels involve the topical application of chemical agents to the skin that in turn cause controlled destruction of part or all of epidermis, and sometimes the dermis.¹⁰⁸ Peels may be categorized as superficial, medium and deep; all stimulate collagen and glycosaminoglycan production, regardless of their depth of action.¹⁰⁹

Superficial peels affect the epidermis and upper dermal layers of skin and are used for rejuvenation and to treat mild dyschromias, acne, postinflammatory pigmentation and actinic keratoses. The most common agents for superficial peels include trichloroacetic acid (TCA, 10–20%), AHAs, such as glycolic acid (GA), and the beta-hydroxy-acids (BHAs), such as salicylic acid. Beta-lipohydroxy acid (LHA) is a derivative of salicylic acid that provides excellent exfoliation at lower concentrations with antibacterial, anti-inflammatory, antifungal and anticomedogenic properties.¹¹⁰ Epidermal regeneration occurs within 3–5 days after a superficial peel. Complications are rare, though transient burning, irritation and erythema are common.¹¹¹

Medium-depth peels use combination solutions containing TCA 35% as described by Brody (solid carbon dioxide + TCA),¹¹² Monheit (Jessner's solution + TCA)¹¹³ and Coleman (70% GA + TCA).¹¹⁴ Superficial peels are used for mild-to-moderate signs of photoageing, including pigmentary changes, lentigines, growths, dyschromas and rhytides.¹¹⁵ The healing process is longer, with full epithelialization within 7–10 days. Penetrating the reticular dermis, deep peels are usually performed with Baker–Gordon phenol in the surgical setting and are reserved for severe photoageing and deep rhytides, scars or lesions.¹¹⁰ Deep peels involve considerable risk of serious complications, such as scarring, changes in pigmentation and cardiotoxicity, and are considered invasive procedures that are frequently used as adjuncts to surgery. Adverse effects associated with medium-depth and deep peels include lines of demarcation, pigmentary changes, delayed healing and persistent erythema, bacterial infection, allergic reactions, scarring, acneiform eruptions, milia and rare instances of toxicity.^{110,115,116}

Conclusion

The ageing face undergoes many alterations, including changes to skin colour and texture, the emergence of wrinkles and furrows, and sagging caused by loss of underlying fat. The focus of rejuvenation today has shifted from surgical or ablative procedures associated with serious adverse events and long periods of recovery to those that are more convenient and less damaging. From injectables to ultrasound, significant advances and increasingly refined techniques have made it possible to subtly correct wrinkles, improve facial contours and irregularities, and restore volume and vitality with immediate aesthetic benefits, fewer complications, and little to no downtime.

CHAPTER 67

Forehead lift

Timothy J. Marten and Dino Elyassnia

Marten Clinic of Plastic Surgery, San Francisco, CA, USA

Introduction

The first forehead lift procedures were performed using an 'open' technique in which long incisions on the scalp or along the frontal hairline were made, a forehead flap was turned inferiorly, and modifications were made to corrugator supercilii and other muscles under direct vision. These breakthrough procedures served several generations of patients well and, while still performed by many surgeons today, they have been rejected by some patients and abandoned by some surgeons who view them as too aggressive and time consuming. As endoscopic techniques made inroads into aesthetic surgery, one of the first procedures they were adapted to by plastic surgeons was the forehead lift. Although a decade or more of technical refinements had to pass before the 'closed' forehead lift procedure finally came of age, it has since come to be widely accepted and continues to be a viable alternative to open procedures for many patients. Experience has since shown that a 'closed' technique without an endoscope can be used to mobilize and release the forehead and modify the corrugator supercilii muscles if the anatomy is understood and the operation is appropriately planned.^{1,2} In addition, transpalpebral corrugator myectomy, when used in conjunction with closed mobilization and re-suspension of the forehead, not only provides a scheme for the performance of closed foreheadplasty without the need for an endoscope, but also give a method by which medial brow elevation can be minimized or avoided. This may, indeed, be one of the procedure's most important merits.

Patient options in forehead rejuvenation

Patients seeking improvement of their forehead appearance have three general categories of procedures available to them:

- open procedures using a coronal incision,
- open 'hairline lowering' and 'forehead shortening' procedures using an incision or partial incision along the hairline and
- closed 'limited-incision' or 'short-scar' endoscopic procedures.

Selection of the 'best' procedure depends on the patient's specific characteristics, including hairline position, the quality of tissues, the condition of the scalp, the amount of improvement sought, and the overall degree of ageing changes that are present.³

Coronal incision techniques

Foreheadplasty techniques using a coronal incision offer certain advantages over closed procedures and should result in an inconspicuous scar and few complications if skilfully performed.⁴⁻⁶ These advantages include that they provide an actual reduction in forehead scalp and/or skin redundancy, and many surgeons feel that this translates into better brow elevation and a more durable and sustained improvement. Procedures performed through a coronal incision also provide optimal access for modification of the frontalis muscles, if necessary, and numbness, dysaesthesias and related problems can be minimized if the anatomy of the sensory nerves is understood and nerve branches are protected during the procedure.⁷ In practice, a procedure using a coronal incision may be the procedure of choice for patients with abnormally low hairlines who wish their hairline to be raised and placed in better proportion with the rest of their face. This is the most common circumstance in which the procedure is performed in the authors' practice (Figure 67.1).

Procedures using coronal incisions have certain well-known possible problems and complications, however, including hair loss, poor scars, hairline elevation, numbness and dysaesthesias, and patients generally have the notion that these procedures will result in a 'surprised' or 'startled' appearance. Although these problems should be uncommon if the procedures are skilfully performed by an artistic surgeon, and can occur when 'limited-incision' and endoscopic techniques are used, patients are nonetheless understandably attracted to 'short-scar' techniques, and perceive them to be less likely to precipitate problems or result in unnatural appearances. In addition, because of the influence of the media, the Internet and other physicians, many patients arrive in the plastic surgeon's office already convinced that they only wish to undergo an 'endoscopic' forehead lift, and thus

Figure 67.1 Coronal forehead lift procedure. Patients with low hairlines and advanced forehead ageing are ideal candidates for coronal incision plans because these procedures provide for maximum improvement in eyebrow position and configuration and produce the most elevation of the hairline. (a) Patient, age 49, preoperatively. Note that suboptimal eyebrow position and configuration impart a sad and melancholic appearance. Note also the low frontal hairline. (b) Same patient seen 14 months following coronal forehead lift. Note that suboptimal eyebrow position and configuration seen preoperatively have been corrected and that hairline retro-displacement has expanded the forehead and placed it in better overall proportion with the rest of the face. (The patient has also undergone upper and lower blepharoplasty, trichloroacetic acid peel of the lower eyelids, and secondary rhinoplasty.) most surgeons will have to offer their patients some kind of limited-incision or endoscopic procedure as an option.

Hairline and partial hairline incision techniques

Many patients seeking rejuvenation of the forehead are troubled by high hairlines and the prospect that surgery will make this problem worse. Hairline elevation occurs in both coronal and closed endoscopic techniques, and hairstyles cannot practically conceal an overly high forehead. A high forehead also appears unnatural, masculine and detracts from an otherwise attractive and agreeable appearance.^{8–11} Hairline elevation can be particularly objectionable after surgery in the older patient with a receded hairline who has marked forehead and scalp redundancy (Figure 67.2).

Unlike procedures using a coronal or endoscopic technique, procedures using an incision or partial incisions along the hairline allow hairline position to be maintained or lowered and hairline shape to be optimized¹² and the improvement thus gained may outweigh the drawback of the resulting scar.

Patients with high hairlines generally are well aware of their own problem and are more than willing to accept the associated trade-offs, including the scar, when informed of this option. In such situations, hairline lowering is arguably of more overall benefit to the patient than is eyebrow elevation or frown-line reduction.

Closed and short-scar techniques

'Closed' foreheadplasty techniques, including endoscopic foreheadplasty, 'limited-incision' forehead lift, and short-scar foreheadplasty employing transpalpebral corrugator myectomy, have found their earliest and widest applications in younger

patients with low or low-normal hairlines who had minimal or modest frontalis hyperfunction and transverse forehead wrinkling and who were undergoing isolated forehead or forehead and eyelid surgery. In these situations, a full coronal incision and scalp excision is indeed not necessary if the surgeon can improve eyebrow position and configuration and perform muscle modification with a near equal degree of precision as in an 'open' technique. Over time, however, 'closed' foreheadplasty techniques have also proven to be useful and effective in older patients troubled by more advanced ageing deformities and in those patients undergoing simultaneous facelifts. Indeed, experience has shown that it is not necessary to remove scalp in many patients to produce an attractive and sustained improvement in upper facial appearance (Figure 67.3).

Experience has also shown that an endoscope is not required to mobilize and release the forehead and modify the corrugator supercilii muscles if forehead anatomy is known, the operation is correctly planned and a transpalpebral approach to treat the corrugators is used. Although an endoscope can be used for these purposes if desired, designing a procedure in which it is not necessary saves time, avoids problems related to the device itself (fogging, mechanical failure, etc.) and avoids the costs of purchasing, leasing and maintaining the expensive equipment needed.

A number of strong arguments can be made against the use of an endoscope for corrugator muscle modification, however, even though this is considered by many to be a breakthrough application of the technology. First, it is exceedingly easy to over-elevate the medial brow in forehead lift procedures but deceptively difficult to raise the lateral eyebrow. Because the corrugator muscles act as partial depressors of the medial brow, simple

(a)

(b)

Figure 67.2 Hairline forehead lift. (a) Patient seen preoperatively. She has previously undergone face lift, upper and lower blepharoplasties and genioplasty performed by an unknown surgeon. Note suboptimal eyebrow position and shape and high forehead. A coronal or closed forehead lift would make her high forehead worse. (b) Same patient following hairline-lowering forehead lift using an incision along the hairline. The poor eyebrow position and shape seen before surgery have been corrected and the hairline has been lowered. Source: Courtesy of the Marten Clinic of Plastic Surgery, San Francisco, CA, with permission.

(a)

(b)

Figure 67.3 Closed, small-incision, non-endoscopic forehead lift. (a) Patient, age 42, seen preoperatively. Note suboptimal eyebrow position and shape. Some would claim that this degree of brow abnormality would be best treated with an 'open' foreheadplasty technique. (b) Same patient, 13 months following closed, small-incision, non-endoscopic forehead lift. The poor eyebrow position and shape seen before surgery has been corrected with minimal elevation of hairline. The patient has also undergone facelift, neck lift, upper and lower blepharoplasty, partial facial fat injections and an upper lip lift. Source: Courtesy of the Marten Clinic of Plastic Surgery, San Francisco, CA, with permission.

muscle excision, regardless of technique, can result in some medial brow elevation. The obligatory undermining of the glabella and dividing the periosteum that is necessary to gain access to the corrugator muscles endoscopically also disrupts the ligaments and attachments that hold the medial brow in an aesthetically optimal low position¹³ and predictably results in additional undesirable central brow elevation. Modifying the corrugators transpalpebrally through an upper eyelid incision preserves ligaments and periosteal attachments in the glabellar area, however, and helps keep the medial brow in a more natural appearing and attractive lower position. As a practical matter,

endoscopic access to the corrugators can also often be difficult in the patient with a high hairline or curved, sloping forehead, because of the endoscope's straight design.

Transpalpebral corrugator myectomy, when used in conjunction with closed mobilization and re-suspension of the forehead, not only provides a method for performing a closed, short-scar foreheadplasty without the need for an endoscope, but also provides a means by which medial brow elevation can be minimized or avoided.

The method of corrugator modification also has an impact on the procedure's outcome and can reduce the frequency of

complaints patients have after surgery. In endoscopic procedures, a near-total corrugator myectomy is generally performed in which the majority of the corrugator muscle is removed and the supratrochlear nerves are skeletonized. This, however, can result in paraesthesias and dysaesthesias, which can be disturbing to patients. When a transpalpebral modification of the corrugator is performed, the muscle can simply be divided (myotomy) between the supraorbital and supratrochlear nerves and an interposition fat graft taken from elsewhere on the face can be placed between the cut ends of the muscle. When this is done, muscle function is usually significantly reduced, but the nerves need not be formally dissected. Typically, this results in fewer disturbing sensations and dysaesthesias in the forehead area. (It should be noted that a simple corrugator myotomy (dividing the corrugator) rarely results in a sustained reduction in corrugator supercilii muscle function in and of itself. In most such cases, the cut ends of the muscle heal together and the muscle regains function.)

A final and initially unexpected benefit of closed techniques, including the non-endoscopic one described here, is that hairline retro-displacement is reduced in comparison to coronal procedures. This is because the majority of the forehead flap elevated in a closed dissection is elevated in a subperiosteal plane, and the flap is thus relatively inelastic as compared with a flap dissected through a coronal incision and elevated in a subgaleal plane. In all, the closed, short-scar non-endoscopic forehead lift procedure provides an overall reduction in incision length, less hairline elevation, decreased operating time, better improvement eyebrow shape and possible reduction in forehead and scalp neurosensory disturbance.

Anaesthesia

Most foreheadplasties performed in the authors' clinic are performed under local anaesthesia with heavy sedation using a laryngeal mask airway, but any skilfully administered anaesthetic is adequate.¹⁴ After sedation has been administered or anaesthesia established, supraorbital, supratrochlear and lacrimal nerve blocks are performed with 0.25% bupivacaine (Marcaine) with 1:200 000 adrenaline (epinephrine). Proposed sites for incisions are subsequently infiltrated with the same solution. 'Hyperinflating' incision sites with additional (and typically more dilute) local anaesthetic solution (0.1% lidocaine (lignocaine) with 1:1 000 000 adrenaline) immediately before incisions are made helps reduce bleeding by establishing a partial hydrostatic tamponade. Local anaesthesia should be administered even if general anaesthesia is used to reduce bleeding and lower the overall amount of narcotics and anaesthetics required. Upon completion of the procedure but before the patient is awake, nerve blocks should be re-administered to minimize patient discomfort in the postoperative period.

Operative technique for closed, non-endoscopic forehead lift

The closed, short-scar, non-endoscopic forehead lift technique is performed through four (or occasionally five) small scalp incisions made just posterior to the hairline, and consists of a blind subperiosteal mobilization of a forehead flap centrally and a subgaleal dissection laterally, a release of the temporal line and periosteum over the lateral brow, flap suspension with permanent suture to converging unicortical bony tunnels (or other method of direct cranial suspension of choice) and transpalpebral modification of the corrugator supercilii muscles (if indicated and desired) (Box 67.1).

Marking incisions

Incisions should be marked after anaesthesia has been administered but before prepping and draping is performed. Four incisions approximately 2 cm in length just within existing hairlines are required. In patients with large foreheads and higher hairlines, a central incision is occasionally made to facilitate subperiosteal undermining in the upper central forehead, though this is seldom needed if proper instruments are available.

The two most superior incisions (see 1 in Figure 67.4) are marked radially near the junction of the frontal and fronto-temporal hairlines (Figures 67.4 and 67.5).

In bald or balding men, the superior most incisions can be placed a bit more laterally along the anterior margin of the temporal tuft of hair in the same approximate location. In either case, the incisions should lie just medial to the temporal line and are used to provide access for subperiosteal undermining of the ipsilateral forehead (Figure 67.6). They also are used as points for flap fixation. Making these incisions radially facilitates closure and results in a scar that is less conspicuous than when incisions are made in transverse fashion or placed along the hairline.

The two temporal incisions are marked just within the temporal tuft of hair behind the fronto-temporal hairline (see Figure 67.4). These incisions lie lateral to the temporal line and are used to provide access for subgaleal undermining of the ipsilateral temple and lateral orbital regions (see Figure 67.6). These incisions also provide access for dividing the bridge of tissue along the temporal line between the central subperiosteal dissection of the forehead and the subgaleal dissection of the

temple and lateral forehead (Figure 67.7), and for dividing the periosteum beneath the lateral two thirds of the ipsilateral eyebrow under direct vision (Figure 67.8). If a facelift is performed at the same time as closed foreheadplasty and the temporal part of the facelift incisions are in a traditional position on the temporal scalp, the upper portion of the facelift incisions can be used to undermine the temporal forehead, divide the bridge of tissue between the subgaleal and subperiosteal planes, and to release the periosteum beneath the lateral two thirds of the eyebrows. In such cases, the separate temporal incisions described above are not necessary.

Making incisions

Incising the scalp is a key step in forehead lift surgery in which the surgeon exercises direct influence over the quality of the resulting scar. All incisions on the scalp, including the small 'closed' ports used in these procedures, must be made precisely parallel to hair follicles to avoid injury to them. An incision made carelessly or other than in this manner will injure hair follicles and result in peri-incisional alopecia.

After each incision is made, the wound edges are retracted and vessels traversing the wound in the deep subcutaneous plane are grasped and cauterized. Care is taken to avoid thermal injury to the more superficially situated hair follicles, and no cauterization is performed in the plane in which the hair follicles are present. Superiorly, incisions are carried down through the galea and the periosteum is incised. Laterally, dissection is deepened through the galea and the temporalis muscle fascia exposed.

Forehead flap elevation

The plane beneath which the forehead flap is raised in 'closed' foreheadplasty procedures has been the subject of debate and surgeons have advocated both subgaleal and subperiosteal dissections. Most surgeons now seem to prefer the subperiosteal plane, owing to its safety, ease of dissection and the protection it affords the deep branch of the supraorbital nerve. It should be noted that when a 'subperiosteal' technique is used, the entire flap dissection is not in a subperiosteal plane. Medial to the temporal line, the dissection is subperiosteal. Lateral to the temporal line, the dissection is in a subgaleal plane.

Forehead undermining and release is usually begun in the temple regions (Figure 67.9). Wound edges are retracted, the galea incised and the subgaleal plane entered. Typically this is a loose areolar plane that is dissected bluntly with closed Metzenbaum scissors, Boise nasal elevator, or similar blunt instrument, and dissection generally proceeds easily up to and over the lateral orbital rim in subgaleal/pre-periosteal plane in this manner. The dissection is then blindly and bluntly extended

Figure 67.6 Flap undermining in closed, non-endoscopic forehead lift. The incision on the temporal scalp (see 2 in Figure 67.4) is used to undermine the lateral forehead in a subgaleal plane (light green shaded area). The superior incision at the junction of the frontal and fronto-temporal hairlines (see 1 in Figure 67.3) is used to undermine the central forehead in a subperiosteal plane (violet shaded area). Note that subperiosteal undermining is carried posteriorly to accommodate flap advancement, but that the inferior central forehead and glabellar region are not released. The interface between the lateral subgaleal and the medial subperiosteal planes is the temporal line of fusion or 'temporal line'. Source: Courtesy of T.J. Marten, MD, San Francisco, CA.

Figure 67.8 Releasing the periosteum over the lateral brow. The lateral incision on the temporal scalp is used to divide the periosteum beneath the lateral eyebrow (dotted line) to mobilize and release the forehead flap. This can be done without an endoscope under direct vision with pistol grip endoscopic scissors (or even Metzenbaum scissors) and small retractor if the patient's head is turned, the table is elevated to eye level, and a fiber-optic headlight is worn. Red lines indicate sites of incisions. Light-green shaded area is area of sub-galeal dissection. Violet shaded area is area of subperiosteal dissection. (Courtesy of T. J. Marten, MD, San Francisco, CA.)

Figure 67.7 Releasing the temporal line. The lateral incision on the temporal scalp is used to divide the bridge of tissue along the temporal line (dotted line) between the central subperiosteal dissection of the forehead and the lateral subgaleal dissection. This can be done without an endoscope under direct vision with Metzenbaum scissors and small retractor if the patient's head is turned, the table is elevated to eye level, and a fibreoptic headlight is worn. Source: Courtesy of T.J. Marten, MD, San Francisco, CA.

Figure 67.9 Subgaleal dissection of temple. Forehead undermining and release is usually begun in the temple regions. Wound edges are retracted, the galea incised and the subgaleal plane entered. Typically this is a loose areolar plane that is dissected bluntly with closed Metzenbaum scissors (as shown), and dissection proceeds up to and over the lateral orbital rim in subgaleal/pre-periosteal plane. The dissection is then blindly and bluntly extended superiorly to the temporal line, and inferiorly over the lateral orbit through somewhat thicker attachments onto the upper zygoma. Due to the location of the access incision and the fact that dissection is made bluntly with a blunt instrument, this can be accomplished without injuring the sentinel vein. Source: Courtesy of T.J. Marten, MD, San Francisco, CA.

Figure 67.10 Subperiosteal dissection of forehead. Wound edges are retracted, the galea and periosteum are incised, and the central-lateral forehead undermined in a subperiosteal plane. This dissection can be quickly made without the aid of an endoscope from temporal line extending posteriorly using an Obwegeser or similar periosteal elevator. Some posterior dissection is required to allow the flap to redistribute itself after it is advanced, and to avoid puckering and gathering posterior to the suspension points when the flap is anchored. Source: Courtesy of T.J. Marten, MD, San Francisco, CA.

superiorly to the temporal line, and inferiorly over the lateral orbit through somewhat thicker attachments onto the upper zygoma. Due to the location of the access incision and the fact that dissection is made bluntly with a blunt instrument, this can be accomplished without injuring the sentinel vein.

Once the lateral forehead has been dissected, attention shifts to the most superiorly situated incision located above the junction of the frontal and fronto-temporal hairlines (see 1 in Figure 67.4). Wound edges are retracted, the galea and periosteum are incised, and the central-lateral forehead undermined in a sub-periosteal plane. This dissection can be quickly made without the aid of an endoscope from temporal line to temporal line, extending posteriorly to the approximate location of the coronal suture using an Obwegeser or similar periosteal elevator. Some posterior dissection is required to allow the flap to redistribute itself after it is advanced, and to avoid puckering and gathering posterior to the suspension points when the flap is anchored (Figure 67.10).

As the mid-inferior brow is approached, the inferior aspect of the supraorbital rims should be palpated through infrabrow skin and the location of the foramen or notch from which the supraorbital nerves exits identified. This manoeuvre helps avoid dissection of these areas, which can vary somewhat anatomically from patient to patient. In the majority of cases, a notch ('frontal notch') is palpable on the inferior aspect of the supraorbital rim along a vertical line passing through the medial limbus. In patients with no palpable notch, the nerve usually exits through a foramen, which often is not palpable, more superiorly. Additional care in dissection is taken under these circumstances or an endoscope can be used.

Figure 67.11 Releasing the adherence along the temporal line. Mobilization of the forehead flap continues by dividing the bridge of tissue along the temporal line of fusion between the subperiosteal dissection in the lateral forehead and the lateral subgaleal dissection in the temple, beginning superiorly and extending inferiorly to the lateral orbital rim (see Figure 67.5). As experience is gained, this can be done without an endoscope through the incision on the temporal scalp under direct vision using a fibreoptic headlight and Metzenbaum scissors by raising the table to eye level, turning the patient's head and retracting the flap with a small malleable ribbon retractor or similar instrument as shown. Source: Courtesy of T.J. Marten, MD, San Francisco, CA.

When corrugator resection is planned through an eyelid incision ('transpalpebral corrugator myectomy'), the centro-inferior forehead and glabella should not be undermined. Indeed, this is a significant advantage of this technique because it limits central forehead dissection and minimizes the possibility that the medial brow will be elevated.

Mobilization of the forehead flap continues by dividing the bridge of tissue along the temporal line of fusion between the central subperiosteal dissection and the lateral subgaleal dissection, beginning superiorly and extending inferiorly to the lateral orbital rim (see Figure 67.7). As experience is gained, this can be done without an endoscope through the incision on the temporal scalp under direct vision using a fibreoptic headlight and Metzenbaum scissors by raising the table to eye level, turning the patient's head and retracting the flap with a small malleable ribbon retractor or similar instrument. If facelift is being performed concurrently and the temporal portion of the facelift incision is in the temporal scalp this manoeuvre will be even easier (Figure 67.11).

Releasing and mobilizing the lateral brow

To fully mobilize the lateral forehead and obtain optimal elevation of the lateral brow, the periosteum beneath the lateral two thirds of the eyebrow must be divided (see Figure 67.8) (Box 67.2). As experience is gained, this can be done without the aid of the endoscope through the incision on the temporal scalp under direct vision using a fibreoptic headlight and Metzenbaum or a pistol grip endoscopic scissors by raising the table to eye level, turning the patient's head, and retracting the flap with a small malleable ribbon retractor or similar instrument (Figure 67.12).

- 5 Blunt mobilization of lateral brow

Figure 67.12 Releasing the lateral brow. To fully mobilize the lateral forehead and obtain optimal elevation of the lateral brow, the periosteum beneath the lateral two thirds of the eyebrow must be divided (see Figure 67.6). As experience is gained, this can be done without the aid of the endoscope through the incision on the temporal scalp under direct vision using a fiberoptic headlight and Metzenbaum or a pistol grip endoscopic scissors by raising the table to eye level, turning the patient's head and retracting the flap with a small malleable ribbon retractor or similar instrument. Source: Courtesy of T.J. Marten, MD, San Francisco, CA.

When the flap is retracted, the periosteum is visible as a dense white fascial layer, and its lateral margin corresponds to the release made previously along the temporal line. Division of the periosteum beneath the lateral brow begins by confirming one's position beneath the flap by pushing up upon it with the closed scissors and visually confirming on the skin surface that one is starting in the proper location. The periosteum only is divided in small increments, beginning laterally and working medially to avoid injury to the deep branch or the supraorbital nerve that lies several centimetres medially and more superficially, but in near proximity to the periosteum. Division of the periosteum continues medially over the lateral two thirds of the brow just at the level of the eyebrow. The superficial (main) branch of the supraorbital nerve should remain well medial to the dissection and should not be seen. If facelift is being performed concurrently and the temporal portion of the facelift incision is in the temporal scalp this manoeuvre will be even easier.

After the periosteum of the lateral orbit has been divided, a Boise (or similar) blunt elevator is used to complete the release of the lateral forehead by applying gentle upward and outward

pressure to the upper lateral orbital area. Typically this manoeuvre provides additional flap mobilization that would not be obtained if the periosteum was only divided. Care must be taken, however, even when blunt elevation is made in the lateral orbital and temporal areas, because delicate terminal fibres of the frontal branch of the facial nerve travel through them. Dissection in this manner continues until adequate and symmetric release of the right and left lateral forehead is obtained. This is determined by returning the flap to the forehead, advancing it superiorly by placing gentle traction on the two most superior scalp incisions, and noting the effect on the eyebrows and brows.

Although it is deceptively easy to elevate the lateral eyebrow preoperatively by pulling superiorly on the suprabrow skin, it is in reality much more difficult to do so intraoperatively by pulling from a point more superiorly on a composite forehead flap dissected in a subgaleal or subperiosteal plane. This is particularly true of thick-skinned individuals with advanced brow ptosis in whom standard flap undermining and release often proves inadequate in releasing the lateral brow and providing adequate elevation of the lateral eyebrow. In these cases, additional lateral brow elevation can be obtained by extended undermining of the temple and lateral face.

Drain placement

Experience has shown that a drain, although not absolutely necessary, helps close down deadspace beneath the parietal scalp behind forehead flap suspension points, reduce fluid collections in this area, and limits the amount of postoperative periorbital oedema and ecchymosis experienced by patients. Because of this, drains are used routinely in most procedures.

Drain placement must be performed properly, however, if a beneficial effect is expected and problems are to be avoided. Careless drain placement can result in alopecia, slough, pain, paraesthesias and other problems.

A 7-F round multi-perforated soft Silastic Jackson-Pratt closed suction drain is placed through a central-lateral site of insertion approximately 1–2 finger-breadths posterior to the hairline and 1–2 finger-breadths medial to the right superior incision (Figure 67.13). The stab incision for drain insertion should be made carefully parallel to hair follicles to avoid injury to them. The drain should then be pulled through in a retrograde inside to outside fashion to avoid pulling hair into the wound and anchored with a 4–0 nylon suture tied loosely to the scalp but securely to the drain itself. Loosely tying the suture to the scalp allows for scalp swelling without hair follicle injury and facilitates drain removal. Overtightening the drain suture to the scalp can result in postoperative discomfort, difficulty in suture removal and peri-incisional alopecia.

After the drain has been properly secured at its exit site, its perforated portion is cut to appropriate length and inserted subperiosteally and directed inferomedially across the mid forehead to the opposite side. After incisions have been closed, the drain tube is attached to a small bulb suction reservoir. This

Figure 67.13 Drain placement. A 7-F round multiperforated soft Silastic Jackson-Pratt closed suction drain is placed through a central-lateral site of insertion approximately 1–2 finger-breadths posterior to the hairline and 1–2 finger-breadths medial to the right superior incision. The drain is then directed across the forehead to the opposite side. Red lines indicate sites of incisions. Solid line indicates external part of drain. Dotted line shows approximate path of internal portion of the drain. Source: Courtesy of T.J. Marten, MD, San Francisco, CA.

provides continuous low vacuum and is easily managed by most patients while in place.

Flap repositioning

Once the drain has been inserted and secured, the forehead flap is elevated by pulling superiorly and slightly medially on the two most superior incisions and proper eyebrow position and configuration confirmed. For most women, this should be in a soft arch with the lateral portion of the eyebrow lying several millimetres above its medial most portion. For men, the eyebrow should be horizontal or near horizontal, with the medial and lateral portions lying at the same level. In thick-skinned individuals with heavy forehead tissues and brows, some overcorrection laterally is usually required.

In 'closed' procedures, the amount of eyebrow elevation obtained is determined by the extent of flap release, and there is no contribution obtained from scalp excision as is the case in 'open' approaches.

If inadequate brow elevation is seen to be present, or if asymmetry is noted, additional undermining and release are indicated and should be continued until the desired effect is obtained. Tying anchoring sutures tightly cannot compensate for incomplete flap release and will predictably result in hair loss at the anchoring point.

There should be no lateral component of shift when repositioning the forehead flap in closed foreheadplasty procedures,

Figure 67.14 Flap anchoring. The periosteal component of the 'closed' forehead flap situated just inferior to the inferior most extent of the superior incision (blue dot) is anchored to converging unicortical bony tunnels in the outer calvarial cortex (grey dot) with a 3–0 braided polyester (Mersylene) suture. Arrow shows proper (superiorly directed or slightly superomedial) direction of flap shift. Red lines indicate sites of incisions. Source: Courtesy of T.J. Marten, MD, San Francisco, CA.

and the best biomechanical effect on the brow is obtained when the forehead flap is elevated along a vertical or slightly vertical–medial vector (see arrow in Figure 67.14). Many surgeons mistakenly add a lateral component of shift in a conceptually and technically flawed attempt to smooth glabellar frown lines. Pulling laterally on the forehead will not correct glabellar frown lines, as proper and effective treatment of these requires attenuation or elimination of corrugator supercilii muscle action.

Flap anchoring

Various methods of forehead flap anchoring have been advocated for use in closed foreheadplasty procedures but it should be recognized that the means by which the forehead flap is anchored is not the definitive step in the procedure and that there is no special 'magic' in any one particular method. How the flap is anchored is unimportant as long as it achieves the intended purpose, and success or failure lies largely in the adequate mobilization of the flap – not the particular method of anchoring used.

Methods of forehead flap anchoring that have been described and reported include cranial flap fixation using an internal microscrews, flap fixation using a microcrew and pledget of Gortex (polytetrafluoroethylene), flap fixation using prethreaded metallic anchors (Mitec anchor), flap fixation using an absorbable polyglycolic acid (PGA) cranial peg (Endotine) or PGA (Lactosorb) screw, and suture fixation to

converging unicortical bony tunnels. Other flap-anchoring strategies include suspension using a removable transcutaneous cranial post (large, removable, externalized screw), an external bolster and tissue glues. The use of small 'T' to 'V' excisions of scalp at endoscopic entry ports has also been reported. Each of these methods has advantages and disadvantages that should be considered, including, but not limited to, poor patient acceptance (external bolsters, external removable screws, internal metallic screws), palpability (PGA pegs and screws), expense (Endotine, Mitec), poor healing and hair loss ('T' to 'V' excisions and other attempts to excise scalp) and concerns regarding disease transmission (pooled plasma-derived tissue glues).

Experience has shown that the effectiveness and longevity of closed forehead lift procedures are significantly improved when some sort of secure and permanent direct cranial fixation of the flap is performed, and suturing the periosteum at the leading edge of the superiorly situated incisions (1 in Figure 67.4) to converging unicortical bony tunnels made in the outer cortex of the calvarium with a 3-0 braided polyester (Mersylene) suture has proven to be a convenient and reliable way to accomplish this. This method, unlike many of the others noted above, is easy to perform, reliably results in excellent healing and is readily acceptable to most patients (see Figure 67.14) owing to the fact that no metal screws are used and the fixation is low profile, non-palpable, non-inflammatory, long-lasting and inexpensive.

Once balanced and symmetric release of the forehead flap has been confirmed and the flap advanced, the edge of each superior incision is retracted and a mark made in the centre of each on the cranium in water-soluble surgical ink (methylene blue). These spots mark the sites at which the flap will be anchored. A Desmarres retractor is then used to protect the wound edge on the side being drilled and converging unicortical drill holes made at approximately 30–45° angles. Care must be taken to ensure that minimal pressure on the drill handpiece is applied while holes are being drilled, and that only the outer cortex is penetrated (Figure 67.15).

After converging holes have been drilled in the outer calvarial cortex at marked sites, a 3-0 braided polyester (Mersylene) suture is passed through each drill hole by bending the needle and passing it in a retrograde fashion through each, or by drawing the back end of the suture through the hole by applying a Frazier-tipped suction to one side. At first, this step can prove to be a bit cumbersome, but, as experience is acquired, it can be performed quickly and easily. The suture is then passed through the periosteum just at the inferior aspect of each incision and tied under modest tension only.

Anchoring the flap superiorly provides the needed mechanical effect on the brow and it is typically not necessary or productive to anchor the flap at the temporal incision sites. It is also not necessary, and will make any secondary procedure more difficult, if temporalis muscle fascia is excised in an effort to create suspensory adhesions in the lateral temporal areas.

Figure 67.15 Flap anchoring to converging unicortical drill holes. A Desmarres retractor is then used to protect the wound edge on the side being drilled and converging unicortical drill holes made at approximately 30–45° angles. Care must be taken to ensure that minimal pressure is applied to the drill handpiece while holes are being drilled, and that only the outer cortex is penetrated. Source: Courtesy of T.J. Marten, MD, San Francisco, CA.

Incision closure

After flap-anchoring sutures have been placed, irrigation is performed with antibiotic solution and scalp incisions are closed in one layer with simple interrupted sutures of 4-0 nylon. No deep suture is required. If closure is performed meticulously and in a way that provides good wound edge alignment without overly tight sutures, an inconspicuous scar will be obtained (Figure 67.16).

Staples are generally inadequate for closing scalp incisions in open and closed foreheadplasty procedures in that a properly made incision on the scalp is typically bevelled to some extent so as to remain parallel to hair follicles and avoid injury to them, and staples are designed to close wounds with perpendicular edges. Attempting to staple an incision with bevel edges often results in overriding of wound edges and poor wound edge alignment. The use of staples is also frequently uncomfortable and disturbing to patients. A ratcheting staple and external screw technique should not be used to suspend the flap in closed foreheadplasty procedures. Such a plan places excessive tension on the scalp tissue in the plane of the hair follicles and commonly results in hair loss.

Corrugator myoplasty

Once flap mobilization, repositioning, anchoring and incision closure is complete, attention turns to the corrugator myoplasty, if indicated and/or desired by the patient. Attenuating corrugator hyperfunction forms the basis of the treatment of glabellar frown lines and is adequate for many patients with mild to moderate problems. The expectations of patients with marked muscle hyperfunction and deep lines must be properly set, however, and all patients must be made aware that the goal of

Figure 67.16 Incision closure. After flap-anchoring sutures have been placed, scalp incisions are closed in one layer with simple interrupted sutures of 4–0 nylon. (Note that the incision on temple scalp had already been closed.) Source: Courtesy of T.J. Marten, MD, San Francisco, CA.

surgical treatment of corrugator hyperfunction and glabellar frown lines is a reduction in frown-line intensity, and not complete elimination of all glabellar movement. Patients should also be made aware that they may want or need to undergo neurotoxin (botulinum toxin (Botox)) injections, even after properly performed procedures.

Proper management of the corrugator supercilii muscles requires a detailed understanding of their anatomy, and their relationship with adjacent agonist and antagonist muscles. The corrugators are obliquely oriented muscles that originate on the medial most portion of the supraorbital ridge. The muscles traverse superolaterally to and insert on the skin overlying the medial and mid brow. The corrugators are intimately associated with a group of important agonists and antagonists that together are responsible for the expression of a wide range of human emotions.¹⁵ These include the procerus, frontalis, orbicularis oculi and the depressor supercilii muscles. The limits of these neighbouring muscles are not always easily defined, and as the corrugators are followed laterally toward their insertion they are seen to overlap, override, intermingle and merge with them, and these relationships allow for complex interactions and are important when contemplating surgical modification of muscle action.

A careful consideration of the anatomic arrangement of the corrugator supercilii muscles makes clear their effect on the eyebrow and the bulges and lines that develop upon their contraction. Each muscle is arranged so that its fibres exert action in several directions, and as such, they exert different effects at various locations along the brow. Over the medial third of the eyebrow, the corrugator acts as an antagonist to the frontalis and an agonist to the procerus and superior medial portion of the orbicularis oculi. There is no specific antagonism to medially directed contraction of the corrugator, however, and thus no opposing force to its medially directed pull on the

brow. This explains why, upon cursory consideration, vertical glabellar wrinkling seems to be the overriding effect of corrugator action. It also explains why resecting the corrugator, in and of itself, can result in medial brow elevation, even if no undermining and advancement of a forehead flap is made.

The corrugator muscle action results in a complex action on the medial aspect of the eyebrow and the inferior central forehead, resulting in vertical glabellar wrinkling and an angry or disapproving appearance. Traditionally, near-total corrugator myectomy was performed to diminish these expressions using an open or endoscopic technique, and when properly performed was effective in doing so. Traditional myectomy, performed using either of these techniques has several disadvantages, however, including disruption of attachments and ligaments that hold the medial brow and eyebrow inferiorly. Traditional open or endoscopic myectomy also typically produces some temporary and occasionally permanent paraesthesia and dysaesthesia due to dissection of the supratrochlear nerves. These problems can often be diminished or avoided if a modified technique and transpalpebral approach is used, in which the corrugator muscle is divided or divided and partially resected lateral to the supratrochlear nerve branches and a fat graft is interposed to defunctionalize the muscle by preventing the divided segments from reattaching upon healing. This approach will henceforth be referred to as 'corrugator myoplasty' and the involved steps are described in the following paragraphs.

Dissection of the corrugator supercilii muscles is facilitated and bleeding is diminished if the medial brow is hyperinflated by injecting a dilute local anaesthetic-adrenaline solution and an adequate time is allowed for a proper anaesthetic and haemostatic effect. The surgeon should also wear a headlight, and fine-tipped cautery, Ragnell retractor and a Frazier-tipped suction should be available.

Upper blepharoplasty incisions are made according to the preoperative plan and need not be modified when transpalpebral corrugator myoplasty is being performed. If a patient does not need upper blepharoplasty but desires frown line reduction, consent is obtained to make an incision along the upper lid tarsal crease to provide access to the corrugator muscle and to allow corrugator muscle myoplasty to be performed. When the advantages of the technique are explained to patients, most will allow an eyelid incision to be made in such situations and, if it is closed properly, the scar will usually be difficult to find once healed. If patients do not wish to have an upper eyelid incision, the muscles can be treated in a traditional endoscopic fashion, or by other means.

The superior margin of the blepharoplasty incision is retracted by the assistant using two 10 mm double-pronged skin hook retractors and dissection is carried down to the orbital septum using needle-tipped cautery and low electrocautery current (Figure 67.17). Dissection is then continued superiorly superficial to the septum up to the supraorbital rim in a preseptal plane. Typically, this dissection is made in a loose areolar

Figure 67.17 Transpalpebral approach to the corrugator supercilii muscle. Figure 67.19 Transpalpebral dissection of the corrugator supercilii muscle. Once the corrugator is identified, the tips of a pair of tenotomy scissors are introduced between the underside of the muscle and the brow, and they are used to bluntly dissect the plane between the muscle and the bony periosteum. Source: Courtesy of T.J. Marten, MD, San Francisco, CA.

plane and as the medial aspect of the supraorbital rim is approached, the outline of the inferior portion of the corrugator supercilii muscle will be seen (Figure 67.18).

Once the corrugator is identified in this fashion, the tips of tenotomy scissors are introduced between the underside of the muscle and the brow bone, and they are used to bluntly dissect the plane between the muscle and the bony periosteum (Figure 67.19). This dissection is performed well medial to the supraorbital nerve, which is typically not seen and need not be specifically identified during the procedure. If the glabella has been hyperinflated with local anaesthetic-adrenaline solution before muscle dissection, minimal bleeding is usually encountered. If bleeding is encountered, however, it is best controlled by placing firm direct pressure on the skin overlying the region against the bony brow for several minutes or until it stops.

Next, the tips of the tenotomy scissors are introduced between the anterior surface of the muscle and the brow skin, and they are used to bluntly dissect the plane between them (Figure 67.20). If the brow has been hyperinflated with local anaesthetic-adrenaline solution before its dissection, little bleeding will typically be encountered during this part of the dissection as well. If bleeding is encountered, it is best controlled as previously described by placing direct pressure on the skin overlying the region until it stops. Once this manoeuvre is complete, the corrugator is isolated and can be grasped with a forceps or a similar instrument (Figure 67.21).

Once the corrugator has been isolated and separated from adjacent structures, it is divided or a small segment is resected (Figure 67.22). This is accomplished by introducing one blade of the tenotomy scissors between the corrugator muscle and the brow bone, and the other between the muscle and the skin. The scissors are then turned parallel to the supraorbital and supratrochlear nerves and the muscle divided between them. If the brow has been hyperinflated with local anaesthetic-adrenaline solution before its dissection, little bleeding will typically be encountered when the muscle is divided. If bleeding is encountered following this manoeuvre, it is best controlled by packing the wound with the corner of a sponge and placing direct pressure on the skin overlying the region until it stops. Alternatively, bleeding can often be controlled directly in some cases by placing a Ragnelle-type retractor in the wound, applying suction with a small Frazier suction, and cauterizing oozing areas with a fine-tipped cautery under direct vision. This is most readily accomplished, when necessary, while the surgeon wears a fiberoptic headlight.

Once the corrugator has been divided and haemostasis obtained (if necessary), the cut edges of the muscle retract and a gap between the cut edges will be seen (Figure 67.23). If fat is available from elsewhere in the face (e.g. from a blepharoplasty, facelift or neck lift procedure), it is used as an interposition graft to defunctionalize the muscle and to ensure that smooth brow contours will be present once healing is complete (Figure 67.24). If this is not done, the muscles will

Figure 67.20 Transpalpebral dissection of the corrugator supercilii muscle. After the deep side of the muscle has been dissected, the tips of the tenotomy scissors are introduced between the anterior surface of the muscle and the brow skin. They are then used to dissect the plane between them. Source: Courtesy of T.J. Marten, MD, San Francisco, CA.

Figure 67.21 Transpalpebral dissection of the corrugator supercilii muscle. Once the superficial and deep surface of the corrugator has been dissected, its central portion will be separated from adjacent structures and can be grasped with a DeBakey forceps or a similar instrument. It can then be divided (see Figure 67.14) or subtotally resected as desired. Source: Courtesy of T.J. Marten, MD, San Francisco, CA.

predictably heal back together and minimal improvement will typically be obtained. If fat is not available from the face, the small amount needed can be harvested through a small incision in the suprapubic or other concealed area where adequate fat is present. Alternatively, the head of the muscle can be subtotally resected by carefully picking it out from between the supratrochlear nerves with a fine-tipped haemostat (Figure 67.25). When this is done, more forehead dysaesthesia and upper eyelid ecchymosis will be more likely to occur and should be expected.

Fat grafts are trimmed to fit the defect and typically measure approximately 10×10×10 mm. Fat grafts are most easily secured using a transcutaneous pullout suture of 6-0 nylon (see Figures 67.24 and 67.26). This is placed while the wound is held open with a Ragnell retractor and 10 mm double-pronged skin hook, and is introduced through the brow skin just at the superomedial aspect of the eyebrow and brought out

Figure 67.22 Dividing the corrugator supercilii muscle. Once the corrugator has been isolated, one blade of the tenotomy scissors is inserted between the corrugator muscle and the brow bone, and the other between the muscle and the skin. Figure 67.24 Transpalpebral placement of interposition fat graft. Fat obtained from elsewhere in the face (e.g. from a blepharoplasty, facelift or neck lift procedure) is used as an interposition graft to prevent the cut muscle edges from re-adhering to each other and to defunctionalize the muscle. The fat graft also ensures that brow contours will be smooth once healing is complete. Source: Courtesy of T.J. Marten, MD, San Francisco, CA.

Figure 67.25 Transpalpebral myectomy. If a fat graft is not available, the corrugator muscle can be subtotally resected by excising a portion of it between the supratrochlear and supraorbital nerves with a fine-tipped haemostat. When this is done, more forehead dysaesthesias and upper eyelid ecchymosis should typically be expected. Source: Courtesy of T.J. Marten, MD, San Francisco, CA.

Figure 67.26 Securing the interposition fat graft. Fat grafts are most easily secured using a transcutaneous 6-0 nylon pull-out suture. Placed while the wound is held open with a Ragnell retractor as shown, the suture is introduced through the brow skin just at the superomedial aspect of the eyebrow and brought out through the eyelid incision between the divided muscle segments. The needle is then passed through the fat graft and then back through the eyelid incision between the muscle segments and out of the skin near the spot it entered. As the suture is pulled up and tied, the fat graft is drawn up into the incision and held between the divided muscle segments. Source: Courtesy of T.J. Marten, MD, San Francisco, CA.

through the eyelid incision between the divided segments of corrugator muscle. The needle is then passed through the fat graft, and then back through the eyelid incision between the muscle segments and out of the skin near the spot it entered. As the suture is pulled up and tied, the fat graft is drawn up into the incision and held between the divided muscle segments (see Figure 67.26).

Because the knot is small and sits at the superior edge of the eyebrow, it is often not noticed by patients during the recovery process (Figure 67.27). The eyelid incision is then closed with a simple running suture of 6-0 polypropylene (Prolene) or another suture of choice.

Not all patients today will need or want corrugator muscle modification surgery that was in one form or another more or less a routine part of foreheadplasty procedures performed in the past. Many patients will now be encountered who are using neurotoxins (botulinum toxin, Botox) to control corrugator hyperfunction who are happy with the improvement they obtain from it (albeit a temporary one) and who wish to continue to use it. Indeed, in many instances it could be argued that neurotoxins produce a more predictable, complete and trouble-free improvement than surgical muscle modification does, and that its use has largely supplanted muscle surgery for treatment of glabellar frown lines. In these cases transpalpebral myoplasty (or other forms for corrugator muscle modification) need not be performed and the foreheadplasty procedure is undertaken to optimize eyebrow position and configuration only (tilt the lateral eyebrow up), and it is referred to as a 'temple lift' to distinguish it from more comprehensive 'forehead lift' and/or 'brow lift' procedures. It is important that the patient has a clear understanding of whether or not corrugator muscle surgery will be performed, however, and when corrugator muscle modification is planned in the authors' clinic 'corrugator muscle modification' is typically listed on the patient's informed consent document and procedure price quote, and

Figure 67.27 Completed transcutaneous anchoring of the interposition fat graft. Because the suture knot is small and sits at the superior edge of the eyebrow (arrow), it is typically not noticed by patients during the recovery process. Source: Courtesy of T.J. Marten, MD, San Francisco, CA.

additional charges are applied for the additional time and materials involved in carrying out the procedure.

Dressings

After all planned procedures have been completed and all incisions have been closed, the patient's hair is washed with shampoo and conditioner and, if long, placed in a soft braid. The hair is then allowed to dry or is blown dry in the recovery room. No dressing is required or applied. Patients are typically discharged with a hat, scarf and sunglasses following the procedure.

Postoperative care

Proper postoperative care of the foreheadplasty patient ensures the best result with the fewest problems and complications. Although most patients are treated as outpatients unless a face-lift or related procedures are simultaneously performed, all are discharged to the care of a responsible adult third party with a specific set of written aftercare instructions.

Cool compresses

Patients are asked to rest quietly and apply cold compresses to their forehead and eyes for 15–20 min of every hour they are awake for the first 3 days after surgery. For most patients, oedema peaks at about this time. It is not necessary or productive to apply ice compresses continually throughout the day or at night.

Medications

All patients are provided oral (usually non-narcotic) analgesics, sleeping pills, oral dissolving antiemetic tablets, preservative-free ophthalmic ointment and preservative-free 'artificial tears' solution with instructions for their use. Patients are required to use ophthalmic ointment each night for the first three weeks after surgery or until all signs of eye irritation are gone. Artificial tears are used throughout the day on an as-needed basis.

Drain removal

The forehead drain is removed the morning after surgery if the patient stays overnight in the aftercare facility, or at the first postoperative visit.

Wound care

Patients are instructed to begin a daily routine of showering and shampooing no later than 3 days after surgery even if their drains are still in place. This helps remove crusting about the suture lines, keeps incisions clean and usually improves the patient's general outlook and wellbeing. Patients are also informed that they need not be as thorough as usual when washing their hair and assured that shower water, shampoo and conditioners are not harmful and will not interfere with healing or cause infection.

Hair care

Patients are allowed to use their usual hair-care products but must be warned that their scalp may be partially numb after surgery and that they must be careful to ensure that shower water is not too hot and that hair dryers are not used on high heat settings. Patients are also instructed not to 'perm', tint, dye, highlight, colour or otherwise chemically treat their hair for two weeks after surgery to limit the chance of hair breakage or hair loss. 'Hot curlers' and 'curling irons' must be used with care for several months following forehead lift surgery as patients might unknowingly burn their foreheads and scalps. Patients are advised to apply hair gel, hair cream, hair spray and similar products sparsely or preferably not at all, until all sutures have been removed.

Suture removal

Sutures are typically removed over a period of 7–9 days after surgery. When incisions have been made along the hairline (hairline-lowering foreheadplasty and partial hairline forehead lifts) the simple interrupted sutures of 6–0 nylon are removed 5 days after surgery and half-buried vertical mattress of 4–0 nylon are removed 7–9 days after surgery. When incisions have been made within the scalp (small incision or coronal procedures) the simple interrupted sutures of 4–0 nylon are removed 7–9 days after surgery. Patients are then checked 2–3 weeks after surgery to ensure that no stray sutures are present and that all have been removed.

Return to work after surgery

How long it is before patients return to work and social life depends upon their tolerance for surgery and anaesthesia, their capacity for healing, the type of work they do, the activities they engage in and how they feel overall about their appearance. Typically, they are advised to set aside 7–9 days, if possible, to recover from forehead lift surgery. Additional time off is sometimes required or desired before an important outing, vacation or similar event.

Patients making uneventful recoveries may return to work and limited social activity when they feel up to it, and many patients have been able to attend social functions a few days after surgery. It is often wise for patients to begin with a limited workday, however, and to adjust their schedules thereafter as tolerated. If a patient's work requires more strenuous activity or physical labour, a longer period of convalescence may be needed. Patients are advised not to drive until they are feeling well, their vision is clear and they are off pain medications and sleeping pills.

After-surgery diet

Patients are allowed to take their usual diet as tolerated after surgery but are advised to restrict their intake of salt. Patients are asked to abstain from the intake of alcohol for two weeks after surgery and until they are no longer taking narcotics, paracetamol (acetaminophen) or sleeping medication. Patients are asked to abstain from smoking and avoid secondhand smoke in the immediate postoperative period.

After-surgery activity

In the first 10–14 days after surgery, patients are advised to avoid bending, stooping and all strenuous activity, exercise and sports. Thereafter, they may begin to exercise, gradually working up to their presurgical level of activity.

Case examples

Figures 67.28, 67.29 and 67.30 show patients before and after the procedure.

Figure 67.28 (a) Patient, age 55, preoperatively. Note that she has a somewhat tired, stern and angry appearance even though her face is in repose. She has had no prior plastic surgery. (b) Same patient, 1 year and 6 months following small-incision non-endoscopic forehead lift. Note that her eyebrow position and configuration has been improved and that she has a more rested and agreeable appearance. A facelift, neck lift, upper and lower eye lifts, chin augmentation and fat transfer to the cheeks and lips have also been performed. (c) Preoperative view of same patient frowning. Note that she has strong frown muscles that produce deep creases and an intense angry appearance. (d) Same patient, 1 year 6 months following small-incision non-endoscopic forehead lift with transpalpebral corrugator myoplasty. Note that she is trying to frown but frown intensity is markedly reduced. Source: Courtesy of the Marten Clinic of Plastic Surgery, San Francisco, CA, with permission.

Summary

Each patient presenting for improvement of their forehead appearance will present with different problems and concerns and no one forehead lift procedure will be best for all patients. Foreheadplasty techniques using a coronal incision offer certain

advantages over closed procedures and should result in an inconspicuous scar and few complications if skilfully performed. These advantages include that they provide an actual reduction in forehead scalp and/or skin redundancy, and as such may provide better brow elevation and a more durable and sustained improvement. In practice, a procedure using a coronal incision

(a)

(b)

(c)

(d)

Figure 67.29 (a) Patient, age 49, preoperatively. Note that she has suboptimal eyebrow position and configuration that imparts a somewhat angry and disapproving appearance even though her face is in repose. She has had prior upper and lower blepharoplasty performed by another surgeon. (b) Same patient, 14 months following small-incision non-endoscopic forehead lift. Note that she has a more rested and agreeable appearance. A facelift, neck lift, upper and lower blepharoplasties and fat transfer to the cheeks, lips, jawline and infraorbital areas have also been performed. (c) Preoperative view of the same patient frowning. Note that she is able to produce deep creases and has an angry appearance. may be the procedure of choice for patients with abnormally low hairlines who wish their hairline to be raised and placed in better proportion with the rest of their face.

Many patients seeking rejuvenation of their foreheads are troubled by high hairlines and the prospect that surgery will make their problem worse. Hairline elevation occurs in both coronal and closed endoscopic techniques, and hairstyles cannot always conceal an overly high forehead. A high forehead also appears unnatural,

masculine and detracts from an otherwise attractive and agreeable appearance. Unlike procedures using a coronal or endoscopic technique, procedures using an incision or partial incisions along the hairline allow hairline position to be maintained or lowered and hairline shape to be optimized, and the improvement thus gained may outweigh the drawback of the resulting scar.

Experience has shown that it is not necessary to use an endoscope to mobilize and release the forehead and modify the corrugator

(a)

(b)

(c)

(d)

Figure 67.30 (a) Patient, age 47, preoperatively. Note that she has a somewhat tired, angry and disapproving appearance, even though her face is in repose. She has had no prior surgery. (b) Same patient, 1 year and 7 months following small-incision non-endoscopic forehead lift. Note that eyebrow position and configuration have been improved and that the patient has a more relaxed and agreeable appearance. A facelift, neck lift, upper and lower blepharoplasties and fat transfer to the cheeks, lips, jawline and infraorbital areas have also been performed. (c) Preoperative view of same patient frowning. Note that she has strong frown muscles that produce deep creases and an intense angry appearance. supercilii muscles if forehead anatomy is understood, the operation is appropriately planned and a transpalpebral approach to the corrugators is used. Although an endoscope can be used for these purposes if desired, a procedure in which an endoscope is not necessary saves time, avoids problems related to the device itself (e.g. fogging, mechanical failure) and avoids the costs of purchasing, leasing and maintaining expensive related equipment. In addition, transpalpebral corrugator myoplasty, when used in conjunction with closed mobilization and resuspension of the fore-

head, not only provides a means to perform a closed foreheadplasty without an endoscope, but also gives a method by which medial brow elevation can be minimized or avoided.

CHAPTER 68

Upper eyelid rejuvenation

Adil Ceydeli,¹ Tong C. Duong¹ and Robert S. Flowers²

¹Plastic Surgery Institute & Spa, Lynn Haven, FL, USA

²Flowers Clinic, Honolulu, Hawaii, USA

Introduction

Upper eyelid surgery is one of the oldest and most common surgical procedures. Descriptions of eyelid surgery were recorded in Indian *Sanskrit* texts more than 2000 years ago.¹ Such eyelid surgery is consistently one of the most common reconstructive and appearance-related procedures and is performed throughout the world. But many people doing this operation are mistaken about its simplicity, as well as the common complications that may be expected when it is done without proper knowledge, training and understanding of the operation and its potential outcomes.

Upper blepharoplasty can indeed be performed under local anaesthesia, and in an office setting. Yet surgeons should not underestimate this detail-oriented, complication-prone procedure as quick and easy because it looks and seems simple. It can, in selected cases, be done in a short period of time, and is widely considered a relatively quick procedure, with a reliable source of insurance income generation in some countries. But we, as surgeons must not fail to choose the needed and indicated (and perhaps more complicated – and longer) periorbital operation(s), in favour of the one that seems quicker, simpler and predictably paid for by third parties.

Indications for surgery

Upper eyelid surgery is done for both functional and appearance reasons. Visual fields are profoundly affected by the upper eyelids, either by excess tissue weighing down on the lids and lashes, or by the attenuation of eyelid – and brow – muscles causing droopy eyelids. Commonly the brow and forehead play a major role in functional and appearance, in lid deformity, lid asymmetry and eyelid ptosis, both unilaterally and bilaterally, often making the corrective operation more complicated functionally, aesthetically (and financially).

Cosmetic and functional correction of baggy eyes is sought by addressing the amount of eyelid, brow and forehead skin

excess, the position of the lid crease, the tilt of the eye, any bulging puffiness, hollowness and other potential asymmetries. This is usually done by carefully examining the patient who is seated vertically, directly in front of the examining surgeon.

Diagnosing lid ptosis preoperatively is important. In the senior author's (RSF) huge number of courses on lid surgery taught around the world, he would traditionally start by asking the class for the most common cause of postoperative lid ptosis. The answer was so simple, but never answered correctly – except by an occasional former student. The most common cause of postoperative ptosis is ... undiagnosed preoperative ptosis. Simple but true.

Another way to separate true ptosis from the weight of the brow causing one or both lids to sag, is to simply elevate the brow slightly with a finger, and see if the lid ptosis disappears. Doing this bilaterally can also make the surgeon aware of unrecognized lid retraction, hidden by brow ptosis, which could result in a most unattractive outcome from lifting the brow.

Preoperative evaluation

Good preoperative evaluation is the key to achieving great results with blepharoplasty. The periorbital region should be evaluated as a whole, including the brow position and lower eyelid characteristics. The effects of adjacent structures such as eyebrows (and sometimes lower eyelids) on the upper eyelids should be pointed out to each patient. Commonly a person's right brow is lower than their left (more than 80% of the time in senior author's personal experience) with the patient's left being lower in only 10% of the time, and the brows proving equal in approximately 7%. These statistics do vary some degree between ethnicities. Know, for sure, however, that upper blepharoplasty does not correct eyebrow ptosis, nor can it overcome any imperfection of the lower eyelid and the orbital bone structures. The senior author pointed out many years ago the importance of combining frontal lift with upper eyelid surgery for the best eyelid results in many, if not most, eyelid patients, while occasionally choosing browlift alone to clean up the brow, lids and upper orbit.²

Often we use that same brow access to restore youthful characteristics of the lower lids (via canthopexy into the bone) for canthal restoration and lower lid correction.^{2,3}

Careful and thorough preoperative evaluation identifies the problems applying to each selected patient, and a surgical plan is crafted accordingly. General physiology of the eye, such as tearing, dry eyes, increased globe tension (diagnosed with a simple tenometer test) and careful diagnosis of globe protrusion is essential. Consultation assuring appropriate candidacy for surgery, confirmed by a friendly ophthalmologist, should be sought when deemed appropriate. General health conditions are also important considerations to ensure the patient is a good surgical candidate for elective surgery, with minimal risks of bleeding, infection, abnormal scarring and adverse medical complications.

Few eye surgeons understand how and why women in particular *always* raise their eyebrows, smile slightly and tilt their heads posteriorly every time they look into a mirror, or have someone look directly at their face, as well as each time a camera is pointed toward their face (especially in the doctor's surgery). Because of this, we rarely have accurate preoperative and postoperative pictures by which to gauge the way our patients look before we do their surgery. As well as hindering our assessment of their postoperative appearance, this behaviour leaves us uncertain of the quality of our patients' surgical results. A large number of patients seek out plastic surgical repair because of a coincidental snapshot looking so different from their expressions and looks in professionally prepared photographs, or their own glances into the many mirrors before which they have posed each day.

Eyelid surgery is commonly referred to in fashion magazines as 'eye lifts'. In general, 'eye surgery' is anything but a 'lift'! Brows are continually and commonly raised to the patient-learned attractive level, even in youthful people. This is done not only to raise the eyebrows and keep them from interfering with vision, but also to convey a more attractive, more youthful 'look'. This is especially significant when being looked at and scrutinized when looking into a mirror, or being 'captured' by a casual camera.³ As mentioned earlier, excision of eyelid tissue encourages the brows to drop, exaggerating that look the person has tried so hard to prevent – looking older, more tired and angry as well. This detrimental appearance is caused by a relaxation-drop in the lateral-upward pull of the frontalis muscle (relaxation of which is responsible for creating a frown), which inserts primarily into the central third of the brow musculature. This lessens the upward pull of the frontalis muscle, allowing a greater prominence of the now less opposed frown activity of the corrugator musculature, causing exaggeration of the frown, while the brows (especially in their medial aspect), and often the upper lids come plummeting down too.

From time to time we see elderly patients in whom maximal brow elevation is still insufficient to have comfortable forward vision, even with the head tilted backwards. In these patients significantly large amounts of upper lid-juxta-brow skin can

often be sacrificed, allowing the patient's profound brow elevation to now have a sufficient effect to have good forward vision. In these patients simple upper blepharoplasty, often exaggerated, is of immense value, even when the brow eventually drops a bit. These patients will be 'blepharoplasty happy', and some even experience significantly improved facial appearance!

In less elderly people the more lid skin removed, the more the brow will drop (making the person look older and more tired) as well as allowing the relaxation of brow, making that same person look more angry and unhappy. The one positive feature is that transverse forehead wrinkles generally diminish to some degree, often enough to significantly benefit a person's looks, and that alone does a great deal to counteract the old, tired and often angry appearance.

One can observe this phenomenon by having the patient sit relaxed in front of you, with eyes closed. Gently stroke the brow and you will see the frown quickly develop as the brow relaxes. When the patient is totally relaxed, note (and record) the symmetry of the eyebrows, and then press the brow skin firmly down against the skull. Holding tight, ask the patient to open his or her eyes, and carefully notice how far caudal the brow is capable of descending by blocking elective brow and lid elevation. This type of examination shows the surgeon where the greater problem commonly lies – in correcting brow position rather than in excising seemingly excess lid skin. This is true for patients as young as in their twenties, thirties and forties, or even in or before their teens. Performed well, browlifting is often far more important than correction of the upper lids, but generally a lot more expensive! Realize, however, that in many patients, especially older ones, lid tissue removal is an important part of the repair, but more so when combined with brow and/or frontal lifts. Remember, if you do nothing to correct the brow, your result is likely to be disappointing to both you and your patient.

Anatomy

The upper eyelid has eight layers that are relevant to surgery, from superficial to deep: skin, orbicularis muscle, preseptal or retro-orbicularis oculi fat, orbital septum, orbital fat, levator palpebrae muscle/aponeurosis, Müller's muscle/tarsal plate, and conjunctiva (Figure 68.1).⁴ The lacrimal gland lies at the same depth as orbital fat, and it is considered as contained in the lateral compartment, whereas orbital fat is organized into medial and middle compartments. The pretarsal portion of skin adheres to underlying layers through a series of septa, forming the eyelid crease and fold, which may be absent in East Asian patients; creating or adjusting the eyelid crease is performed with this adhesion in consideration. The palpebral muscle and Müller's muscle determine the degree of eyelid opening, with somatic nervous control for palpebral muscle and autonomic control for Müller's muscle; correction of ptosis involves these muscles. Orbital fat and preseptal fat contribute to the bulging and puffiness of the eyelid. The line where the orbital septum

Figure 68.1 Essential surgical elements of upper eyelid anatomy.

fuses with levator muscle creates the depth of the upper eyelid, which can appear hollow if this line is retracted. The surgeon should keep in mind the correlation between these anatomical structures and the eyelid appearance and function while performing the art of upper eyelid surgery.

Operative techniques

The operative techniques should address the concerns detected in the preoperative evaluation, layer by layer of the eyelid.⁵

Skin incision and excision

Mark the incisions while the patient is sitting upright. The amount of skin excision will depend on whether a browlift accompanies the upper eyelid surgery or not. Try a combination of a frontal lift with upper blepharoplasties, when possible, to achieve better outcomes. Know that only about 1 out of 10 patients have brows that do not drop precipitously as a result of eyelid skin excision.

Marking is done prior to local anaesthetic infiltration, first with eyes open and the patient sitting up for determination of the level of eyelid and brow ptosis (as described earlier), then with eyes closed while the patient is lying down in relaxed position. The skin incision line (eyelid crease line) is marked along the natural line of the eyelid; positioned at the desired level of the eyelid crease, usually 7–9 mm above the lash line in women

and 5–7 mm above the lash line in men. It is curved superiorly at the lateral ends to provide the pleasing upward slant and to avoid puckering or ‘dog-ear’ formation distally (Figure 68.2a,b). The amount of excess skin to be removed is commonly estimated by pinching with a fine forceps above this incision line at mid-pupil vertical axis and tapered toward both ends (Figure 68.2c). Symmetry of the pretarsal lid segments (lash margin to lid crease distance) is much more important than symmetry of lid crease to brow distances.

One should always keep in mind the position of eyebrows. If a browlift does not accompany the upper eyelid surgery, then more skin and orbicularis muscle should be removed on the side where the brow is lower to compensate for the asymmetry caused by brow location (Figure 68.3).⁵ But the more lid skin excised, except in the elderly, the greater will be the brow drop, and the more lid and brow excision necessary to visualize the juxta-brow covered eyelid and pretarsal lid skin.

Lidocaine (lignocaine) 1% with 1:100 000 adrenaline (epinephrine) is the usual local anaesthetic, injected subcutaneously at the beginning, with additional injection as needed when dissection is carried to deeper layers.

Orbicularis muscle layer

A strip of muscle along the incision can be excised to reinforce the new position of the eyelid crease, or to create a crease for those who do not have it. The sliver of orbicularis muscle excision should occur separate from the skin excision (Figure 68.2d).

Figure 68.2 (a) At the beginning of procedure, turn the lid over and measure the tarsus. (b) With the skin under uniform tension, mark the lower skin incision with a Jameson caliper. Usually the height of pretarsal skin incision mark is less than the height of the tarsus. (c) Mark the upper skin incision. (d) Skin excision occurs separate from the orbicularis muscle excision. (e) Remove sliver of orbicularis muscle carefully. Never tent the muscle up during excision for fear of inadvertently transecting the aponeurosis.

Make sure you do not injure the aponeurosis when trimming the muscle. One must never tent the muscle up during excision for fear of inadvertently transecting the aponeurosis (Figures 68.2e and 68.4). A larger strip of muscle can also be removed to reduce

any existing looseness or redundancy. This step can be bypassed if there is no need to adjust the eyelid crease or muscle excess, and access to orbital fat is achieved by splitting the muscle layer at respective compartments in that case.

Figure 68.3 Different ways to correct eyelid asymmetry due to asymmetrical brow position. (a) Asymmetrical frontal lift. (b) Insert a superiorly based periosteal flap into the junction of the middle and lateral thirds of the brow which is lower. (c) Excise more lid skin on the side of the lower brow. (d) Excise more muscle on the side of the lower brow. (e) Make the pretarsal skin segment taller on the side of the lower brow, and anchor it at the higher level into the tarsus or the aponeurosis or both.

Figure 68.4 Inadvertent injury to levator aponeurosis during orbicularis muscle excision, when the muscle is mistakenly tented during excision.

Preseptal and orbital fat layers

Orbital fat is approached through openings on the orbital septum, although care should always be taken to open the septum in a way that preserves maximum length of the aponeurosis (Figure 68.5), or at least of the septo-aponeurotic extension

thereof, to assure a proper connection without creating lid retraction. The orbital septum should be entered laterally to prevent damage to the aponeurosis, which may cause further lid ptosis. The septo-aponeurotic sling that houses the orbital fat descends lower laterally, and migrates cephalad nasally. If this direction of sling is not appreciated, an attempt to open the septum across the lid is likely to sever the aponeurosis instead. Once the orbital septum is open across the lid, then the fat excision is quite simple. Be conservative! The baggy and puffy appearance of upper eyelid can be softened with conservative removal of excess preseptal and orbital fat. (Figure 68.6).

Lacrimal gland

The lateral bulging of upper eyelid can be a result of a sagging lacrimal gland. The orbital lobe of the lacrimal gland can be sutured to the periosteum lining the inner side of the superior orbital rim to correct this appearance.

Levator muscle and orbital septum

Preoperative diagnosis of lid ptosis is essential. Ptosis caused by attenuation or laxity of levator muscle can be corrected with imbrication of the muscle to the superior edge of tarsal plate, using interrupted absorbable suture such as 6-0 Vicryl or PDS. This manoeuvre also brings the orbital septum–levator muscle

Figure 68.5 The septo-aponeurosis sling housing the orbital fat descends lower laterally and migrates cephalad nasally. If this direction of sling is not appreciated, an attempt to open the septum across the lid may sever the aponeurosis instead.

fusion line forward, softening the hollowness of the upper eyelid. In case of severe upper lid hollowness, tighten the suspensory ligament of the globe with the same orbital rim suture used in the canthopexy, commonly described in the senior author's publications and many lectures and courses. This is the best treatment when the thickening on the orbital septum between medial and middle compartments is weakened by ageing or previous surgery. Tightening the orbital septum with the same canthopexy suture gives additional tightness to the lower lid, which lifts the globe and tightens the lower lid and orbital contents significantly, pushing on and lifting the upper lid fat so it fills out the hollowing of the upper lid that frequently accompanies ageing, especially when accompanied with weight loss.

Closure of incision

The incision is closed simply with a running suture. Another advantage of simple running closure is the ability to recreate or further define the lid crease by incorporating the edges of the aponeurotic tabs into the skin closure across the lid (Figure 68.7).

Examples

Examples of upper blepharoplasties and coronal browlifts are shown in Figures 68.8 and 68.9.

Postoperative care

Patients should be advised to sleep at 45° head elevation post operatively. This diminishes the swelling, which can be significant for the first three weeks. To minimize the early excessive swelling, compressive bandage can be used overnight for periorbital protection, although this will blindfold the patient, and may not be well tolerated by some. It does, however, speed up the recovery and minimize haematoma. Cold compressions should be used for the first few days after the

bandages are removed to further control the swelling. They need not be used for longer than 2 days. Usually the swelling has diminished by around two weeks, however rarely it may last longer than several weeks.

Patients should avoid any vigorous activity for several weeks, with no sudden increase in heart rate and blood pressure, thus minimizing the risk of postoperative bleeding.

Pain is usually minimal, and well tolerated with paracetamol.

The sutures are usually removed within 5–7 days, and the patient should avoid rubbing the eyes, so the fine sutures are not loosened or broken within the early stage.

During the first week or two, ophthalmic ointment should be used, particularly at night, since most patients are unable to close the lid fully (postoperative temporary lagophthalmus) due to early tightness on the lid as well as swelling.

Complications

Complications of eyelid surgery are usually due to bleeding, transient disturbances in tear mechanism and excess skin excision. Good compressive overnight bandaging diminishes bruising, swelling and damage, as does avoidance of rubbing of the eyes.

Haematoma

Superficial haematoma usually occurs when a patient experiences a surge in blood pressure, such as during vomiting, coughing, straining, pain or anxiety. Some over-the-counter medications, such as aspirin or ibuprofen, taken inadvertently, could contribute to this complication. Haematoma that appear to extend posterior to the orbital septum must be addressed urgently, with exploration under good light for irrigation and haemostasis. Ice compresses, head elevation and pain medication are some routine measures that might prevent this kind of complication.

Figure 68.6 (a) Fat excision is quite simple with the orbital septum open across the lid. (b) There is often a prominent tuft of lateral orbital fat tucked behind the orbital rim, next to the lacrimal gland. This fat may be excised, or it may be transposed into the hollow defect. (c) Careful haemostasis is performed with bipolar cautery.

Subconjunctival haemorrhage

This is a collection of blood under the conjunctiva; it is usually absorbed in 10–14 days. Irritation and tearing can result from this condition. Ice saline compresses, artificial tears or ocular lubricant can keep the patient comfortable until resolution.

Conjunctivitis

Inflammation of the conjunctiva can be from sutures, blood clots, pieces of tissue, corneal abrasion or infection. A severe reaction to light suggests corneal abrasion, and examination with

fluorescein should be done. Obvious pus should be cultured. Artificial tears and ocular lubricant are used for inflammation without infection. Antibiotic drops such as Sulfamyl or antibiotic ointment such as bacitracin can be used for infection. An eye patch provides relief for corneal abrasion or severe irritation.

Abnormal tearing

The tearing mechanism may need some time to return to normal functioning after surgery. During the first couple weeks post-op, patient may experience excessive tearing (epiphora),

Figure 68.7 Skin closure and recreating or further defining the lid crease by incorporating the edge of the aponeurosis into the skin during closure.

Figure 68.8 Isolated upper blepharoplasty. Before and after pictures. (Performed by RSF.)

dry eye syndrome and visual blurring. Symptomatic treatments with artificial tears, lubricant and patching usually resolve the condition over time.

Lagophthalmos and ectropion

Lagophthalmos is a condition where an eyelid cannot close completely. If this occurs post operatively, it may mean that too much skin has been removed. Often patients can tolerate 1–2 mm lagophthalmus, but 2–3 mm can lead to desiccation of the ocular surface. Factors causing lagophthalmos are excess skin excision, weakness of orbicularis muscle, paralysis of the temporal branch of the facial nerve, tethering of the eyelid to deeper structures or bad scar formation. Initial treatments include the usual supportive measures of artificial tears, ocular lubricant and eye patch; and stretching eyelid massage.

Ectropion is the turning outward of the eyelid, exposing palpebral conjunctiva. This condition is the result of excessive removal of skin, especially in patient with pre-existing laxity of eyelid. Treatments are similar to those for lagophthalmos.

Profound drop of brows and accentuation of corrugator frown

This commonly occurs after upper blepharoplasty when compensated brow ptosis is not recognized before surgery, and simultaneous or planned browlift is not incorporated into the plan.

Asymmetry

Failure to recognize brow ptosis preoperatively, failure to accurately measure and mark the skin for the lid incision and skin excision, failure to recognize and compensate for asymmetrical eyelid ptosis are all causes of postoperative eyelid asymmetry. The most important manoeuvre to minimize this happening is a superb preoperative exam, and careful marking and planning.

Lid ptosis

Varying degrees of lid ptosis are common in the early postoperative period due to swelling, usually subsiding without intervention. The commonest cause of persisting lid ptosis after

Figure 68.9 Upper blepharoplasty and coronal browlift. Before and after pictures. (Performed by AC.)

surgery is undiagnosed preoperative ptosis, which is often exacerbated in the early postoperative period by stiffness and increased weight of lid oedema. If the preoperative ptosis is not well documented and pointed out to the patient, the postoperative ptosis will inevitably be blamed on the surgeon. Another common cause of ptosis is iatrogenic injury to levator muscle or aponeurosis, commonly caused by careless lifting of the tissue while excising a strip of orbicularis muscle. Bleeding to Müller muscle may also cause prolonged ptosis.

Conclusion

Upper blepharoplasty can be a splendid operation when done by skilled surgeons on the right selection of patients, under the correct conditions. The operation usually occurs under local anaesthesia, assisted by light oral or intravenous sedation.

Good outcomes soar after upper blepharoplasties, especially when combined with skilled browlifts, and even more so when globe-lifting lower lid-tightening procedures are added.

CHAPTER 69

Lower eyelid–cheek junction rejuvenation

Sam T. Hamra

Department of Plastic Surgery, University of Texas Southwestern Medical Center, Dallas, TX, USA

Introduction

Ross D. Farhadieh

Background

The appearance of tired eyes, saggy skin or bulging lower lid fat are the most commonly sighted reasons for seeking remedy from a plastic surgeon. Traditionally, lower lid ageing is considered in isolation by textbooks and surgeons but is a more complex phenomenon. Anatomical nuances and support structures of the lower lid profoundly influence what we perceive as blemishes of age. Moreover, ageing of the surrounding terrain profoundly influences the lower lid appearance. A complete lower lid assessment should not be carried out in isolation but at the very least should include the midface.

As operative techniques have evolved over the years, our anatomical knowledge and understanding of the ageing process has grown. Arguably, many traditional operative techniques are not a restoration of anatomy to its youthful appearance, but camouflage techniques addressing part of outward appearance. This chapter provides a basic background to lower lid blepharoplasty, before following the evolution of thought and techniques of Dr Hamra over the last 40 years, allowing the reader to benefit from his enormous experience, innovations and philosophical approach.

Anatomy

The lower eyelid and the cheek must be considered together in aesthetic surgery. At the level of the inferior orbital rim the lower eyelids transition to cheek. The lower lid crease, extending 3–4 mm inferior to the lid margin medially, extends to 5–6 mm below the lid margin laterally. This corresponds to the fibrous connections of the pretarsal orbicularis oculi to the skin. The papebral aperture is approximately 30 mm wide and 15 mm high. The lateral canthus is approximately 2 mm superior to the medial canthus. Normally, in neutral gaze there is no scleral show, with the eyelid touching the lower limbus. The thin lower eyelid skin covers the orbicularis oculi muscle, which is divided into pretarsal, prepetal and orbital components. The lower

orbicularis oculi muscle covers the origins of nose and lip elevators. At the medial canthus a deep slip inserts onto the posterior lacrimal crest, a tripartition of the canthus inserts anteriorly, superiorly and inferiorly. The lateral canthal tendon is made up of four components:

- lateral horn of levator palpabrae superioris;
- Lockwood's ligament;
- check rein ligaments of the lateral rectus muscle;
- preseptal and pretarsal orbicularis oculi muscle

The lateral raphe is a complex structure, which consists of a thickening of the pretarsal orbicularis oculi, lying superficial to the lateral canthal tendon, medial to the orbital rim. The lower eyelid is divided into three components: the anterior lamella formed by skin and orbicularis muscle, the middle lamella by the septum and the tarsus, and the inner lamella formed by the conjunctival lining. Beneath the orbicularis oculi muscle and superficial to the septum lies the suborbicularis oculi fat (SOOF) (Figure 69.1). The septum extends from the inferior border of the tarsal plate to a periosteal thickening at the inferior orbital rim, the acrus marginalis. The tarsal plate is 4–5 mm wide and the capsulopalpebral fascia, the lower lid retractor, originating from the inferior oblique, inserts onto its lower border. Orbital fat is divided into three compartments: medial, central and lateral. The inferior oblique muscle separates the medial and central compartments (Figure 69.2). Orbital fat is physiologically different to the rest of the body in that it:

- has smaller cells,
- has less lipoprotein lipase,
- is less metabolically active and therefore unaffected by diet, and
- is more saturated.

An arcade formed by the inferior medial and lateral palpebral arteries supplies the lower lid. Aesthetically, the cheek supports the lower lid, with the orbimalar ligament serving as a retaining structure preventing descent. The nasojugal groove or tear trough extends from the medial canthus to mid-pupillary level. Lateral extension of this groove as the palpabromalar groove forms the lid–cheek junction.² More recent anatomical studies have elucidated an osteocutaneous ligament, the tear trough

ligament, extending from the maxilla through the septal and orbital orbicularis oculi components.³ More details about the process of lower lid ageing can be found in earlier sections of this compendium and more specialized texts.

Examination

After a thorough medical and ocular history, a focused physical examination is undertaken. A general observation of the face, its subunits, presence of scars, asymmetry, globe position and general skin condition from multiple views is performed. Medications including antiplatelet and blood thinners are noted.

In neutral gaze there should be no scleral show. Lid retraction and snap test are used to assess lower lid laxity. A superomedial and superolateral gaze cause protrusion of the medial, central and lateral fat pads respectively. Gentle palpation of the globe with the eyes closed also enhances their appearance. Where the globe is more anterior to the most anterior part of the zygoma, a negative vector position is noted. The normal intercanthal tilt is 10–15°, with the lateral canthus lying more superior. Both a negative vector and/or canthal tilt have unfavourable aesthetic implications for the lower eyelid.

Operative approach

Although the lower eyelid should be considered as part of a larger lid–cheek subunit, traditional division in approach persists. Here we will discuss the basics of isolated lower lid blepharoplasty as a background, to Dr Hamra's more comprehensive approach to lower lid rejuvenation. Operative surgery can be thought of as addressing the three major components in the lower eyelid in different measures:

- skin only or skin/muscle,
- orbital septum, and
- orbital fat.

These are undertaken through either transcutaneous or transconjunctival approaches.

Where a transcutaneous approach is taken, a standard subciliary incision is made, elevating the marked redundant skin or a skin and muscle flap. A preseptal approach is taken to the level of the infraorbital rim. Where the septum is not addressed, stab incisions and gentle pressure on the globe allow excision of the fat compartments before closure of the cutaneous incision. Resection of the fat compartments however, leaves the eye with a hollow and ultimately aged appearance. Moreover, it does not adequately address the tear trough deformity. Although use of soft tissue fillers to address this deformity has become common place it was Loeb who first suggested release of the medial fat compartment, its transposition and fixation against the more medially placed nasal and lip elevator muscles to address the nasojugal groove.⁴ Septal release at the level of arcus marginalis allowing free draping of the fat compartments over the orbital rim followed by the septal reset procedure was conceived by Dr Hamra and is discussed in more detail in the next section.^{5,6}

Where a transconjunctival approach is taken, the skin is either in very good condition with no redundancy or is expected to be amenable to surface laser rejuvenation. In this approach an incision is made below the tarsal and either a direct approach through the capsulopalpebral fascia or a

preseptal approach to the fat compartments is taken.⁷ More recently the nuanced nature of septal support has been appreciated. Plication of the most inferior part of the septum, thought to have become redundant with age and contributing to appearance of fat herniation, is undertaken through this approach. The proponents of this technique cite preservation of the anterior lamellar and subsequently reduced risk of scleral show as a major advantage.⁸

There are many other permutations and combinations of the surgical approach to lower eyelid rejuvenation. The interested reader is referred to more specialized texts in this field.

Complications

The most catastrophic complication is a retrobulbar haematoma related to fat excision, which may cause blindness. Fortunately, the rates of this complication are estimated around 0.05%. The surgeon must be vigilant for its signs and expeditious in its treatment. Disproportionate pain, proptosis, lid ecchymosis, dilated pupils, decreased vision and reduced extraocular movements are signs of an evolving retrobulbar haematoma. If untreated, central retinal artery occlusion and subsequent blindness will ensue. This is considered irreversible after 100 min. Its treatment is a matter of surgical emergency, the patient's head is elevated, surgical incisions are released, mannitol (12.5 g IV bolus over 3–5 min), acetazolamide (carbonic anhydrase inhibitor 500 mg IV bolus), topical beta blockers, large dose of steroids (Solu-Medrol 100 mg IV) are administered, surgical cantholysis and re-exploration of the surgical field is undertaken urgently.

Corneal injuries, dry eyes, scleral show, ectropion and lid position asymmetry are among other complications. Where an early postoperative scleral show and evolving ectropion is noted during follow-up, increased massage and consideration of administration of steroid or 5-fluorouracil could be given to reduce this risk. Persistent scleral show and established ectropion will ultimately have to be thought of as cicatrization or shortness in one of the eyelid components, anterior or middle lamella. In extreme circumstances revisional surgery must be undertaken to address the tissue deficit. Dr Hamra's philosophy and evolution of personal techniques over the last few decades follows and entails many lessons in approaching lower lid rejuvenation.

Lower lid rejuvenation: evolution of approach and technique

Sam T. Hamra

Lower eyelid rejuvenation has been a part of facial surgery since the early part of the twentieth century. As early as 1928, removal of the lower eyelid fat was a consistent manoeuvre in most eyelid surgery in an attempt to remove the stigmata of fatigue and age.

My experience with lower blepharoplasty began in 1970 with my residency training. Initially a skin flap was elevated, followed

by three stab wounds to retrieve the three pockets of fat always described under the lower eyelid orbicularis. About that time, British surgeons began elevating a skin muscle flap, which seemed to be an advance by producing less ecchymosis, although many surgeons at that time were still excising a pre-marked pattern of skin without muscle by doing a 'skin pinch' manoeuvre with small forceps. Even without undermining, this was a satisfactory approach, as the width of the pattern was rarely 2–3 mm so that primary closure could be done without muscle excision. As a resident, I was not in a position to follow these patients any length of time, therefore I have no idea how many eventually developed some degree of lower lid malposition. When I entered private practice in 1973, my procedure choice was a skin muscle flap, with fat removal when indicated, which of course was very often, in my opinion.

I continued this approach throughout the 1970s and 1980s in spite of the fact that frequently neither the patient nor I were happy with the results. In general, all facelifts of that era were skin lifts with superficial musculoaponeurotic system (SMAS)⁹ elevation. I was fortunate to have learned the Skoog rhytidectomy several years earlier. Forehead lifts were not commonly done. In the majority of blepharoplasties that I performed, results were acceptable, at least by the criteria known to me at that time. There were occasional problems with scleral show, which would become manifest often after several months, as oedema from both the facelift and eyelid procedure subsided. It was during this period also that the transconjunctival lower eyelid fat technique became popular. I used it frequently for young patients, depending on any loose skin to shrink as it did with liposuction and rhinoplasty. As with standard blepharoplasty results, I still felt that the lower eyelid anatomy and contour were not in many cases sufficiently rejuvenated.

From this point going forward my experience and philosophy of orbital rejuvenation became intimately integrated with facial rejuvenation. Although this chapter emphasizes blepharoplasty procedures, my experience, as opposed to many surgeons around the world, must be described in terms of the impact of facelift operations on the orbital zone. In order to fully describe my personal steps on the way to the technique that I utilize today for the lower eyelid I must give the reader a background of my facelift experience, and how these milestones in my personal journey impacted the results I can achieve today.

In 1985 I began exploring the possibility of improving the nasolabial fold, which at the time seemed the most unimproved with facelift surgery. I discovered that the fat of the cheek overlying the zygomaticus major and minor muscles could be elevated with the skin. Since 1973 I had routinely performed a Skoog rhytidectomy.^{10,11} When adding the cheek fat to the Skoog flap that contains the platysma muscle of the lower face, my facelift results seemed much better. I called this technique a 'deep plane rhytidectomy', as published in 1990.¹² The results of this technique caused me to look more carefully at the lower eyelid. Moving the fat of the cheek, or malar fat as some surgeons labelled it, in a superior lateral vector seemed to impact

Figure 69.3 (a) Postoperative standard blepharoplasty with orbital fat removal. (b) Following a deep plane rhytidectomy. (c) This patient then underwent an isolated orbicularis repositioning with a coronal brow lift. (d) The brow lift and orbicularis repositioning then gave the patient a harmonious facial rejuvenation.

the orbicularis oculi, which at the time was not elevated. This is to say that the juxtaposition of the elevated malar fat next to the unelevated orbicularis created an even deeper appearing lower eyelid following blepharoplasty than I had seen before. This appearance was made more severe with the removal of lower eyelid fat. This was the first time that I realized the balance between the lower eyelid and cheek anatomy historically following cosmetic surgery was suboptimal, since frequently the patients appeared less attractive and less youthful than they had before surgery was done.

It was in 1990 that I decided to reposition the lower orbicularis oculi along with an isolated forehead lift. The patient in Figure 69.3 was the first to undergo this combination. I had done a conventional upper and lower blepharoplasty on her in 1984, with what I thought to be an acceptable result

(Figure 69.3a). In 1989, however, I performed a deep plane face-lift (Figure 69.3b). As described in the deep plane article, the cheek fat had been moved in a superior lateral vector. Rather than creating an attractive person, I had in fact disrupted the harmony of the ageing face with the combination of procedures that I thought were innovative and acceptable. Faced with a dilemma of what to do, but having no previous experience that would direct my next move, I decided to return to the operating room to perform the isolated orbicularis repositioning with a coronal forehead (Figures 69.3c,d). I then witnessed for the first time in my career what I thought to be the closest I had seen to a harmonious facial rejuvenation. It was for me a 'Eureka' moment.

I then decided that if I had in fact included the cheek fat with the platysma muscle in the facelift flap, perhaps I could simply

add the orbicularis muscle to the same flap. Searching for a new description of this technique, I decided on the term 'composite rhytidectomy'^{13,14} since the orbicularis, cheek fat and platysma muscle maintain their intimate relationship with each other in the flap, very much like the 'composite' grafts from the ear that contain skin, fat and cartilage, which have been used for many years for nasal reconstruction. The word 'composite' is defined in the dictionary as 'made of many parts', which reaffirmed my feeling that this was an excellent name for a surgical procedure, rather than the commonly used acronyms in plastic surgery that lend themselves to marketing for the lay public. Unfortunately, because of my earlier use of 'deep plane', some confusion naturally arose. However today, as then, a composite rhytidectomy absolutely must include the elevation and repositioning of the orbicularis oculi muscle of the lower eyelid.¹⁵

A deep plane or high SMAS procedure does not impact the lower eyelid at all in spite of claims of vertical movement. This composite facelift technique was presented at the American Society for Aesthetic Plastic Surgery annual meeting in New York City in 1991. Part of the explanation of the advantage of the composite technique was demonstrated with the patient in

Figure 69.4, who achieved a very obvious shortening of the height of the lower eyelid, with the pre- and postoperative results marked to demonstrate this result. To my knowledge this was the first presentation that clearly demonstrated the shortening of the height of the lower eyelid.

Unfortunately, the concept was so new that few understood what I was trying to accomplish. Mainline plastic surgery thinking, which included the surgeons who had been doing SMAS techniques, allowed little room for what appeared to be an approach that was too new for many to accept. For many, it appeared to be a technique needing a generous amount of time for the steep learning curve.

From 1990 to 1992 as I performed the orbicularis repositioning with a composite facelift, I continued to remove lower eyelid fat, as tradition dictated. In spite of what I thought was a marked improvement in the harmony of the face, I still noticed a certain hollowness of the lower eyelids (Figure 69.5) when comparing my results to daughters of my patients who bore a strong resemblance to their mothers. In fact I published a series of mothers and daughters in my 1993 book entitled *Composite Rhytidectomy* in an attempt to draw attention to my target of a youthful eyelid-cheek junction. I received one day

(a)

(b)

(c)

(d)

Figure 69.4 In 1990 this patient underwent a composite facelift with orbicularis repositioning, plus removal of lower eyelid fat. This was the first demonstration of the shortening of the lower eyelid, which was presented in 1991.

Figure 69.5 In the latter half of the third decade, the soft tissue covering of the bony framework of the human face loses tone exposing the underlying anatomy. It is at this point that a 'eye socket' seems to become manifest.

in the mail a list of new plastic surgery books. One was a book on eyelid surgery from Raul Loeb, a Brazilian surgeon. He described a 'fat sliding procedure' in which he took the medial fat pocket of the lower eyelid and put it under the orbicularis medial attachment to improve the 'nasal-jugal groove'.¹⁶ However, he continued to remove the middle and lateral fat pockets and did not reposition the orbicularis muscle. The problem I saw with my results was a generalized hollowness of the complete lower eyelid. Since I had the orbicularis elevated, I then attempted to use all the fat of the lower eyelids and to suture it over the orbital rim under the repositioned orbicularis oculi muscle. Because I had been trained that the septum orbitale should not be manipulated, else an ectropion may occur, I felt it best to excise the septum. I published this paper in 1995 and called the procedure an 'arcus marginalis release' with preservation of all of the lower eyelid fat.^{17,18} Up to that point I had never heard the term *arcus marginalis* used when surgeons described periorbital rejuvenation, and I had never seen an operation where this manoeuvre was utilized. However, when I used the bovie to free the lower eyelid fat at the orbital rim, I was in fact releasing the anatomical barrier that was keeping the fat within the orbit. In this paper I attempted to describe the advantage of not removing the lower eyelid fat, which was commonly done throughout the world since it was described in 1928. By comparing the youthful contour of an eyelid–cheek junction to the ageing contour, it appeared to me that removal of the lower eyelid fat quickly created an even deeper and more hollow lower eyelid that was neither attractive nor youthful. I attempted to demonstrate in this paper that preservation of the lower eyelid fat with transposition of all of the lower fat over the orbital rim and superior vector repositioning of the orbicularis oculi muscle would prevent the hollow lower eyelid syndrome (Figures 69.6 and 69.7).

Although early results were impressive, I was still not satisfied with the tightness and smoothness of the lower eyelid. There are two separate issues I wanted to improve. The first was the fact that regardless of how aggressively I repositioned the orbicularis muscle, the cheek tissue seemed not to reflect the same degree of superior repositioning that I could demonstrate with my fingers before surgery. I did have some experience with subperiosteal cheek dissections, but I felt that the thick cheek flap did not have the elasticity when the periosteum was lifted with the flap. It also seemed that the intermalar distance changed, since the origin of the zygomaticus muscles was elevated in the flap and repositioned.^{19,20} My goal was to preserve the location and original attachment of this muscle origin, but at the same time to move the cheek fat and the orbicularis muscle in a superior medial vector. I discovered I could elevate the soft tissue over the periosteum and extend this elevation both lateral and medial to the origin of the zygomaticus major and minor muscles. To clearly distinguish this flap from the subperiosteal dissections that had become^{21,22} popular due to endoscopic approaches that were being taught around the world, I called it a zygomaticus orbicularis flap (Figure 69.8), and abbreviated the name to the 'zygorbicular' cheek lift. It was very strong and allowed me to effectively reposition the cheek fat that was elevated in the deep plane approach. Moreover I could actually move the cheek fat in a superior medial vector. I became immediately impressed with the very natural youthful appearance of the tissue that was repositioned over the malar eminence.

At the same time, in an attempt to create the youthful 'positive vector' of the lower eyelids, I decided to take a chance and include the septum when I moved the fat of the lower eyelid. I incised the arcus marginalis as before, which was the lower extent of the septum. I then reset this border including lower eyelid fat to the pre-periosteal soft tissue inferior to the orbital rim, and named this procedure the septal reset (Figure 69.9). In this way, the undersurface of the lower eyelid orbicularis was now resting on a

Figure 69.6 The ageing eye has a double convexity, and the youthful eye has a single convexity. The youthful convexity with no evidence of an eyelid-cheek junction is a goal of periorbital rejuvenation.

Figure 69.7 This is an example of a patient following an arcus marginalis release with preservation of the lower eyelid fat. The single convexity has been reestablished.

firm foundation rather than on the softness of only the repositioned lower eyelid fat when the septum was not included. This firm lower eyelid, coupled with a very strong purchase of the cheek tissue to the orbital rim with sutures, completed the mission to create an optimal rejuvenated eyelid-cheek junction.

The septal reset²² had been included in the 1998 article on the zygorbicular dissection but it appeared to be to be buried in the content concerning the flap. Therefore it was published again in 2004 along with an article in the same journal by Barton²³ reaffirming the advantages of the septal reset.

Indications of the composite cheek lift

Primary patients

Essentially every patient I see who is seeking facial rejuvenation, with rare exception, is a candidate for a primary 'composite cheek lift' with or without a facelift. A composite cheek lift consists of a

Figure 69.8 Through the lower blepharoplasty incision, the orbicularis-zygomatic complex could be undermined medial and lateral to the origin of the zygomaticus without disrupting the origin as one must do in a subperiosteal dissection.

Figure 69.9 After excising the arcus marginalis, the septum could be left intact and then reset over the orbital rim.

Figure 69.10 In order to shorten the lower eyelid there are only three possibilities.

Figure 69.11 This 50-year-old had only a composite cheek lift and septal reset.

septal reset and a superior medial vector of the zygomaticus orbicularis manoeuvre. In order to effectively impact the anatomy of the lower eyelid the surgeon has three choices: reposition the orbicularis oculi muscle only; reposition the cheek with a subperiosteal

dissection; or use the zygomaticus orbicularis procedure. I find this last option the most advantageous (Figure 69.10).

Obviously, the normal ageing of the human face progresses from the absence of any landmark of underlying bony anatomy

Figure 69.12 This 48-year-old underwent an upper blepharoplasty and composite cheek lift.

to a point, usually beginning in the late thirties, where a definite 'eye socket' with an eyelid–cheek defining border begins to take shape. The bony anatomy of the facial skeleton changes little, if any, between the second and fourth decades of life. It is the ageing of the soft tissues of the face that changes the surface topography of the face. This proceeds throughout life (see Figure 69.5). The ageing of the lower eyelid skin, while variable with different skin types, loses tone and turgor. The amount of lower eyelid fat is also a variable, and usually genetic in distribution and position. This is naturally true throughout the human species, as DNA no doubt determines the appearance of the face humans inherit. In youth, the septum orbitale confines the fat to the infraorbital space. With the loss of tone of the septum orbitale, the lower eyelid fat, whether normal in volume or excessive, is no longer confined to the original space but manifests itself with 'bags' at the eyelid–cheek junction. It is this appearance that commonly directs the patient to the plastic surgeon.

This ageing becomes manifest in the late thirties and early forties and, coupled with the ageing of the skin of the lower eyelid and the obvious prolapse of the underlying fat of the lower eyelid, clearly differentiates the patient from the youthful-appearing anatomy they enjoyed perhaps 10 years earlier. In these years, I commonly perform an upper blepharoplasty and composite cheek lift, since in most cases the remainder of the facial anatomy shows little, if any, advanced ageing. The patient in Figure 69.11 had essentially no facial ageing except the natural hollowness of the eyelid–cheek area. She had an isolated zygorbicular cheek lift with an arcus release and septal reset. This is an excellent example of the youthful appearance that can be obtained with this technique. A patient of the same age with excess lower eyelid fat will obtain the same endpoint with the same procedure. (Figure 69.12).

By the late forties and early fifties, however, with ageing of the lower face and neck coupled with forehead ptosis, the patient is

a candidate for a comprehensive facial rejuvenation. In my practice, if in fact there is sufficient ageing of the overall facial contour, I usually perform a composite facelift, which includes rejuvenation of the forehead, cheek and face, and the neck.

The criteria for impressive postoperative results following facial rejuvenation has changed over the last 40 years. Initially one was happy with a more youthful jawline. Then in the late 1970s, the emphasis was on the neck contours. The mid-1980s seemed to concentrate on ways to improve the nasolabial folds. In my experience, impressive periorbital rejuvenation began in the early 1990s, with much attention directed at the eyelid–cheek junction. My criteria have now changed, with the emphasis and endpoint being a higher cheek mass that had not been previously created (Figure 69.13a,b,c).

In my 2004 article on the septal reset,²⁴ and after many years in practice, I was able to demonstrate many patients under my care when they were very young who, in time, returned for facial rejuvenation. For every type of primary and secondary anatomy, their eyelid–cheek junction became similar to their youthful contour, and in some cases even better. However, in the past 7 years, by omitting an SMAS elevation during the facelift dissection, I discovered that I could even more effectively reposition the upper cheek tissues. Omitting the SMAS elevation now allows me to create a higher cheek mass, which I believe is the endpoint for youth and beauty (Figures 69.14 and 69.15).

Even patients with an appearance of the malar crescent, or malar bags, or festoons can be optimally corrected, since the deformity is created by excessive and redundant orbicularis musculature that can be totally changed with zygorbicular repositioning (Figures 69.16 and 69.17).

Secondary patients

Conventional facelift and eyelid techniques often result in an appearance that is neither youthful nor attractive. In 1995, while I was developing the zygorbicular dissection with the septal reset,

Figure 69.13 (a) This patient underwent a composite facelift, including the septal reset and the zygomaticus orbicularis elevation. The hairline was lowered. (b) The cheek fat repositioning is the key to a higher cheek mass without need for fat injections or alloplastic implants. (c) The shortened vertical height of the lower eyelid and the absence of a discernible eyelid–cheek junction is the endpoint of lower eyelid–cheek rejuvenation.

Figure 69.14 In a comprehensive facial procedure, one must be prepared to surgically change every part of facial anatomy.

Figure 69.15 The three-quarters view can definitively show most parts of the surgical rejuvenation. The best scientific assay of an effective surgical procedure is to compare the same side before-and-after surgery with a half-and-half rather than just viewing side-by-side views.

Figure 69.16 Even with overt festoons that are inherited, a composite rhytidectomy can effectively reposition the orbicularis muscle that creates the 'malar crescent' deformity.

Figure 69.17 This is a primary patient with 'malar bags' preoperatively.

Figure 69.18 This is the classic appearance of the patient who had a previous facelift and standard blepharoplasty, with resulting 'hollow eyes and a lateral sweep'. Both have been effectively corrected.

Figure 69.19 This patient had a previous standard blepharoplasty and rhytidectomy, with a subsequent lateral sweep and malar crescent deformities. In addition to the facelift and eyelid correction, she had a secondary rhinoplasty.

I was very pleased to discover that when patients came for a secondary correction of their previous facelift that they felt was suboptimal, I was able to create an exciting rejuvenation by reversing the stigmata of prior surgery. This was done by elevating essentially all tissues of the face except the upper eyelids, nasal area and perioral area and then repositioning these anatomical segments in accordance with the principle of composite facelifting.

After analysing numbers of these patients, it became clear to me that there were two distinct areas that created the 'facelifted' appearance. The first was the hollow lower eyelid that resulted from previous fat removal. The second was a 'pulled' lower face that seemed swept to the side. I then published in 1998 a sister paper to the paper on the zygorbicular dissection, entitled 'Frequent facelift sequelae: hollow eyes and the lateral sweep'.^{25,26} To my knowledge it was the first paper published analysing the

cause of the surgically created faces seen everywhere. As one would imagine, it was not well received by plastic surgery colleagues as it seemed an indictment of techniques that were time-honoured and easy to accomplish. In almost every case, an impressive improvement can be demonstrated (Figures 69.18 and 69.19).

I had previously described the hollow eyes following traditional blepharoplasty techniques in 1995 with the paper on the arcus marginalis release. Even though I could obtain satisfactory results in secondary patients at that time, it was the advent of the septal reset that was the key that allowed me to effectively correct almost any patient with hollow eyes. As I looked back on almost every patient I had done between 1973 and 1991, I routinely in most cases removed lower eyelid fat. Wherever I went socially, I was fixed on the lower eyelids when I observed people known to have had facial rejuvenation surgery. It was the same

with patients I saw in my office, whether I had done them or they were done by other surgeons. No matter how attractive the facelift results, the lower eyelids never seemed as rejuvenated as other parts of the face.

The second part of the stigmata of a 'facelifted' appearance was what I named the 'lateral sweep' of the face. The effective lateral repositioning of lower face anatomy, frequently made more dramatic with an SMAS manoeuvre, is in my opinion the aetiology of the lateral sweep. The appearance of the lower part of the face, particularly in patients with lighter dryer skin and obvious rhytids, is a deformity obvious to any observer; in the lay press it is commonly called the 'wind tunnel look'. Since the tissues were essentially swept in a lateral vector to the ear, a lateral sweep sounded like an appropriate description. To my knowledge, the lateral sweep and the hollow lower eyelids had never been described before in the plastic surgery literature, except for the article on the arcus marginalis release in 1995. Moreover I am sure that the standard SMAS facelift technique had never been indicted as the primary aetiology of the 'facelifted' appearance since it had become the accepted standard of facelifting in 1976. With the exception of the 'mask lift' created by Paul Tessier, the vast majority of surgeons all over the world were disciples of either a subcutaneous facelift or an SMAS manoeuvre incorporated into a subcutaneous lift.

The mask lift is a subperiosteal dissection that gained popularity particularly with craniofacial surgeons. There is frequently a widened intramalar distance due to the fact that the origin of the zygomaticus major and minor is displaced in a superior lateral vector. The blepharoplasty component remained traditional with either a transconjunctival fat removal or a conventional skin muscle flap. In order to create a higher cheek mass, Tessier advocated the placement of bone grafts on the zygomaticus eminence. The placement of malar silicone implants had been done for many years with conventional facelift procedures. With removal of lower eyelid fat causing a depression which adjoined the increased height of the malar eminence appearance, the eyes seemed more hollow. In addition, the hard tissue augmentation with bone or alloplastic materials frequently created an angular and unattractive 'bony' appearance. Surgeons recognized the high cheek mass as seen in young people, so the popularity of malar augmentation became widespread. Since it is a very simple procedure to accomplish, and since it did create a change that the patient could observe, it remains a very popular and marketable technique. Like so many procedures in aesthetic surgery, 'since so many surgeons are doing it, it must be okay'. This is a phenomenon seen repeatedly with endoscopic facelifts, CO₂ laser, so-called liquid facelifts and, of course, the string lifts.

When I had patients who had these unfortunate facial changes, I was pleased to find that these deformities were reversible when I applied the principles of the composite facelift with the septal reset. Removal of the malar implants is almost always obligatory. Because they are normally placed in a subperiosteal level one

Figure 69.20 This patient had a conventional facelift and blepharoplasty with malar silicone implants. Postoperative results after removal of implants and composite rhytidectomy. Note neck changes, and correction of preauricular incisions and earlobe deformity.

must be careful when removing them so that a level of preperiosteal fat still exists over the orbital rim in order to do the septal reset. The patient in Figure 69.20, in addition to the placement of malar implants, had hollow lower eyes. The preauricular incision was poorly placed away from the tragus, and neck contouring was incomplete.

Conclusion

In order to completely reverse the hollow eye and lateral sweep, one must perform a comprehensive rejuvenation procedure that almost always includes attention to the neck, the lower face, the cheek, and forehead lift. The sequence is as follows: initially the neck is dissected in a preplatysma plane. Excess fat, if any, is removed with scissor dissection. A deep plane dissection is done on the face without elevating the SMAS. Since 2005 I have observed that the tissues of the face can be moved effectively in a superior medial vector without elevating the SMAS, making the traditional lateral vector movement of the SMAS unnecessary. When employing Feldman's corset procedure on the

Figure 69.21 A 13-year follow-up on a primary facelift patient. Note the continuation of the high cheek mass.

Figure 69.22 This is the first patient who had a septal reset and cheek lift procedure. He is now 17 years postoperatively. All orbital fat was preserved. (a) Preop, (b) one year post, (c) 10 years post, and (d) 17 years post.

platysma anterior edges,²⁷ it makes no sense to counter that very strong platysma tightening in the neck with tension on the platysma of the lower face toward the ear. The dissection on the prezygomaticus fat is exactly as it was described in 1990. One must visualize the zygomaticus major muscle in order to be sure that all of the fat of the cheek remains adherent to the skin. This is absolutely necessary since the zygomaticus orbicularis flap developed from the lower blepharoplasty incision is now joined with the deep plane flap. In this way the cheek fat can be repositioned in a superior medial vector very high.

The lower blepharoplasty incision, which is the gateway to the zygomaticus orbicularis flap, can be done as an isolated cheek lift procedure or is done with a facelift after the deep plane dissection from the pretragal incision. With the septal reset one can be sure that the cheek fat will remain high and

the lower eyelid height will be significantly shortened as a lower eyelid positive vector is created regardless of the original anatomy.

For standard subcutaneous lifts or various conventional SMAS lifts, the surgeon can elect either not to do a forehead lift, or do a lateral vector open forehead lift or an endoscopic forehead lift. In contrast, if one does a composite facelift and cheek lift then the forehead lift becomes obligatory to prevent ‘bunching of the temporal skin’ and the vector must be a superior medial vector for the forehead lift.

The disadvantage of this technique is that many patients for many reasons do not choose a comprehensive procedure based on cost, recovery time and the ability of the surgeon they choose to do a rejuvenating technique. On the other hand, the advantage of this technique is a uniquely balanced and harmonious appearance

Figure 69.23 This patient had a primary composite facelift when she was 70 years old. At 84 she has maintained a high cheek mass with a youthful eyelid–cheek junction. (a) Preop, (b) one year post, and (c) 14 years post.

that not only will never have the stigmata of cosmetic surgery, but is very stable, as long-term follow-ups will demonstrate. Having done the composite facelift with the zygomaticus orbicularis dissection with the septal reset since 1997, I am now in a better position to evaluate long-term results. The most stable part of this procedure is the eyelid–cheek rejuvenation. (Figures 69.21, 69.22, and 69.23). The upper blepharoplasty and obligatory open forehead lift are equally long lasting, but it is the obvious permanent change of the lower eyelid that will continue to give the patient a very youthful appearance, which is the goal and endpoint of periorbital rejuvenation.

³Australian National University, Canberra, Australia

Introduction

Trainees in plastic surgery appreciate early on that one of the defining and most satisfying features of the specialty is the logical biological approach to solving clearly defined clinical problems. There tends to be broad agreement on the principles, objectives and outcomes, as well as the appropriateness of the surgery, across surgeons of different generations and from different 'schools', which unites plastic surgeons while allowing for differences.

However, on exposure to facelift surgery, it is as if an entirely different world has been entered. The trainee is confronted by a situation in which consultant plastic surgeons of similar stature and ability seem to interpret clinical situations differently and perform different facelift procedures based on a different logic. There is often a defensive awkwardness in addressing questions on this. When the patient's immediate result 'on the table' looks good after different facelift techniques, how can trainees decide what approach to take when they come to perform facelift surgery?

Facelift theory

The facelift world is indeed different, because of the many dimensions it embraces. Foremost it is about appearance, which is central to a person's identity. A person's identification of self, their psychological wellbeing and, indeed, their life, revolves around their face. The face is the most defining feature of a person's appearance, which is why there are national portrait galleries filled with images of faces. A person's self-image and self-esteem are powerfully influenced by their appearance. The way people are judged and treated by others, whether supportive or discriminatory, is largely determined by others' perceptions of their character and personality, initially based fallaciously on their facial appearance. People requesting a facelift have experience of this. This aspect places a significant responsibility for the patient's future psychological wellbeing in the hands of the

facelift surgeon; it is an added dimension that trainees are usually not prepared for but must quickly appreciate.

The human face is uniquely adapted for the higher social functions of communication, including expression of emotion. It is therefore inherently difficult to alter a face surgically while retaining the nuances of natural expression, especially as some elements of expression are so subtle as to be scarcely detectable to the naked eye, appreciated only at a subconscious level by the recipient. A compromise in the patient's ability to communicate and to be responded to naturally affects the patient's future wellbeing.

The anatomical demands for facial movement in expression are complex. While the anatomy of the hand is recognized by plastic surgeons as being complex, most of the detail was defined during the classical era of anatomy. Yet after nearly 100 years of facelifting, only recently has a different level of facial anatomy been gradually revealed and this has happened during the lifetime of the current generation of surgeons. For these surgeons, trained in traditional, essentially empiric facelift techniques, this is a significant change. Acceptance and application of the rational 'new anatomy' based techniques tends to be largely in proportion to the surgeon's certainty of anatomical understanding. Fortunately, the detail of this new anatomy is almost complete, and will provide the next generation of plastic surgeons with a better understanding of the pathophysiology of ageing and its logical application in rejuvenation surgery.

Good surgeons are risk averse and appreciate that complex anatomy involves greater surgical risk. This is especially important where complications lead to visible alterations of appearance, resulting in psychological ramifications. The surgeon's choice is stark: to prioritize safety or to prioritize exceptional results! The gap between these two options is reduced by the surgeon's level of anatomical understanding and facelifting experience.

What constitutes an exceptional result cannot be defined absolutely. There is not necessarily agreement about this between the patient and the surgeon, between patients and, indeed, between surgeons themselves. An undetectable facelift is, at the least, a desired part of the result, meaning that the

patient's appearance has improved in a way that is not visibly the result of having had a facelift. A detectable facelift, in contrast, can vary in significance between stigma and status, according to the prevailing cultural and social standards in the particular society. As these standards vary between societies, contrast London with Los Angeles for example, so the definition of a good facelift result may vary according to geographical location.

Facelifts do not fit into the previously mentioned category of 'clearly defined clinical problems', because the end point, namely the patient's satisfaction, has a subjective element. Unconscious factors in a patient's background, whose influence is commonly not appreciated or expressed, have an influence on the patient's motivation and expectations of a facelift, and so on his or her perception of the result. Despite good-quality preoperative consultations and planning, this subjectivity can lead to disappointment, to the chagrin of the surgeon.

For the surgeon to obtain good results in aesthetic surgery requires more than the usual surgical attributes of anatomical understanding and technical skill, with an appropriate measure of psychological patient management. Considerations of aesthetics in appearance are paramount; while facelift surgery is inherently a technical specialty, the importance of the surgeon's aesthetic eye is often unappreciated, being an intangible, yet critical factor in the outcome. Many facelift patients will have a more advanced visual aesthetic than the young technical surgeon who does not intuitively have, or has not yet developed, this level of aesthetic appreciation. Just as a young musician learns by listening to music, the young plastic surgeon should cultivate the habit of analysing faces. Without an understanding of what looks attractive and why, the practitioner of aesthetic surgery does not have an appreciation of the specific outcome to be aimed for.

In considering rejuvenation procedures and the aesthetics of the face, an appreciation of the gestalt of the face, the patient's face as a whole, is no less important than the assessment of the component parts and the way they relate. A key consideration is whether to correct only the part that most concerns the patient or to address the whole. A piecemeal approach in stages can result in a disharmonious and unnatural outcome in some patients, and yet for others it can be a clever way to surreptitiously introduce an undetectable refinement of appearance.

Finally, we should consider the pervasive influence of the media, and its effect on attitudes and opinions, even before people are old enough to contemplate the effects of ageing for themselves. Informative and responsible in-depth analysis of facelifting is rare in the media, compared to the superficial entertainment stories that sensationalize negative aspects of cosmetic surgery. While the media focus is intended to satisfy the fascination of the public, prospective patients can understandably become confused as they try to define what they want and what they can expect for themselves. A consequence of the World Wide Web becoming the foremost source of patients' information is the heightened expectation of facelifts. The influence of marketing in that medium is diminishing the

perception of the reality that a facelift still carries the limitations and risks of a surgical procedure. Even for people who would not consider this option, this incorrect perspective becomes reinforced when facelifts are now marketed in such an appealing way, as a commodity included in a glamorous and affordable vacation package. It is important for the individual surgeon to recognize this modern day background to presurgical consultations and to realize the difficulty of fully controlling patients' expectations of their surgery.

The ageing face

The face is a complex three-dimensional structure, having areas of intrinsic movement and varied foundations of solid bone and supporting soft tissue volumes held together by visible and invisible ligamentous extensions upon which the canvas of our life, emotions and expressions is spread. Genetics, time, environment, lifestyle and, ultimately, gravity all take their toll on our appearance. This canvas bears the blemishes of ageing from inside and out. A tired look, wrinkles, sagging with changed shape of the face, jowls and loose neck are the exacting toll of life's vectors on the face.

The original surgical techniques from the early 1900s were limited to the skin envelope, and because such work had not been thought possible before this time, the improvements to a person's ageing look were considered to be remarkable. To be tackling facial appearance was bold surgery, even if addressing laxity of the facial skin was not. The procedures evolved gradually over the years with progressively more undermining and redraping of the facial skin. The risks were few, mainly to do with bleeding and skin circulation. With patient expectations being relatively low, surgeons were not pushed to risky surgery and the progress in technique was slow.

Then in the 1960s deeper contouring surgery commenced, with direct submental lipectomy introduced by Millard¹ and with profound results in the era before liposuction. The modern facelift era started in the early 1970s with Skoog's revolutionary 'anatomical' approach.^{2,3} Then, Mitz and Peyronie's seminal 1976 paper on the anatomical details of the superficial fascia introduced the important concept of the superficial muscular aponeurotic system (SMAS).⁴ Skoog developed the first sub-SMAS dissection plane facelift. The next milestone, over a full decade after the SMAS description, explained many of the frustrating limitations of SMAS surgery and a way to overcome them. First it was shown that for proper SMAS mobilization of the anterior face, it is necessary to detach the SMAS from fixed attachments to the zygoma.⁵ During the 1980s Furnas discovered that these attachments are actually retaining ligaments and that there is a system of named retaining ligaments that attach the facial soft tissues to the skeleton.⁶ Even now, 25 years on, the full surgical potential of the facial ligaments is not widely appreciated.⁶⁻¹⁰ Understanding how to use the SMAS and retaining ligaments to best advantage has been ongoing.^{8,11-19}

In recent years attention has turned towards the role of soft tissue atrophy, specifically fat, to add to our increasingly nuanced understanding of facial ageing.^{20,21} The final piece in this jigsaw is a unifying theory, recognizing that ageing is a universal phenomenon, not only of the facial skin envelope and the deeper soft tissues, but also of the underlying foundations, the facial skeleton on which the soft tissues are built.^{22–25} Correct rejuvenation technique must address all of these components, taking into consideration the unique individual and regional variations. This chapter provides an overview of the field while the more specialized facial aesthetic surgery chapters provide operative details of the specific techniques.

Overview of facelift techniques

Facelift surgery is a remarkably diverse specialty. In no other field of surgery is such a wide diversity of techniques being practised for the same operation. It may seem strange that this absence of uniformity is regarded as acceptable in this evidence-based medicine era and for a procedure whose quality of result is of such importance to the patient. The absence of consensus determining which technique the individual surgeon should practise partly reflects the paucity of objective evidence (randomized controlled trials). There is insufficient evidence to resolve the debate on which facelift technique provides the ‘best’ result. This leaves the responsibility for choosing the ‘most appropriate’ technique to the individual surgeon, based on the catalogue of ‘best facelift’ results presented by the leading surgeons at presentations and in textbook chapters. Yet when viewing photographs of good results it is not possible to discern which particular technique had been used. A good result, by definition, is undetectable. This confusing situation points to the importance of the ‘surgeon factor’, in which masterfully performed surgery using a ‘lesser’ technique provides a better result than a theoretically better technique with less well-performed surgery. Using an analogy from competitive equestrian eventing, the winner may not be the best horse or the best rider, but the best combination of horse and rider, with the benefit of training and experience together.

In the world of facelifts, however, there is no absolute correct result. It is not about winning and clarity about the result can be hard to define. Success can be defined by degrees of improvement, or the number of years erased, or by some other individual patient requirement. An excellent result may be high in the broad grey zone between overdone and underdone, well expressed by the term ‘age appropriate’. Providing the patient with the youngest look does not necessarily provide the best result. Reversing a person’s appearance to being exactly what it was in the past results in an incorrect-looking rejuvenation that is clearly the result of surgery.

When comparing facelifts for ‘best result’ it is useful to focus on specific areas of the face – for example the lid–cheek,

nasolabial fold, jawline and neck – as some procedures inherently improve some areas better than others.

The best facelift

The ‘best facelift technique’ is, in theory, the one that provides the outright ‘best facelift result’, if indeed there is one. The variation in facelift techniques being performed reflects a number of important related factors that need to be taken into consideration by the surgeon: the social situation of the patient and their psychological expectations, moderated by the competing consumer demand for short recovery time, predictability with low risk, reasonable cost (meaning shorter surgical and recovery time) and naturalness of appearance of the result. The longevity of the result is another factor; this is usually less of a priority in the patient’s mind when making the decision. Balanced against this are the surgeon factors that determine the selection of which of the multiple tissues layers of the facial structure should be the foundation for a patient’s facelift. In reality, the surgeon chooses the ‘most appropriate facelift technique’ for this matrix of factors.

Although improvement of appearance is common to all facelifts, there is great variation in the degree of improvement of the various regions of the face. Concomitant facial rejuvenation procedures are commonly performed at the same time, such as blepharoplasty, temporal lift or browlift, contributing together to the refreshed appearance. The debate about facelift technique selection has become clouded by the emergence of appropriate hybrid procedures that combine with the lift; either additional volume (using lipofilling or other fillers or skeletal implants or a combination) or additional suspension, tightening/lifting using non-surgical thread/facelift combinations and even major resurfacing.

For the patient (whose first impression when looking at their new postsurgery ‘improved’ face must be one of suppressed horror) there is usually relief within a short time that a ‘tell tale’ overdone result has been avoided. Patients are usually pleased with the improvement, without considering that a greater degree of improvement may have been possible by ‘better’ facelift surgery.

Impact of the new anatomical understanding on facelift practice

Understanding the historical evolution of the facelift operation helps to explain the diversity of facelift techniques being performed. This history largely reflects the steps in the surgical application of improved anatomical understanding. In its early years, the facelift benefit was localized to the lateral cheek, as all corrections were in small separate areas, upper eyelid, lower lid, etc. Hence the early medical terms used for facelifts, such as *meloplasty* (‘shaping of the cheek’) and *rhytidectomy* (‘excision of wrinkles’). This progressed to *cervicofacial rhytidectomy* (‘neck and face’) with extension of the improvement to the neck.

The subsequent trend was to merge the improvement of an area into the adjacent areas. When browlifts were introduced

Figure 70.1 The objective of a modern facelift is to restore youthful shape to the face. (a) A 56-year-old woman with significant cheek laxity. (b) One year following a composite facelift, which emphasizes tightening of SMAS laxity of the anterior face. The patient's look is refreshed and the typical facelift pulled look avoided.

they soon overlapped with the upper lid and the temporal lift benefit improved the upper outer cheek. The midcheek, remained a 'no man's land' between the territories of the lower lid blepharoplasty and facelift until the advent of the 'extended lower lid blepharoplasty' to improve the upper part of the midcheek. The facelift correction eventually extended into the midcheek and from there its impact continued to the lower lid. This has allowed the focus of modern facelifts to be less about skin tightening for the correction of wrinkles and all about restoring the youthful shape of the face, from the lower lid down to the lower neck²⁶ (Figure 70.1).

Subcutaneous facelift

The earliest application of surgery in facial rejuvenation early in the twentieth century²⁷ consisted of the simple excision of carefully located and shaped ellipses or half moons of skin at the back of the face (hairline, pretragal). These were performed under local anaesthesia without undermining and using direct closure with controlled skin tension and often involving multiple sessions. By the late 1920s the benefit of undermining the skin for a short distance was appreciated.²⁸ Interestingly, even with this advance in technique a pattern was emerging, acknowledging the advance as being 'too much for the would-be surgeon'.²⁹ Similarly, poor facelift results were being seen, with an unnatural appearance resulting from tightly stretched skin.³⁰

Modern subcutaneous lifting started being performed in the 1930s as a result of linking the multiple skin excisions with a continuous incision, along with the release of subcutaneous attachments. These tentative first steps in facial aesthetic surgery gained momentum with surgical experience. Increased demand coincided with the increased social affluence of the post World War II years and general medical progress, with the advent of antibiotics and improved anaesthesia. The technique entails dissection of large, random-pattern subcutaneous skin flaps of the cheek and

jowls with a superolateral suspension vector and resection of excess skin.³⁰ To improve the cheek correction, the skin dissection progressively extended towards the nasolabial fold, usually, but not always, stopping a few centimetres short of this landmark. Furnas, in describing the retaining ligaments of the cheek, noted that early surgeons recognized the upper area of dissection over the lower zygoma as being more difficult to dissect and more vascular in the area known as McGregor's patch.⁶ Subsequently, the reason for this was found to be the dermal attachments of the zygomatico-cutaneous ligament, which extends through the underlying SMAS and divides at the subcutaneous level. The extent of neck skin undermining below the mandible has variously extended towards the mentum. After haemostasis, with appropriate tension applied to the skin flaps, the excess skin is marked and key sutures placed before trimming the redundant skin and closure of the incisions, with or without drains. A thin face with little soft tissue ptosis, excess skin and little bony resorption or indeed a revision facelift may be an appropriate case where a subcutaneous technique can still be considered.

There are innumerable variations in the extent of undermining. The dermal attachments across the face are not uniform, but reflect the underlying pattern of facial ligamentous attachment and this is the rational basis for deciding the extent of surgical release.

There are also variations in the depth of the subcutaneous dissection, the decision being determined by the surgical objective. A superficial subcutaneous dissection has the advantage of being the most remote from the facial nerve branches, hence minimizing the risk of facial nerve damage. Where the subcutaneous layer is thin, particularly over the temple and in the elderly, there is less than usual protection of the underlying temporal branches of the facial nerve. In secondary facelifts, the nerves are at greater risk due to their fixation by fibrosis from previous surgical intervention, and especially when this is more than usual as a result of previous haematoma. When

a separate SMAS flap is planned, it is beneficial to leave most of the retinacula cutis (in the subcutaneous layer) attached to the SMAS, as this fibrous component reinforces the strength of the SMAS flap.³¹ When superficial subcutaneous dissection is performed, a meticulous dissection technique is required to avoid damage to the dermal circulation and visible irregularities.

In contrast, a deep level of subcutaneous dissection is required when the surface of the SMAS is to be exposed preliminary to superficial SMAS platysma manipulation techniques. At this deeper level the subcutaneous dissection is considerably easier, with less bleeding, but the dissection plane is closer to the nerves. This level of dissection has been described as the superficial musculo-aponeurotic plane (SMAP).^{32–34} This plane of dissection, directly on the surface of orbicularis oculi overlying the zygoma, when extended medially provides direct access to the malar fat pad, the thicker subcutaneous fat inferomedially that forms the volume of the nasolabial fold. Specific suture suspension of the malar fat pad provides a controlled correction of the nasolabial fold contour, but unfortunately at the expense of prolonged postoperative oedema.⁸

The skin flap technique maintains popularity with surgeons because of its surgical simplicity, safety, short operative time with relatively speedy recovery, and relatively satisfactory early postoperative results. The long-term shortcomings with this technique are inherent, due to the viscoelastic properties of skin. Tightening the skin envelope alone cannot maintain shape. Additional manipulation of the underlying parenchyma is required, as in other plastic surgery procedures, most notably breast reductions. Depending on skin tension has other specific limitations, including scar widening, traction on the pinna and skin necrosis.

SMAS manipulation techniques

Following Skoog's technique and the subsequent anatomical description of Mitz and Peyronie, it became evident that utilization of the underlying SMAS was the key to controlling tension on the skin closure.⁴ This was the first accepted advantage of SMAS surgery but it took many years, with further anatomical studies and improved understanding of the potential of the SMAS, for it to be appreciated as the tool for true facial reshaping and more lasting outcomes.^{8,11,12,14,16,17,35,36}

SMAS plication/imbrication

The original version of this technique was to first perform the standard type of skin-only facelift dissection and then to add mobilization of the SMAS, as a completely separate layer, locating the SMAS incision directly beneath the facelift incision. The SMAS dissection over the preauricular area is difficult due to the absence of a natural cleavage plane, as a result of the strong adherence of the SMAS to the parotid capsule (the fixed SMAS). The early SMAS mobilizations were limited in extent to the anterior border of the parotid, as originally advised by Mitz and Peyronie, to avoid the risk of damage to the facial nerve branches. It was only later appreciated that it is necessary for the

SMAS to be mobilized forward of the parotid capsule (the mobile SMAS) if the medial cheek and jawl is to be tightened (Figure 70.2).

After the SMAS dissection, the subsequent handling of the SMAS could be varied according to individual facial morphology, specifically the SMAS thickness, included plication (simple infolding of the excess SMAS) and imbrication (undermining of the SMAS and subsequent overlapping), tightening perpendicular to the nasolabial fold using buried sutures. After haemostasis, redundant pre- and postauricular skin is marked in a similar superolateral vector, with key sutures placed at the top of the helix, prior to excision.

Variations of this technique continue to have wide popularity. Its advantages include relative safety in relation to the sub-SMAS facial nerve branches, while providing effective manipulation of the mobile SMAS, combined with relatively quick postoperative recovery, yielding a more lasting improvement than skin-only rhytidectomies. Limited release of the SMAS from its retaining ligaments and deep attachments is a limitation of this technique. Superolateral traction on the SMAS without release of its more anterior retaining ligaments (masseteric cutaneous) restricts the tightening of the more anterior laxity towards the nasolabial fold and oral commissure. For this reason correction of the anterior midface has traditionally been limited.

The deep plane and composite rhytidectomy

The role of the SMAS was the major topic of discussion in facelifts through the late 1980s and 1990s. In this context the newly introduced deep plane and then composite facelift techniques introduced by Hamra became hot topics.^{12,37} These operations were an evolution of the original Skoog operation. Skoog did not describe his operation as being sub-SMAS as it preceded the introduction of the term. He described the plane of dissection used in his revolutionary facelift in correct anatomical terms as being under the superficial fascia.^{2,3} For surgeons of the time, for whom considerations of anatomy were not usual in the context of facelifts, this concept was not

Figure 70.2 SMAS imbrication.

readily accepted until a surgical term – the deep plane – was introduced. Hamra's deep plane concept, being clearly descriptive of the dissection plane, was less anatomically confusing and the term became widely adopted and remains in use to this day. Although it is worth noting that Hamra's surgical plane of dissection transitioned from being sub-SMAS to becoming more superficial, as the dissection continued medially over zygomaticus major.

Some clarification regarding use of the term 'composite' is required, as two different, yet similar, meanings are attributed to it. In the context of flaps, a composite flap is one in which the several concentric tissue layers in a compound flap remain in their natural fused anatomical relationship. A scalp flap is the archetypal composite flap, consisting of the outer three layers – skin, subcutaneous layer and galea aponeurotica – forming a vertical composite. Elevation of a scalp flap involves dissection through the subgaleal areolar tissue glide plane beneath the flap (layer 4), allowing it to be separated from the underlying fixed deep fascia, the periosteum.

In Hamra's composite facelift, described in 1990, the term composite was used to denote the surgical extension medially of the same SMAS layer to incorporate the orbicularis oculi. According to Hamra's description, it is the inclusion of the lower lid orbicularis in the flap (elevation and repositioning) that determined the composite. Otherwise, a deep plane facelift does not impact the lower eyelid despite obtaining vertical cheek movement. Hamra's composite concept later progressed to include a Hamra composite cheek lift.³⁷ Essentially, this consists of a package of procedures: elevation of the lower lid through the deep plane (i.e. extended submuscular flap), using a 'zygobuccal' dissection and redraping the lid cheek in a superior medial vector after performing a septal reset procedure.³⁸

These techniques provide direct benefit to the midcheek and nasolabial fold. A standard facelift incision is made with 2–3 cm subcutaneous skin dissection. The fixed SMAS is incised over the parotid and a sub-SMAS dissection is continued to the malar eminence superiorly, dividing the zygomatico-cutaneous ligaments and their masseteric counterparts. Dissection is continued medially over zygomaticus major muscle towards the nasolabial fold, dividing the remaining zygomatico-cutaneous ligaments and providing access to the malar fat pad. Musculocutaneous flap is thus developed which is advanced and rotated superiorly. In the neck, the anterior neck is opened with approximation of the upper platysma edges and excision of the redundant medial platysmal border in the lower neck. This communicates with a superficial, preplatysmal dissection plane from the preauricular approach, with dissection carried 8–10 cm below the mandibular angle and defatting of the flap where indicated. This leaves separate dissection pockets in the face and the neck, which do not anatomically communicate. Excess skin is excised and closed, with tension on the SMAS applied in the temporal fixation.¹²

Hamra further addressed a limitation of facelifts – the failure to correct the upper cheek. He recognized that correction of the ageing changes of the lid-cheek junction (the lengthening of the

lower lid with lowering of the position of the upper cheek) are essential for complete facial rejuvenation. He further observed the benefit of correction of the orbicularis oculi laxity in the roof of the prezygomatic space, which is responsible for the appearance of malar mounds (crescent, bags) and modified his facelift to address this. To correct laxity of the orbicularis oculi of the upper cheek required an inferior extension of the submuscular lower lid blepharoplasty dissection, with communication through into the pocket of the previously dissected deep plane facelift. It was necessary to release the restraining effect of the ligamentous attachments along the orbital rim (later recognized to be the orbicularis retaining ligament) for this to occur.³⁸ In contrast to the superolateral vector usually used in redraping a lower lid blepharoplasty flap, a superomedial vector is applied to oppose the inferolateral vectors of upper cheek ageing. The tightening is achieved at the completion of the facelift by an orbicularis flap suspension to the lateral orbital rim.^{13,37}

Hamra's composite facelift clinical series demonstrated impressive outcomes as a result of the anatomically composite musculocutaneous flap that provides robust vascularity with reduced tension on the skin closure. In addition, the surgically composite access to the malar fat pad and superomedial cheek-lift vector corrects the lid-cheek area more effectively than do the extended and high SMAS counterparts. Similar to these techniques, potential damage to facial nerve branches in the dissection field and higher operative technical requirements with longer postoperative recovery are disadvantages that have limited usage of this specific technique.

Lateral SMASectomy

In the 1990s Daniel Baker developed this practical technique (Figure 70.3), which became extremely popular, usually in association with a 'short scar' (shorter skin incision) technique.³⁹ Baker recognized the lack of benefit from dissection of the fixed lateral SMAS, whereas the real benefit came from tightening the mobile SMAS over the anterior masseter area. Accordingly, the tedious sub-SMAS dissection over the parotid was avoided.

Figure 70.3 SMASectomy.

Baker also popularized the 'short scar' technique by limiting the postauricular skin incision and undermining behind the ear. Of course, this is successful in proportion to the amount of neck skin redundancy and the degree of its correction. The standard SMASectomy dissection begins with the lateral cheek skin flap dissected in the subcutaneous plane to within 2–3 cm of the nasolabial fold, and 5–6 cm below the level of the mandible into the neck. The mobile SMAS anterior to the parotid border is identified and, depending on the individual patient's facial morphology, the redundant SMAS here is either resected or plicated. Where a resection is planned, the mobile SMAS anterior to the parotid is manipulated in a vector perpendicular to the nasolabial fold from the lateral malar eminence to the angle of the mandible. The redundant SMAS is marked and superficially excised before the anterior, mobile SMAS is secured against the fixed lateral SMAS overlying the parotid, commencing inferiorly and moving superiorly. In a thinner face this technique allows for 'stacking' of the SMAS to augment that lateral cheek. Various modifications of the technique have been reported.⁴⁰

Similar to simple SMAS plication, this technique corrects the lateral cheek and jowls, and in addition provides for resection of redundant SMAS where indicated. Its shortfall is the failure to address the deep ligamentous attachments of the mobile SMAS along the anterior masseter border. While relative simplicity is its attraction, by design this technique does not fully address the midface.

Extended SMAS

This is an early SMAS technique that evolved to incorporate the understanding of the ligamentous anatomy on the zygoma and its relationship with the SMAS of the anterior face (Figure 70.4).^{16,41}

Visible contour changes of the cheek are a key part of the ageing process, particularly the reduction of prominence over the zygoma and loss of the contrasting infrazygomatic (submalar) youthful concavity over the buccal recess. The zygomatic liga-

ments are recognized as suspending the cheek soft tissues, including the malar fat pad from the zygoma.^{6,9} Descent of this facial fat has been the explanation for these contour changes and presumed to be secondary to attenuation of the zygomatic ligaments with age. In reality, given the stout nature of these ligaments, the weakening more likely occurs in the SMAS attachments of the ligaments.

The principles of this technique are based on the anatomical details of the retaining ligaments of the face, as well as consideration to vectors of facial and neck rejuvenation originating from the pioneering work of Bruce Connell.¹⁷ A bidirectional manipulation of skin and SMAS is advocated. A standard facelift skin incision is used; the skin is dissected widely in standard fashion to a few centimetres short of the nasolabial fold and below the mandible. The skin overlying the lateral two thirds of zygoma is mobilized. It is imperative to leave some fat on the SMAS, especially medially as it thins out to reduce proneness to tearing during the subsequent SMAS dissection and elevation. Following the standard posterior dissection of the fixed SMAS over the parotid, the forward extension of the SMAS incision commences 1 cm below the zygomatic arch (to protect the frontal branch of the facial nerve) and continues to the junction of the arch and body of the zygoma. Then the SMAS incision is angled towards the lateral canthus for a distance of about 3 cm, following which the SMAS incision is continued at 90°, away from the lower lid towards the superior nasolabial fold.¹⁶ The SMAS dissection provides access to the zygomatico-cutaneous ligaments, including the strong medial ligament just medial to zygomaticus minor that extends from the zygomatico-maxillary suture.⁷ The preauricular SMAS incision is extended below the mandibular border for 5–6 cm along the posterior border of the platysma. In the malar region the flap is elevated superficial to the orbicularis oculi as well as superficial to the zygomaticus major and minor muscles. Mobility of the SMAS flap is obtained by freeing it from the zygomatic prominence along with release of the masseteric ligaments. Often some extended dissection of the SMAS is undertaken medial to the zygomaticus minor, beyond the boundaries of the subcutaneous dissection, in the plane between the malar fat pad and levator labii superioris.

The malar SMAS flap is redraped in a superolateral vector parallel to zygomaticus major and fixed to the zygomatic prominence. The excess tissue is either excised or used as a soft tissue auto-augmentation over the zygoma. The remaining cheek SMAS flap is rotated in a perpendicular direction to the mandible to contour the jowl area. To accentuate the jawline and contrasting submental contour and neck concavity, a strong posterior vector is obtained by securing it to the mastoid using an inferiorly based flap of a preauricular SMAS as a strip transposed behind the ear. Drains are usually required on account of the extensive subcutaneous dissection.^{16,41}

This SMAS rejuvenation technique is based on sound anatomical principles of releasing the SMAS from its deep fixation by key retaining ligaments. Its advantage over the other SMAS

Figure 70.4 Extended SMAS facelift.

Figure 70.5 The high SMAS facelift.

techniques discussed so far is the access to the malar fat pad and improvement of the anterior part of the midface.

The high SMAS facelift (Fig 5)

The 'high SMAS facelift' conceived by Barton in the early 1980s and also advocated by Owsley, another pioneer in the application of SMAS anatomy, continues to grow in popularity among experienced plastic surgeons.⁸ It is not dissimilar to the extended SMAS but utilizes a simpler and higher approach to the upper SMAS to improve the benefit of SMAS redraping over the body of the zygoma and into the area of the lid-cheek (Figure 70.5). This area is not addressed with standard SMAS operations (imbrication/plication and lateral SMASectomy).¹⁴ Leverage of the upper SMAS over the zygoma results from raising the transverse SMAS incision, from inferior to the zygomatic arch to slightly cephalad.

Although a standard facelift incision is used, the skin undermining is minimized to 4–5 cm in the preauricular area and extends above the zygomatic arch and forward to the lateral border of the orbicularis oculi. The inferior subcutaneous dissection in the neck is continued superficial to the platysma from mastoid to the midline. To establish the correct plane, the fixed SMAS dissection commences over the parotid, then at the anterior border of the parotid the mobile SMAS is undermined using blunt dissection, protecting the facial nerve branches. The risk of damage to the frontal branches of the facial nerve is avoided by keeping the transverse SMAS incision superficial, where the nerves are deeper on the periosteum. The lateral edge of orbicularis oculi is used as a guide to the origin of the zygomaticus major. A thin layer of fat is left over this muscle to protect those zygomatic facial nerve branches passing superficially to innervate the lateral orbicularis oculi. The pattern of nerve supply and anatomical boundaries of the prezygomatic space are detailed by Mendelson *et al.*⁹ Releasing the SMAS from the fixation of the zygomatico-cutaneous retaining ligaments and

accessing the subcutaneous plane over zygomaticus major allows mobilization of the midface cheek mass, including the malar fat pad. The flap is strong as it is reinforced by the multiple ramifications of the zygomatic ligament and is lifted in a vertical direction and secured to the deep temporal fascia above the arch, where it not only suspends the cheek but also provides supports to the lower eyelid.¹⁹

The advantage of this technique is that, similar to its extended counterpart, it incorporates midface rejuvenation in addition to the jowls and neck. Elevation of an anatomically composite skin-SMAS flap provides a better vascularized flap than separate skin and SMAS flaps, with less bruising, induration and haematoma risk. The reluctance over the years to use a high SMAS incision had been the concern about the risk of damage to the temporal nerve branches as they cross the zygomatic arch. However, this has been strongly repudiated by good anatomical descriptions and the combined results from Owsley and Barton of 3000 cases with no permanent temporal branch injury.^{42,43} The traditional concern about not being able to redrape the skin and SMAS in different vectors is not a realistic shortcoming.⁴²

Subperiosteal facelift

In 1980, Tessier extended his craniofacial approach to facial rejuvenation. Conceptually, the technique not only repositions the origins of midface muscles but also provides access for manipulation of the orbicularis oculi through a 300° range.⁴⁴ Utilizing a bicoronal or hairline and, later, endoscopic approach and subperiosteal dissection plane, the lateral and midface are detached from the zygoma and maxilla. The origins of the superficial muscles, zygomaticus major and minor, levator labii superioris, levator anguli oris, as well as orbicularis oculi and related ligaments are inherently detached with this dissection and are repositioned. In the lateral cheek the dissection continues with detachment of the overlying masseteric fascial layer from the zygomatic insertion, but is limited by its masseteric attachments. A fronto-glabellar dissection, if used, can continue to the tip of the nose, preserving the medial canthal ligament. The entire facial soft tissues is thus freed from its underlying skeletal attachment, is advanced 2–3 cm in the superior direction and is fixed against the deep temporal fascia.

Initial reports of this technique reported unacceptably high rates of frontal facial nerve palsies (up to 20%), as well as zygomatic branch palsies. The injuries were sustained over the zygomatic arch and body, respectively, where the zygomatic branch may be caught in suspending sutures.⁴⁵ An extended technique was developed after further anatomic studies addressing these concerns. The vital dissection over the zygomatic arch where facial fascial layers coalesce was modified. About 2 cm above the zygomatic arch an incision is made in the continuation of the subperiosteal pocket into the superficial layer of the deep temporal fascia, breaching the superficial temporal fat pad to protect the overlying temporoparietal fascia and frontal nerve branch. A periosteal incision at the superomedial margin of the zygomatic arch along its length allows access to the lateral cheek where the masseteric fascia

Figure 70.6 The MACS lift.

is detached from its zygomatic origin. This is combined with a minimal preauricular subcutaneous dissection. The redundant skin is excised after suspension of the face and the wounds closed.⁴⁶

The disadvantages of this technique include the steep learning curve and need for increased familiarity with craniofacial principles, but most significantly, the prolonged swelling that leads to longer postoperative recovery times. The periosteum strongly reattaches to the bone, carrying the facial soft tissues including the retaining ligament and muscle origins previously detached. Studies demonstrate that origins and insertion of the facial muscles do not attenuate with ageing.⁴⁷ Relocating the origins of these mimetic muscles inevitably leads to unnatural vectors of facial animation, which may account for the name 'mask lift'. Although effective, interest in this procedure diminished with advances in anatomical understanding. The original attraction had been the quality of correction obtainable over the zygoma, while avoiding the nerve risks of sub-SMAS dissection in this area, at the time when this lack of anatomical understanding was prohibitive.

Minimal access cranial suspension (MACS lift)

This technique was developed more recently, at a time when each advance in facelifting seemed to be further anatomically complicated. The original attractions of the MACS lift were its simplicity and safety, with short operating time and short postoperative recovery. Developed by Tonnard and Verpaele, it is based around a subcutaneous dissection with unusual short scar, utilizing a simple SMAS manipulation with a vertical skin vector, without displacement of the hairline (Figure 70.6). The original MACS lift addressed the lower third of the face, the jowls, marionette lines and neck.⁴⁸ A subsequent modification addresses the midface and malar fat pad and is called the extended MACS lift.^{49,50}

A zigzag temporal pre-hairline incision is made from the level of the lateral canthus and the lower end of the incision finishes at the earlobe, not extending postauricular. In the extended variant the temporal incision is extended 1–2 cm cephalad. Wide skin undermining is performed for 5–6 cm, extending to approximately 2 cm below the mandibular angle until the posterior platysma border is visualized. The facial shaping is achieved by a pair of U-shaped loop sutures anchored above to the deep temporal fascia above the zygomatic arch, 1 cm anterior to the helical root and weaved into the SMAS below. In the standard

technique the posterior suture extends down to the posterosuperior border of the platysma and because of the mobility of the platysma, as the pursestring suture is tied the platysma laxity and displacement is tightened, which contours the cervicomental angle and the pre-liposuctioned neck. A second, more open O-shaped suture originating from the same site is angled at 30° towards the jowls. Tightening the second suture places the mobile SMAS under concentric tension, reducing the laxity that contributes to the jowls and marionette lines. Where an extended technique is performed, a third U-shaped suture is placed in the furthest anterior limit of the deep temporal fascia and is directed towards the malar fat pad, suspending it with an oblique vector. The redundant skin is then excised in a purely vertical vector. The redundant subciliary skin at the lower lid is excised (4–8 mm on average) through a lower lid blepharoplasty incision.^{48,50}

Well performed, the results are surprisingly good for such a non-invasive technique, making it an excellent facelift procedure for the occasional facelift surgeon. Selection of the technique is based on a personal risk–benefit analysis, where an extensive skin undermining is considered preferable to more involved SMAS techniques. The shorter operative time advantage has diminished due to the requirement to enhance the result with further suspension sutures, yet the safe plane of dissection and reduced risk of major complications are the real advantages of this technique. It is often performed under local anaesthetic and sedation; patients are frequently discharged home the same day.

The focus on a pure vertical preauricular lift, which is considerable, is designed to avoid the skin redundancy behind the ears that results from neck correction, and instead transfers the skin excess to the temple, where it is removed without displacement of the temporal hair. The necessity for a pre-hairline scar is considered a disadvantage compared to the usual postauricular scar and is debated. The location of the loop sutures avoids a 'flat' facelift look. Although the anatomical basis of the technique does not require any release of the facial retaining ligaments at the sub-SMAS level (with its attendant drawbacks), the procedure does cleverly take advantage of the mobility of the platysma and the midcheek SMAS. Its critics consider the disadvantages of the technique manifold. The results are lasting as the SMAS plication suture causes multiple small imbrications with fibrosis induced around the suture, whose benefit is maintained after the suture has resorbed.

Directions in the further evolution of the facelift operation

Although facelifting has progressed beyond understanding of the SMAS and the retaining ligaments, concerns about the facial nerve location remain a major consideration in the selection of facelift procedure. The nerves and retaining ligaments are two of the main structures that traverse the sub-SMAS plane (the deep plane between the superficial and deep fascias). However, the largest area in this interval is occupied by the sub-SMAS (glide plane) facial spaces, whose clinical significance has only recently become appreciated. Although the spaces function to

Figure 70.7 Minimal dissection composite facelift. Skin flap undermining is limited to the cross-hatched area. Sub-SMAS dissection only is employed forward of this, and is limited to the pre-masseter spaces. No dissection is required forward of the yellow line at the anterior border of the masseter.

allow facial movement, their presence accounts for many of the characteristic ageing changes of the face, such as malar mounds and jowls. For surgeons, there are significant advantages in knowing that the spaces are effectively, 'pre-dissected' and are 'safe spaces'. These characteristics allow for a relatively rapid, bloodless and safe surgical access into the face, as the facial nerve branches and vessels remain outside the spaces. The nerves are at all times behind the walls of the spaces. Where the nerve branches become superficial and are exposed to shearing forces, they travel under the 'protection' of retaining ligaments. In surgery, the nerves are only at potential risk when dissection is performed outside the spaces; and then only at real risk where they are in close relation to the retaining ligament the surgeon intends to lyse. In short, the nerves and major ligaments are found close together outside the walls of the spaces.

The surgical principle is to first locate and enter and then define the boundaries of the spaces using blunt dissection. Then, when dissecting in the area between the boundaries of the spaces, the dissection technique is changed, to a precise, controlled vertical spreading. This technique safely and progressively releases the areolar tissue, allowing gentle definition of the nerves and their relationship to the ligaments that need release. For safety, the nerve may be eased aside before the ligament is released. Then for the facelift reconstruction a suture is placed into the upper end of the ligament where it embraces the overlying SMAS.

An important future direction, to make facelifts more acceptable, is faster postoperative recovery. Postoperative bruising following an anatomically composite facelift does not occur under the composite flap, it occurs only in the posterior subcutaneous dissection part. With a change in surgical emphasis it is possible to design the facelift flap so that there is, essentially, no residual area of subcutaneous dissection and therefore no bruising on the face as a result of the facelift (Figure 70.7). A complete composite facelift is the absolute opposite of the MACS lift, which requires the use of an extended subcutaneous flap. To perform a complete composite, the location of the vertical

SMAS incision is planned so that the posterior edge of the mobilized SMAS flap reaches, and is sutured to, the fixed SMAS at the level of the skin incision. This enables the entire facelift flap to be composite (i.e. without any subcutaneously undermined skin) so that bruising and induration is avoided.⁵¹

Complications

Haematoma

This remains the most common early postoperative complication of facelifts. Correct treatment of haematomas is required to avoid secondary consequences of skin necrosis, prolonged facial oedema or pigmentation. Large series have reported rates of 0.01–4.5% and as high as 8% in males.^{37,52–55} In general, there is much less bleeding with sub-SMAS dissection compared to subcutaneous dissection and the haematoma rate is considerably less. In their series of 1078 consecutive facelifts, Waterhouse and Jones reported a 4.5% haematoma rate.⁴⁰ They identified statistically significant relationships between anterior plastysmaplasty, systolic blood pressure, male gender, smoking and consumption of non-steroidal anti-inflammatory drugs (NSAIDs) and postoperative haematoma requiring evacuation.⁵⁴

Nerve injury

The sensory innervation of the facial skin flap is always damaged from subcutaneous dissection, the extent of numbness being in proportion to the extent of dissection. This usually resolves in 15–18 months. The greater auricular nerve branches are at risk during the neck dissection.

All facial motor nerve branches are considered at risk during facelifts. Traction neurapraxia is the most frequent injury, leading to temporary muscle paresis that resolves with time. A major neurapraxia may be evident for 12–16 weeks. The buccal branch is thought to be the most commonly affected, but fortunately, because it has multiple interconnecting branches with intraneural overlap, its clinical significance is small. Frontal and marginal mandibular branch injuries are more clinically significant as these are terminal branches. Permanent facial nerve injury is a major complication and fortunately rare, being reported in several large series with a range of 0–0.3%. Most nerve injuries recover during the postoperative months.^{37,46,55}

Skin loss

Traditional facelift techniques utilize large random, often thin, flaps sutured under tension that predispose to areas of skin loss from circulatory deficiency. These are most often postauricular and managed conservatively to allow secondary healing. Skin loss is an avoidable complication with recognized predisposing risk factors, smoking being the major risk. Smoking was implicated in 74% of patients with skin loss in a major retrospective analysis by Rees and smokers estimated to be 12.5 times more likely to suffer skin necrosis.⁵⁶ Another prospective series estimated skin necrosis in 19.5% of smokers and only 5% of non-smokers.⁵⁷

Unsatisfactory scars

Skin hyper- or hypopigmentation, hypertrophic and keloid scarring are possible general scarring complications. Earlobe distortion and temporal hairline deformities are consequences of incision design error and traction from excess skin tension, as are loss of hair and scar widening.

Infection

Infections are not a problem in facelift surgery and occur in less than 1% of cases.⁵⁸

CHAPTER 71

Neck lift

Timothy J. Marten and Dino Elyassnia

Marten Clinic of Plastic Surgery, San Francisco, CA, USA

Introduction

Why perform a neck lift?

Why perform a neck lift? Why not just lift the cheeks and jawline or perform other procedures that rejuvenate the eyes or upper face? The simple answer is that a well-contoured neck is an artistic imperative to an attractive and appealing appearance. A good neckline conveys a sense of youth, health, fitness and vitality, and lends an appearance of decisiveness, sensuality and beauty (Figure 71.1). Neck improvement is of high priority to almost every patient seeking facial rejuvenation, and the results of 'facelift' procedures are largely judged by the outcome achieved in the neck. If the neck is not sufficiently improved our patients will feel we have failed them.

How should a neck lift be performed?

It is unlikely there will ever be a consensus on how a neck lift should be performed and it is a fact that no one procedure will be best for all patients. The technique used cannot be arbitrary, will depend on deformities present, and will necessarily vary from patient to patient. Success or failure in treating the neck lies in the diagnosis of problems and the application of a logical surgical plan, and any surgeon capable of identifying the anatomic basis of patient problems and forming a sound plan for their correction can achieve excellent outcomes.

So how should one perform a neck lift? Perhaps it is easiest to start by stating what not to do. Despite the fact that it is a common practice, it is not enough to perform submental liposuction and tighten the skin in most patients as such an approach ignores a number of anatomical problems present in many patients seeking neck improvement, including platysmal laxity, platysma bands, excess subplatysmal fat, large submandibular glands, digastric muscle hypertrophy and developmental factors such as the size and shape of the bony jaw and chin. Removing subcutaneous fat and tightening skin over these problems does not correct them, and the presence or absence of each must be looked for in order to create and apply an appropriate surgical plan (Figure 71.2).

Treatment options

Patients seeking neck improvement have a range of options available to them depending on the problems present, the degree of improvement they seek, and the time, trouble and expense they are willing to undergo to obtain the improvement they desire. And while it is incumbent upon us to discuss these options and the advantages and disadvantages of each, patients are also seeking our guidance as to what is possible, what is practical, and what is really best. It is not enough to steer patients to procedures we are comfortable with. We are professionally bound and ethically obliged to refer patients for the care they need and desire if we are not able to provide it ourselves.

Submental liposuction

Submental liposuction is the simplest and likely the most commonly performed procedure to improve neck contour in the range of options available to patients. It does not constitute a true neck lift, however, and only occasionally produces optimal outcomes. Patients and surgeons are predictably drawn into a sense of denial of this by the fact that submental liposuction will occasionally produce worthwhile improvement, and it is these atypical outcomes that are predictably displayed in offices, placed in advertisements, shown on TV and websites, published in the beauty press, and even included in presentations at plastic surgery symposia. Adding to the deception is that fact that these photographs have usually been taken in the early postoperative period when swelling is still present, which obscures irregularities and underlying but untreated deep layer problems.

In reality, submental liposuction is an incomplete solution to neck problems for most patients. As a standalone treatment it suffers the significant drawback that it falsely assumes poor neck contour to be solely the result of the accumulation of subcutaneous fat, and it is conceptually flawed in that it does not address platysma laxity and other deep layer problems, which together typically play a much larger and more important role in the ageing neck and neck contour deformities. As a result, most patients undergoing this procedure achieve improvement, but

Figure 71.1 Patient seen before and after neck lift. A good neckline conveys a sense of youth, health, fitness and vitality, decisiveness, sensuality and beauty. (The patient has also undergone facelift, foreheadplasty, eyelid surgery and facial fat injections.) Surgical procedures performed by Timothy J. Marten, MD, FACS. Figure 71.2 Patient seen before and after neck lift. It is not enough to perform submental liposuction and tighten the skin in most patients. Such an approach ignores anatomical problems present in many patients seeking neck improvement. A careful evaluation shows patient preoperatively (*before*) to be troubled by platysmal laxity, platysma bands, excess subplatysmal fat, large submandibular glands and digastric muscle hypertrophy. Removing subcutaneous fat and tightening skin over these problems does not correct them and cannot produce the type of improvement shown (*after*). Surgical procedures performed by Timothy J. Marten, MD, FACS. Source: Photos courtesy of the Marten Clinic of Plastic Surgery.

Figure 71.3 Typical outcome seen with submental liposuction, which is an incomplete solution to neck problems for most patients as it falsely assumes that poor neck contour is solely the result of the accumulation of subcutaneous fat, and it does not address platysma laxity and other deep layer problems which usually play a much larger role in the ageing neck. Note that the large submandibular salivary gland is still present, platysma laxity has not been corrected, and aggressive fat removal has made platysma bands more obvious.

not comprehensive correction of their neck problems, and ultimately relying on this technique as the only method to obtain improved neck contour will seldom be successful (Figure 71.3).

Submental liposuction is also a frequent cause of many vexing patient problems and complications as it often leads to unintended but inappropriate removal of subcutaneous fat essential to a natural and youthful appearance, and this can, in turn, expose underlying problems of deep layer origin. Misapplied

and overused, or when aggressive 'ultrasonic' and 'laser' techniques are overzealously employed, submental liposuction can also result in extreme over-resection of precious subcutaneous fat and very unnatural and objectionable appearances. These problems are typically not evident in the operating room or in the early post-op period when cervicosubmental tissues are swollen however, but appear later, and once present, are very difficult to correct (Figure 71.4).

Figure 71.4 Overexcision of subcutaneous fat with liposuction. The patient (*left*) has had aggressive 'small cannula micro-liposculpture' by an unknown surgeon, which resulted in too much fat being removed. The neck and submental region are irregular, unnatural and unattractive. A different patient (*right*) has had 'laser liposuction' performed by an unknown surgeon. Inappropriate over-resection of fat has resulted in harsh and unnatural contours along with unattractive exposure of platysmal bands.

Figure 71.5 Overexcision of postauricular skin. It is a common error to attempt to lift the neck by tightening neck skin. It is not possible, however, to create a sustained improvement in neck contour in this manner and ill-conceived overtightening of neck skin will result in wide postauricular scars. Neck contour is properly created by modification of deep layer structures and only skin that is truly redundant should be removed. (Procedures performed by unknown surgeons.)

Liposuction, in combination with ill-conceived overtightening of neck skin, can add the additional objectionable problems of hairline displacement and wide postauricular scars, and compound the overall deformity (Figure 71.5).

Despite its many drawbacks and propensity to precipitate troublesome and vexing problems, the conceptual and comparative technical simplicity of submental liposuction is particularly appealing to inexperienced surgeons and non-surgeons performing aesthetic surgery procedures. Indeed, these characteristics of the technique almost guarantee that, effective or not, it will continue to be overused and inappropriately recommended to patients who are not good candidates for the procedure for the foreseeable future.

'Short-scar' neck lift (neck lift with submental incision only)

Although submental liposuction alone will rarely produce optimal neck improvement, a neck lift performed through a submental incision without any removal of skin can create attractive cervical contour in many patients (Figure 71.6).

This is due to the fact that, unlike liposuction, a neck lift performed through a submental incision allows deep layer problems and platysmal laxity typically present in the majority of patients seeking neck improvement to be addressed. This,

however, begs the question, how can good neck contour be created without removing and tightening the skin, and what happens to the 'excess' skin if only the deeper layer treatment is made and no skin is excised? The answer to this question is twofold: First, it is important to appreciate that in a properly performed neck lift contour is created by modification of deep layers of the neck, *not* by tightening the skin. Skin is intended to be a covering layer and serve a covering function. It is meant to stretch and give as we move and express ourselves. It is not intended to be a structural supporting layer, or to hold up sagging muscle and fat or lift hypertrophied structures lying beneath it. The second part of the answer lies in the increase in neck surface area that occurs when deep neck contour is improved. Improving neck contour by removing excess pre-platysmal fat when present, excising redundant subplatysmal fat and performing other deep layer manoeuvres as indicated, followed by tightening a lax platysma will result in a deepened cervicomenal angle, a longer curvilinear distance from the mentum to the sternal notch, and a more concave and geometrically larger and longer neck surface. When neck skin is re-draped and redistributed over the deeper, more concave surface, 'excess' skin is absorbed and none need be removed. These simple but not intuitive or immediately obvious facts underlie the reason that skin excision need not be performed in

Figure 71.6 Neck lift with a submental incision only. Although submental liposuction alone will rarely produce optimal neck improvement, a neck lift performed through a submental incision without any removal of skin can create an attractive cervical contour in many patients. Both of these patients had their procedures performed through a submental incision only. No incision was made in the periauricular area and there are no periauricular scars. Surgical procedures performed by Timothy J. Marten, MD, FACS. Source: Photos courtesy of the Marten Clinic of Plastic Surgery.

patients with good skin quality and mild to moderate skin excess to obtain a good result.

Once the fact that increased neck surface area is produced by deepening the cervicomental angle is acknowledged and accepted it becomes clear why it is counterproductive to excise any skin from the submental incision as this can create a 'bow-string' effect and actually blunt the cervicomental angle. The submental skin incision is used for access to the neck only in a properly performed neck lift, and if skin excision is necessary it is more practically, effectively and logically removed from the postauricular area.

There is a limit to the amount of neck skin that can be absorbed and managed in this manner, however, and an isolated neck lift performed through a submental incision only is typically best for male patients and younger women with mild to moderate skin excess, good skin elasticity and minimal or modest ageing in the midface, cheek and jawline.

Neck lift with a chin implant

The difference between the presence of poor neck contour and microgenia is commonly misunderstood, and it is a common misconception that placement of a chin implant improves neck contour. A chin implant is a treatment for microgenia – not a poor neckline – and the presence or absence of microgenia and the need for a chin implant is a cephalometric determination that is independent of the condition of the neck. Placement of a chin implant when microgenia is not present is a conceptual and artistic error that will create unnatural appearances.

When true microgenia is present, however, placing a chin implant in combination with a neck lift will produce a more harmonious and balanced profile and a more aesthetic and attractive cervicofacial profile (Figure 71.7).

'Extended' neck lift and neck lift with facelift

If a significant amount of redundant skin is present, it must be excised to obtain the best result, and in such situations it is most logically and effectively excised in the postauricular areas using periauricular skin incisions. Skin excision from the submental incision is conceptually flawed and will actually degrade neck contour rather than improve it, and skin excision using large midline Z-plasties will result in a poorly concealed scar, and bizarre changes in beard hair inclination in men.

Skin excision can be combined with treatment of the neck through the submental incision as an 'extended' or 'long-scar' neck lift, or as part of a facelift procedure (Figure 71.8).

Practically speaking, most patients in need of a neck lift with skin excision also need a facelift as it is unusual to encounter patients with excess skin in the neck but not elsewhere on the face. This is particularly true in women and it is aesthetically inappropriate to perform an isolated neck lift in most women who present for facial rejuvenation. Lifting only the neck but not the cheeks, jowls and jawline can create an unnatural and unfeminine appearance.

Combining a facelift with a neck lift is almost always the best approach to obtain a balanced, natural and harmonious rejuvenation of the female face, although not all patients will recognize or accept this (Figure 71.9).

Figure 71.7 Neck lift with a chin implant. The difference between the presence of poor neck contour and microgenia is commonly misunderstood, and it is a common misconception that placement of a chin implant improves neck contour. When true microgenia is present, however, placing a chin implant in combination with a neck lift will produce a more harmonious and balanced profile and a more aesthetic and attractive cervicofacial profile. Surgical planning

Planning the submental incision

Whether performing a neck lift alone or in combination with a facelift, optimal improvement in the neck can generally not be obtained in most patients unless a submental incision is made. Traditionally this incision is placed directly in and along the

submental crease in a well-intended but counterproductive attempt to conceal the resulting scar (Figure 71.10).

This incision plan should be avoided, however, as it will surgically reinforce the crease and accentuate a 'double chin' or 'witch's chin' deformity. Exposure of the submental region will also be compromised, and difficulty will be encountered when suturing or dissecting low in the neck. A more posterior placement

Figure 71.9 Comprehensive rejuvenation of the face. Combining a neck lift with a facelift and related procedures is almost always the best approach to obtain a balanced, natural and harmonious rejuvenation of the female face, although not all patients will recognize or accept this. This 55-year-old woman underwent facelift, neck lift, limited incision forehead lift, upper and lower blepharoplasties, chin augmentation, and fat transfer to the lips and cheeks. Addressing all regions of the face has produced a natural balanced outcome, and a far better result than neck lift alone (see also Figure 71.1). Surgical procedures performed by Timothy J. Marten, MD, FACS. Source: Photos courtesy of the Marten Clinic of Plastic Surgery.

of this incision will eliminate these problems, but still result in an inconspicuous and well-concealed scar (Figures 71.11 and 71.12).

The submental incision should be placed well within the mandibular shadow and well posterior but parallel to the submental crease at a point lying roughly one half the distance between the mentum and hyoid. This usually corresponds to a site situated 1–2 cm posterior to the crease (Figure 71.13).

The incision should be approximately 3–3.5 cm in length, but may be made longer as long as neither end will be advanced up upon a visible portion of the face when skin flaps are shifted. Healing will be best, and the scar will be best concealed, if it is made as a straight, and not as a curved line (Figure 71.14).

Planning treatment of the platysma

Assessing platysma deformity

The cervicosubmental region of each patient must be carefully examined both at rest and during platysmal activation if complete assessment of platysmal deformity is to be made. This

is best accomplished by asking the patient to ‘push the jaw forward and tighten the neck’. It is often helpful if the surgeon demonstrates this manoeuvre first for the patient to be sure it is correctly performed. Frequently an insignificant-appearing deformity at rest will be obvious upon muscle activation (Figure 71.15). Failure to recognize and appropriately correct these ‘dynamic deformities’ is the reason too many facelift patients appear improved in repose, but unnatural or bizarre in conversation, animation and during other activities that result in platysma muscle activation.

Examination of the cervicosubmental region with and without platysmal activation allows one to distinguish between ‘hard’ dynamic and ‘soft’ adynamic cervical bands. Soft, adynamic bands change little during platysma activation and are predominantly a problem of loose skin or horizontal platysmal laxity. Hard dynamic bands become tight or exaggerated upon platysmal activation and indicate a problem of platysmal hyperfunction.

Figure 71.10 Traditional, but incorrect, plan for the submental incision. The incision should not be placed directly along the submental crease (arrow) as this will reinforce the submental retaining ligaments and accentuate the 'double chin' appearance. Note that typical plan of skin undermining (yellow area) also promotes a double chin appearance because the crease is not undermined, retaining ligaments are not released, and the fat of the chin and the neck cannot be readily blended to create a smooth transition between them.

Figure 71.11 Correct location for the submental incision. Placing the submental incision 1.5 cm *posterior* to the submental crease prevents accentuation of the 'double chin' and witch's chin deformities and provides for easier dissection and suturing in the anterior neck (compare with Figure 71.10). Note that this incision plan allows the submental crease to be undermined and submental retaining ligaments to be released, and the fat of the chin pad and neck to be blended to create a smooth transition between them (Figure 71.12). Surgical procedures performed by Timothy J. Marten, MD, FACS. Source: Photos courtesy of the Marten Clinic of Plastic Surgery.

Treatment of horizontal platysma laxity and 'soft' bands

If submental support is poor due to horizontal platysmal laxity or platysmal diastasis and optimal improvement in the anterior neck is desired, *anterior platysmaplasty* is planned (Figure 71.16). Anterior platysmaplasty is the procedure in which the medial borders of the platysma muscle are sutured together to help consolidate the neck, reduce horizontal platysmal laxity and improve neck appearance when the patients flexes the neck and looks down (Figure 71.17). It is *not*, however, adequate or effective in the treatment of excess subplatysmal fat, prominent submandibular glands, hypertrophy of the anterior bellies of the digastric muscles, or the treatment of 'hard' dynamic platysmal bands. Treatment of these problems will require that other manoeuvres be performed.

Treatment of platysma hyperfunction and dynamic 'hard' bands

It is important to distinguish between 'hard' dynamic bands and 'soft' adynamic platysmal bands as treatment will vary depending on the type present. Patients with soft bands are usually adequately treated with skin excision or skin excision and platysmaplasty alone. Patients with 'hard' bands, however, require *transverse platysma myotomy*. The result of platysma myotomy is immediate, dramatic, long-lasting and superior to any suture, suture suspension or 'corset' technique. The length of trans-section required can be varied depending on the location and configuration of bands present, and will thus differ from patient to patient.

Platysmal bands are generally seen to lie in medial and lateral locations. Each band is situated near the medial and lateral

Figure 71.12 Correction of the 'double chin' deformity. (a) Patient with 'double chin' seen preoperatively. (b) Same patient seen after facelift and neck lift. The submental incision was made posterior to the submental crease to allow undermining and release on the submental retaining ligaments and blending of chin and neck fat. Surgical procedures performed by Timothy J. Marten, MD, FACS. Source: Photos courtesy of the Marten Clinic of Plastic Surgery.

Figure 71.13 Plan for the submental incision. The submental portion of the facelift incision (solid line) should be placed posterior to the submental crease (dotted line), approximately one half the distance between the mentum and hyoid (arrows). Usually this corresponds to a point about 1.5 cm posterior to the submental crease.

platysma muscle borders, but does not usually correlate precisely with them. Patients with anterior platysmal bands only are planned to undergo transverse platysmal myotomy medially through the section of muscle on which the band is present at the level of the cricoid cartilage (Figure 71.18). The platysma muscles need not be completely transected when an anterior band only is present, just the region where the platysmal band is located.

If lateral, as well as anterior bands are present, the myotomy is carried more laterally to include them as well (Figure 71.19). If poor definition is present over the lateral mandibular border, in addition to anterior and lateral neck bands, platysmal myotomy is planned to continue 'full width' superolaterally up to the anterior border of the sternocleidomastoid muscle (Figure 71.20). A similar full-width myotomy of this type is also indicated in a firm obtuse neck with a 'short platysma' and poor definition over the mandibular angle, but no bands.

In many necks a subtotal myotomy only is indicated and need be performed. As a practical matter, however, complete transection of the platysma is performed in most patients to ensure the best contour possible, and to limit the possibility of band recurrence or that residual platysmal bands will be present. Despite assertions to the contrary, full-width platysmal myotomy will not result in an overly thin appearing neck or reduced support of the submandibular glands when properly performed. Medial wedge resections of platysma at the hyoid and vertical excisions of platysma bands, although shown in many textbooks, are not effective and usually result in unaesthetic exposure of underlying cervical anatomy and other secondary deformities. These procedures are not recommended and experience has shown that they should not be performed. Similarly, attempts to place rigid support across the cervicomental angle in the form of a mastoid to mastoid 'noose' of suture or commercially available straps to lift platysmal bands is conceptually flawed and practically problematic. Experience has shown that these manoeuvres do not work and are the source of many patient problems.

Figure 71.14 Healed submental incisions. Placement of the submental incision posterior to the submental crease will still result in an inconspicuous, well-concealed scar and simultaneously provide better access and exposure when working in the deep layers of the neck. (a) Repose

(b) Platysma contraction

Figure 71.15 Dynamic assessment of the cervicosubmental region. The neck is examined in repose (a) and as the platysma is contracted (b). Dynamic platysma muscle irregularities are often referred to as 'platysma bands'.

Planning the modification of the submental region

Traditional neck lift techniques do not adequately address many aspects of ageing in the submental region and it is not enough in most situations to limit treatment of the neck to pre-platysmal lipectomy alone or with postauricular skin excision. For many patients subplatysmal fat accumulation, submandibular salivary gland 'ptosis' (enlargement) and digastric muscle hypertrophy will contribute significantly to the neck deformity present and necessitate additional treatment.

In all but the unusual or young patient the majority of cervical fat accumulation will be present in a subplatysmal location, and little if any will need to be removed from the pre-platysmal layer. Indeed, as patients age fat stores generally shift from a pre-platysmal location to a subplatysmal one, and the small amount of subcutaneous fat present in the typical patient presenting for a neck lift is necessary and must be preserved if a soft, youthful and attractive appearance is to be obtained. Although the necks of patients undergoing liposuction may look good initially when swelling is present, once it resolves, they typically display an unnatural and unaesthetic 'guttled'

appearance. Once one acknowledges this fact, the futility and undesirability of cervicosubmental liposuction in most patients becomes obvious.

Abnormal collections of subplatysmal fat can be identified by preoperative palpation of the neck with and without platysmal activation. Fat lying predominantly in a pre-platysmal position will generally feel 'soft' and will remain in the examiner's grasp upon platysmal muscle activation. Fat lying in a subplatysmal position, however, will have a firmer feel, and will tend to be pulled superiorly out of the examiner's grasp when the platysma is contracted (Figure 71.21).

Two typical scenarios where subplatysmal fat is likely to be present is in patients with firm, obtuse necks who have been troubled by lifelong cervicomenal fullness and patients presenting for secondary surgery who have poor cervical contour (Figure 71.22). In these individuals, partial subplatysmal lipectomy will likely be required, but complete removal of all subplatysmal fat is rarely indicated and deep cervical fat (intra-digastric fat) should not be removed. When subplatysmal and/or deep cervical fat has been erroneously overexcised, an objectionable depression in the submental region may result,

Figure 71.16 Anterior platysmaplasty. Repair of platysmal diastasis reduces horizontal platysmal laxity, improves submental support and helps consolidate the neck. It is not adequate or effective treatment of platysmal bands, however.

Figure 71.17 Anterior platysmaplasty. Platysmaplasty improves submental support and enhances neck appearance when the patient looks down. Surgical procedures performed by Timothy J. Marten, MD, FACS. Source: Photos courtesy of the Marten Clinic of Plastic Surgery.

commonly referred to as the 'dug out neck' deformity (Figure 71.23). Typically this depression is more evident when the neck is flexed somewhat or when the patient swallows.

Planning treatment of the prominent submandibular gland

Preoperative assessment must be made of the submandibular glands as they often contribute to the appearance of a full, 'obtuse', and 'lumpy' neck. Large submandibular glands are most

easily seen in the secondary facelift patient who has had prior aggressive cervicosubmental lipectomy (Figure 71.24). Large glands are frequently hidden by submental fat or lax platysma muscle in the patient with a full neck presenting for a primary procedure, however, and a plan that does not recognize this fact will lead to disappointing and unexpected bulges in the lateral submental regions postoperatively.

Submandibular glands are usually palpable as firm, smooth, discrete, mobile masses in the lateral submental triangle, lateral

Figure 71.18 Plan for treatment of 'anterior' platysmal bands. Transverse platysma myotomy is performed in the region of the platysma muscle where the platysmal band is present. **(a)** Anterior neck after platysmaplasty but before anterior platysma myotomy. **(b)** After anterior platysmal myotomy. (Note: myotomy is most easily and effectively performed after platysmaplasty has been completed.)

Figure 71.19 Plan for treatment of 'anterior' and 'lateral' platysmal bands. If lateral bands are present, the myotomy is carried more laterally to include them as well. **(a)** Anterior neck after platysmaplasty but before anterolateral platysmal myotomy. **(b)** After anterolateral myotomy. (Note: myotomy is most easily and effectively performed after platysmaplasty has been completed.)

to the anterior belly of the digastric muscle and medial to the inner aspect of the ipsilateral mandibular border. Submandibular glands lying superior to the plane tangent to the inferior border of the mandible and the ipsilateral anterior belly of the digastric muscle do *not* disrupt neck contour and will usually *not* require treatment. Glands protruding inferior to this plane are likely to be problematic, however, if excess cervical fat is removed, the platysma muscle is tightened and redundant skin is excised. These glands warrant treatment.

Despite claims to the contrary, experience has shown that prominent submandibular glands are actually large, *not* ptotic, and that the platysma contributes little to their position or support. Attempts at tightening the platysma when a prominent gland is present usually results in modest improvement that is short lived. The same is true with the various suture suspension methods that have been proposed and now largely abandoned. Careful sculpting of the periglandular fat will sometimes allow 'small' prominent glands to be disguised, but large, prominent

Figure 71.20 Plan for 'full-width' platysmal transection. Full-width myotomy not only corrects anterior and lateral bands, but also provides improved definition over the lateral mandibular border. (a) Anterior neck after platysmaplasty but before full-width platysmal myotomy. (b) After full-width platysmal myotomy. (Note: myotomy is most easily and effectively performed after platysmaplasty has been completed.)

Figure 71.21 Assessing the location of cervicosubmental fat. (a) Submental 'waddle' is grasped with the face and neck in repose. (b) The patient is then asked to activate the platysma muscle. In this example, fat is pulled superiorly from the examiner's grasp, indicating a predominantly subplatysmal position. Fat lying predominantly in a subcutaneous pre-platysmal position would tend to remain within the examiner's grasp when the platysma is activated.

glands will require that the protruding portion be resected if optimal improvement is to be obtained (Figure 71.25).

The decision to perform submandibular gland reduction should be made in conjunction with the patient after appropriate

discussion of the advantages and disadvantages of the procedure. Patients should know that the procedure may prolong submental induration and oedema, and carries a small theoretical but unlikely risk of resulting in bleeding,

Figure 71.22 Patients likely to have subplatysmal fat accumulation. (a) Young patient with firm, obtuse neck who has been troubled by lifelong cervicomenmental fullness. These patients typically have large collections of subplatysmal fat and are suboptimal candidates for submental liposuction. (b) Patient presenting for secondary surgery who has poor cervical contour. It can be seen that superficial subcutaneous fat has been stripped out at the primary procedure and the remaining fat is almost completely in a subplatysmal location.

Figure 71.23 The 'dug out neck' deformity is a term used to describe situations in which too much subplatysmal and/or deep cervical fat has been erroneously overexcised, resulting in an objectionable depression in the submental region.

sialoma, salivary fistula and dry mouth symptoms. Patients should also be informed, however, that such problems are rare, that only the protruding portion of the gland is excised and that the majority of the gland is left in place and is not removed.

Planning treatment of prominent anterior belly of the digastric muscle

A small subgroup of patients will present with large, bulky anterior bellies of their digastric muscles that are evident as linear paramedian submental fullness (Figure 71.26).

Figure 71.24 Prominent submandibular glands are usually evident as protruding masses in the lateral submental triangle, lateral to the anterior belly of the ipsilateral digastric muscle and mandibular border. **(a)** Patient with residual prominent submandibular gland after facelift and submental liposuction. His prior procedure has made the prominent glands more obvious. **(b)** Patient with residual prominent submandibular gland after 'weekend neck lift'. Aggressive resection of subcutaneous fat has exposed the prominent gland, which was not treated.

Figure 71.25 Prominent submandibular glands. Despite claims to the contrary, experience shows that prominent submandibular glands are actually large and not 'ptotic' and will require that the protruding portion be resected if optimal improvement is to be obtained. **(a)** Patient with prominent submandibular gland that contributes significantly to poor neck contour. **(b)** Same patient seen after neck lift that included submandibular gland reduction. Surgical procedures performed by Timothy J. Marten, MD, FACS. Source: Photos courtesy of the Marten Clinic of Plastic Surgery.

Large anterior bellies of the digastric muscles are most easily seen in the secondary facelift patient who has had prior aggressive cervicosubmental lipectomy. Large muscles are frequently hidden by excess submental fat or lax platysma muscle in the patient presenting for primary procedures, however, and failure to identify them may lead to unexpected and objectionable sub-

mental bulges postoperatively. When large, prominent digastric muscles are identified, subtotal *superficial digastric myectomy* should be considered. The final decision as to whether partial digastric myectomy should be performed is often best deferred until the day of surgery and the improvement produced by other modifications of the submental region can be evaluated.

Figure 71.26 Prominent anterior belly of the digastric muscle. The anterior belly of the digastric muscle can be seen as objectionable linear paramedian fullness in the submental region. Prominent digastric muscles often go unnoticed at the time of the primary procedure due to the fact that they are frequently hidden by cervical fat and lax platysma muscle.

Surgical Technique

Anaesthesia

Properly and comprehensively performed neck lift techniques can be time consuming, technically demanding, and can test the patience and composure of almost any surgeon. It is highly recommended that any surgeon new to these techniques enlist the services of an anaesthetist. This is particularly important when the procedure is to be performed upon a patient who is apprehensive, has a history of anaesthetic difficulties, hypertension or other significant medical problems.

The majority of our neck lifts are now performed under deep sedation administered by an anaesthetist using a laryngeal mask airway (LMA). The use of a laryngeal mask allows the patient to be heavily sedated without compromise of their airway, but she or he need not receive muscle relaxants and can be allowed to breathe spontaneously. An LMA is also less likely to become dislodged during the procedure than an endotracheal tube, and will not trigger coughing and bucking when the patient emerges from the anaesthetic. The *flexible* LMA is particularly useful in neck surgery. When this device is used and the breathing circuit is separately draped, the breathing circuit can be moved from side to side as needed to obtain unobstructed access to the cervicosubmental region. Most surgeons when initially considering using an LMA airway are understandably fearful that the bladder on the device when inflated will distort the cervical region and interfere with neck assessment and treatment. Fortunately, experience has shown this not to be a valid concern.

Preoperative preparations and care

Each patient receives a full surgical scrub of the entire scalp, face, ears, nose, neck, shoulders and upper chest with full strength (1:750) benzalkonium chloride (BAK or Zephiran) solution after anaesthesia is begun and bland ophthalmic ointment is instilled into each eye. The patient's head is then placed through the opening of a 'split sheet' or a split adhesive-backed disposable transverse laparotomy sheet, leaving the entire head and neck

region unobscured from the clavicles up. No 'turban' or 'head drape' is used. This allows unimpaired examination of the cervicofacial profile in its entirety throughout the procedure and provides complete access to the periauricular areas when required.

The breathing circuit is draped separately from the patient by wrapping it with a sterile paper drape secured with Steri-Strips (sterile adhesive wound tapes) or other sterile fastener of choice. This allows it to move during the procedure as the patient's head is turned from side to side. When drapes are applied in this manner it is not necessary to secure the LMA with tape or by other means as long as its position is watched by the anaesthetist and/or other members of the operating room team present. If an endotracheal tube is used, it can be conveniently and effectively secured to the perioral skin with a TegaDerm or similar sterile adhesive-backed plastic dressing.

Administering local anaesthesia

Local anaesthetic is administered even if deep sedation or general anaesthesia is used. This limits stimulation of the patient and the overall amount of narcotics and anaesthetics needed. A significant and helpful haemostatic effect is also obtained when adrenaline (epinephrine)-containing solutions are used.

Sensory nerve blocks are performed using 0.25% bupivacaine (Marcaine) with adrenaline 1:200 000. This allows the neck or face to be injected with a reduced degree of stimulation. Skin marked for incision is then infiltrated with the same solution. Areas of subcutaneous dissection are generously infiltrated with 0.1% lidocaine (lignocaine) (Xylocaine) with adrenaline 1:1 000 000 solution. It is not necessary, however, to over-inject local anaesthetic in a 'tumescent' fashion.

Infiltration of the preauricular cheek and postauricular areas is carried out using a 22 gauge spinal needle if an 'extended' neck lift or a facelift is being performed. Infiltration of the neck and submental region is carried out with a 1.6 mm multi-hole blunt-tipped infiltration cannula. No direct infiltration beneath the superficial muscular aponeurotic system (SMAS) or platysma is

necessary if the overlying subcutaneous tissues are infiltrated generously at the beginning of the procedure as described above.

Skin flap elevation

The submental incision should be made 1.5 cm or more posterior to the submental crease approximately half way between the mentum and hyoid. Making the incision in this location helps conceal it in the shadow of the mandible, avoids surgical reinforcement of the crease and accentuation of the 'double chin' and 'witch's chin' deformities, and provides better exposure of the deep neck.

Once the submental incision has been made, the surgeon should stand at the head of the table during dissection of the submental region, while the assistant retracts the edges of the incision with a pair of 10 mm double-pronged skin hooks. Skin undermining should be made using Metzenbaum scissors and the dissection should be made subcutaneously, leaving the majority of the subcutaneous/pre-platysmal fat on the platysma surface. This makes fat excision and sculpting easier later in the procedure if required, and precludes the need for difficult and tedious excision of fat from the undersurface of the cervical skin flap. Unlike the dissection of the facelift skin flap, in which a conscious effort must be made to prevent the flap from becoming too thick and the SMAS being compromised, a slightly deeper dissection should be made in the neck to preserve a slightly thicker layer of subcutaneous fat. Preservation of a thicker layer of fat helps avoid a hard or over-resected appearance in the cervicosubmental area, and objectionable overexposure of underlying neck anatomy postoperatively.

Submental dissection is continued inferiorly and laterally. If an 'extended neck lift' or concomitant facelift is being performed, this dissection will join the upper lateral neck dissection made through postauricular and peribulbar incisions.

Upon completion of subcutaneous undermining of the anterior neck and submental regions, a retrograde dissection should be made subcutaneously up onto the inferior chin. This will ensure the submental restraining ligaments have been divided and that the submental crease has been released from its bony attachments. Some bleeding is usually encountered during this manoeuvre, but this should not prevent one from completing this important step.

If a facelift or 'extended' neck lift is being performed and the upper lateral neck is being approached from a postauricular incision, care must be taken to avoid injury to the great auricular nerve. This nerve provides sensation to the lower two thirds of the ear and travels superficially superiorly in the upper lateral neck over the sternocleidomastoid muscle fascia. The most superficial portion of the nerve is anatomically constant and lies approximately 6.5 cm inferior to the auditory meatus, midway between the anterior and posterior borders of the sternocleidomastoid muscle and it is helpful to mark this spot preoperatively on the neck skin surface to guide one during dissection. If the dissection is performed correctly, however, the nerve will lie deep to the plane of skin flap elevation and will be

covered by a thin layer of subcutaneous fat. It is neither necessary nor advisable to attempt to specifically identify or isolate this nerve through additional dissection.

Patients with thin faces, or those undergoing secondary face-lifts, will not uncommonly have little subcutaneous fat between the superficially situated portion of the great auricular nerve and the skin, however. For this reason, extra caution must be taken in these patients if elevating the skin flap in this area, and a clear knowledge of nerve anatomy is required.

Cervical lipectomy

Cervical lipectomy is a technically demanding manoeuvre that requires patience, perseverance and artistic sensitivity. Contrary to what is traditionally practised, if a facelift is being performed in conjunction with the neck lift, subcutaneous lipectomy (including liposuction) should be performed *after* deep neck manoeuvres and shifting and suturing of the SMAS and platysma, and not at the beginning of the procedure. If subcutaneous lipectomy and/or submental liposuction is performed at the beginning of the procedure, fat will be mistakenly excised from regions of the neck that will be raised onto the face when SMAS flaps are advanced and suspended, and this can result in inadvertent creation of harsh or irregular mandibular contours (Figure 71.27). In almost all cases it is best to leave the subcutaneous fat layer untouched until all other manoeuvres are completed and improvements obtained with them assessed.

The key to obtaining good outcomes in the neck is in understanding the distribution of fat in the cervicosubmental region and choosing a treatment plan accordingly. Cervical fat is present in three distinct anatomic layers – pre-platysmal, subplatysmal and deep cervicosubmuscular ('intra-digastric'). In almost all cases cervical lipectomy should be limited to the two more superficially situated regions. Lipectomy technique is not as important as the contours created and it should be the aim of the surgeon to produce an attractive neck, and not simply one devoid of fat.

Exploration of the subplatysmal space is indicated if preoperative assessment suggests a significant collection of subplatysmal fat is present, large digastric muscles are noted or large submandibular glands are identified, or if uncertainty exists as to any aspect of the subplatysmal condition. Significant accumulations of subplatysmal fat can also be demonstrated intraoperatively by placing gentle superior traction on the cheek flaps (if facelift) or cheeks (isolated neck lift) and flexing the neck. If the neck appears full upon this manoeuvre, consideration should be given to exploration of the subplatysmal space and the removal of redundant subplatysmal fat and/or protruding portions of other enlarged structures.

Subplatysmal exploration is performed through the submental skin incision. The subplatysmal space is entered by incising the superficially situated fascia between the medial platysma muscle borders using a Metzenbaum scissors. A combination of blunt and sharp scissors technique is used to isolate each muscle edge. The muscle edge is then grasped and retracted by the assistant

Figure 71.27 Sequencing excision of preplatysmal fat when simultaneous facelift and necklift are performed. If submental liposuction is performed before the SMAS is elevated, denuded areas will be subsequently advanced onto the lower face. This can result in a harsh mandibular contour. To avoid this problem, preplatysmal fat should be removed, if indicated, after the SMAS flap has been raised. (a) Incorrect plan for preplatysmal fat excision (grey shaded area). Submental liposuction is performed at the beginning of the procedure before SMAS flap is raised. (b) After SMAS elevation, areas stripped of fat (grey shaded area) are moved up onto the lower face.

using a 10mm double-pronged skin hook or an Allys forceps. The dissection is subsequently carried laterally, over the anterior belly of the digastric muscle hugging the underside of the platysma. If this dissection is carefully made, a well-defined and relatively avascular plane can usually be identified. Small communicating vessels are not infrequently encountered, however, especially near the medial muscle borders. These should be carefully fulgurated and divided as required. Subplatysmal fat should be left on the deep surface of the neck and *not* raised with the platysma flap. This will facilitate fat removal, as it is technically more difficult to resect fat from the undersurface of the muscle.

The plane tangent to the anterior bellies of the digastric muscles with the neck in neutral or slightly flexed position should be used as the landmark for subplatysmal fat removal. All fat lying superficial to this plane should theoretically be removed if optimal contour is to be obtained. If fat excision is made with the neck flexed, inadvertent overexcision can occur.

In practice, overall neck contour must be considered, as it is the curvilinear plane across the submental region tangent to the borders of the mandible and the anterior bellies of the digastric muscles that ultimately determines attractive neck contour. If large submandibular glands and/or anterior bellies of the digastric muscles are present and it is elected that they should not be treated, subplatysmal fat removal should be more conservative if accentuation of these problems is to be avoided. Fibrous fat in the pre-hyoid region should also not be arbitrarily removed, especially in women, as accentuation and masculinization of the larynx can occur. If prominent submandibular glands and digastric muscles are appropriately treated, however, more aggressive resection of subplatysmal fat can be made.

Subplatysmal fat will be evident as a centrally situated triangular-shaped fat pad with its base lying at the hyoid and tip

near the mentum (Figure 71.28). It should be removed incrementally, as appropriate, and as determined by the position and size of the digastric muscles and the size of the submandibular glands. Fat removal should not be arbitrary, and close attention must be paid to the new contours created. Subplatysmal fat excision often results in division of tributaries of small pretracheal vessels and a long shielded cautery forceps and good suction should be available to obtain adequate haemostasis when required.

Fat situated deep to the plane tangent to anterior bellies of the digastric muscles and beneath the deep cervical fascia (deep cervical or 'intra-digastric' fat) should not be removed and the overwhelming temptation to 'clean out' the deep cervical space resisted. Platysmaplasty, invaginating platysma in a 'corset' fashion, suturing the anterior bellies of the digastric muscles together, and other similar manoeuvres cannot compensate for overzealous excision of deep fat and, in time, an objectionable submental depression will appear in the necks of patients so treated.

Submandibular gland reduction

If large submandibular glands are present, they can usually be seen and palpated lateral to the ipsilateral belly of the anterior digastric muscle on each side within its respective submandibular triangle, protruding inferiorly to a plane tangent to the digastric belly and the mandibular border. The protruding portion can be incrementally resected through the submental incision before submental platysmaplasty is performed to improve neck contour, if indicated (Figure 71.29).

Prominent submandibular glands will be encountered as subplatysmal dissection is carried over the anterior belly of the ipsilateral digastric muscle. The prominent gland will appear as a

(a)

(b)

(c)

(d)

Figure 71.28 Subplatysmal fat. (a) Illustration showing the position of the triangular-shaped subplatysmal fat pad located in the submental space with its tip near the mentum and base at the hyoid bone. (b) Cadaveric view of the submental region and subplatysmal fat similar to that shown in illustration above but closer-up. The arrow is pointing to the subplatysmal fat that has been outlined with a dashed line. The right and left borders of the platysma have been elevated showing the contents of the submental space. The subplatysmal fat pad can be seen overlying the digastric muscles to the upper right and left of the triangle. The hyoid bone at the base of the triangle. (c) Cadaveric demonstration of subplatysmal fat. The head is slightly turned to the viewer's right and the chin is at the upper right hand corner of the photo. The two upper arrows point to the anterior bellies of the right and left digastric muscles and the lower arrow to the subplatysmal fat pad. In this photo, the fat pad has been reflected inferiorly but still attached at its base. The hyoid is now visible along with the interdigastric space. There is a small amount of deep cervical fat visible between the two upper arrows that has been reflected to the right. (d) Intraoperative demonstration of the subplatysmal fat specimen lying over the submental space from which it was removed. The patient's chin is pointing superiorly and is presenting the upper left corner of the photo. The neck is in the lower right corner of the photo.

smooth pink to tan-coloured mass covered by a smooth capsule. Reduction is begun by incising the capsule overlying the gland inferomedially just lateral to the anterior belly of the digastric muscle. The submandibular gland will be evident once exposed in this manner due to its distinctive lobulated appearance. Its inferior portion can be grasped and easily separated from adjacent tissue inside its capsule using a gentle blunt scissors spreading

technique. Although all vital structures are outside the glandular capsule, care should be taken when mobilizing the gland superolaterally, as both the retromandibular vein and the marginal mandibular branch of the facial nerve are in proximity in that area.

An examination of the gland once mobilized inside its capsule will show it to be large, and not merely 'ptotic', and this observation forms the basis of the recommendation that partial resection

Figure 71.29 Surgical approach to submandibular gland reduction. (a) Cadaveric demonstration of submandibular triangle. Chin is in the upper right corner of the photo. The excessive portion of the submandibular gland (SMG) is found protruding inferiorly to a plane tangent to the digastric (lower arrow) and the mandibular border (small upper arrow). (b) Intraoperative photo demonstrating exposure of the submandibular gland. A submental incision has been made approximately 1 cm posterior to the submental crease and the neck subcutaneously undermined. The right platysma muscle has been elevated and is retracted with a double-pronged skin hook and a malleable retractor. The gland will be seen as a distinct bulge just lateral to the ipsilateral anterior belly of the digastric (scissors tips rest on digastric). The capsule has been incised inferomedially and the submandibular gland isolated using blunt dissection. (c) Intraoperative photo prior to resection of the excess portion of the gland. The gland has been mobilized and gently pulled inferiorly. The dotted line represents the level at which the inferior portion of the gland will be excised. (d) Intraoperative photo just prior to excision of the protruding part of the gland. This should be performed incrementally with electrocautery in such a manner that the portion protruding inferior to the plane tangent to the ipsilateral anterior belly of the digastric muscle and the ipsilateral mandibular border will be resected. (e) Patient seen immediately after neck lift that included partial submandibular gland reduction but no skin resection. The photo shows the excellent contour created without skin tightening. The excised portions of the submandibular glands are also demonstrated on both the right and left sides.

of the protruding portion be performed. Examination of the exposed gland will also clearly demonstrate that attempts to reposition it more superiorly by suture suspension, or by tightening overlying platysma muscle will ultimately be fruitless.

A key step in the safe performance of the procedure is adequate mobilization of the gland, and a modest overmobilization will make both gland resection and the control of any intraglandular bleeding that might be encountered much easier.

Once adequately mobilized inside its capsule, the inferior portion of the gland is grasped, and pulled gently inferiorly and medially out of its fossa and away from adjacent structures. The redundant portion is subsequently excised incrementally under direct vision in a medial-to-lateral direction along the planned line of resection with coagulating current cautery. Excision of the excess part of the gland should be performed in such a manner that the portion protruding inferior to the plane tangent

to the ipsilateral anterior belly of the digastric muscle and the ipsilateral mandibular border will be resected. It is usually best that initial resection is conservative and that the gland is incrementally reduced thereafter as required. Never is it necessary or appropriate to remove an entire gland. This would most likely result in a depression or other contour abnormality, and could precipitate an objectionable depression or 'dry mouth' condition.

Excision of the redundant and protruding portion of the submandibular gland should be performed using an extended flat-tipped cautery and a long, high-quality pair of insulated forceps. A flat-tipped, extended cautery is better for controlling bleeding of an intraglandular vessel, should it be encountered, than a needle-point cautery tip. As in all surgery of the neck and submental region, a fiberoptic headlight or retractor is mandatory, as is a competent assistant and a second scrubbed team member to pass instruments and sutures as needed. One person cannot

safely perform both these roles. A suction cannula or smoke-evacuating retractor should also be placed, and the position of the cautery tip relative to vital adjacent structures must be known at all times during the resection. If a smoke-evacuating retractor is used, a second suction set-up for a Yanchor suction should be available in the event that bleeding is encountered during the resection and suction is needed to obtain haemostasis.

Submandibular gland reduction must not be performed without good light, proper instruments, requisite exposure, adequate suction, sufficient personnel and considered caution, as intraglandular vessels may be encountered. These vessels are more commonly encountered when larger resections are necessary and are most easily managed by immediate and thorough fulguration before further dissection is made. Typically, bleeding will occur from both the gland and the specimen side and this is usually best controlled by quickly moving the cautery back and forth between each end of the cut vessel. If only the gland side is cauterized, bleeding will often continue from the specimen side, obscuring the surgical field. If bleeding is brisk and not easily controlled by simple cauterization as described above, the cut edge of the gland should be compressed with forceps and the vessel isolated. It may then be grasped with a second instrument and cautery applied. In the unlikely event that bleeding cannot be controlled by these means the submandibular fossae should be packed with gauze and digital pressure firmly applied for several minutes. In most cases when the gauze is carefully removed, the bleeding will be seen to have stopped and a search for the bleeding point can be made and any suspicious areas cauterized. The submandibular artery enters the submandibular gland superolaterally and will not be encountered when performing typical resections made for aesthetic purposes. Dissection should always be made carefully in this area, however, and as one becomes more practised in the procedure and more comprehensive resections as a result are made, this vessel will often be seen. In most cases, if care is exercised, resection of the most superolateral portion of the protruding portion of the gland can be made without injuring it or the need to ligate it. Should the vessel be inadvertently injured suction should be applied and it should be grasped with a high-quality DeBakey-type forceps. It can then be grasped with a right-angle or similar forceps and ligated.

Once excision of the protruding portion of the gland is complete, the submental region is irrigated and a check for haemostasis along the gland's cut edge is made. It is not necessary or productive to attempt to oversee the cut edge of the gland, or to close the glandular capsule. These manoeuvres are not only technically difficult, but could result in injury to nearby neurovascular structures. It is also not necessary or productive to overcauterize the cut edge of the gland in an attempt to shrink or seal it. This typically results in more pain and swelling, and prolonged submental induration. Subtotal submandibular gland excision to date has not resulted in any cases of haematoma, airway compromise, salivary fistula or gustatory sweating in our practices.

Experience has shown that when submandibular gland reduction is performed, a drain should be placed in the subplatysmal space for at least several days after the procedure to reduce oedema and induration in the submental area and to speed the patient's overall recovery. It is safest to perform the platysmaplasty before drain placement, and then to thread the drain into place. If the drain is placed before platysmaplasty is performed there is a chance that the drain could be caught in one of the sutures, making its removal problematic.

Submandibular gland reduction, although important in the rejuvenation of many necks, will not in and of itself result in attractive neck contour. Other problems must be identified and addressed if optimal results are to be obtained.

Submandibular reduction should be regarded as an advanced technique. It should be undertaken by surgeons well versed in cervical anatomy and experienced in more basic manoeuvres used to rejuvenate the neck. It is highly recommended that any surgeon uncertain of the anatomy of the submental triangle or the exact relationships of important structures in this area review them carefully before undertaking this dissection.

Partial digastric myectomy

After subplatysmal lipectomy and submandibular gland reduction have been performed, assessment should be made of the anterior bellies of the digastric muscles and whether partial digastric myectomy would produce further improvement in neck contour. A subset of patients will be encountered who will be identified as having objectionably large anterior digastric muscle bellies. Usually these are most evident after subplatysmal lipectomy and submandibular gland reduction has been performed, but they may sometimes be evident preoperatively in patients seeking secondary, and occasionally, primary surgery. In these situations additional improvement in neck contour may be obtained by performing superficial, subtotal anterior digastric myectomy.

Superficial, subtotal anterior digastric myectomy is performed under direct vision, through the submental incision after the subplatysmal space has been opened, the platysma muscle mobilized, and subplatysmal fat and protruding portions of the submandibular gland resected, if indicated. The redundant portion of muscle can be excised by either a tangential strip excision technique or by a partial division and excision technique. Although both are reliable and effective, in most cases tangential strip excision provides the simplest and most intuitive and straightforward means of removing the protruding portion of the muscle belly.

Tangential strip excision is performed by visually gauging the muscle redundancy, grasping the redundant portion with a DeBakey or similar forceps, and tangentially excising a strip of muscle longitudinally from the muscle belly with Metzenbaum or similar scissors. Excision is begun near the muscle origin at the mentum and continued to the muscle belly insertion at the lateral hyoid. The muscle is then reassessed and the action repeated until the protruding portion is fully removed and optimal contour has been established. Typically, tangential excision will result in modest bleeding from the excised area

Figure 71.30 Partial division and excision technique of digastric muscle reduction. (a) Excess muscle present is gauged and isolated on a tonsil forceps by pushing the tips of the instrument through the mid-muscle belly at the level of optimal contour and spreading to split the muscle along the length of its fibres. View from patient's right of right digastric muscle through submental incision. Patient's chin is at the left upper corner of the photo and the neck is on right. (b) The isolated muscle segment resting on the instrument consisting of the superficial, protruding portion of it is then excised with scissors or cautery by dividing it near the mandible and the hyoid. The neck is re-examined and the manoeuvre repeated again if necessary until an improved contour is obtained.

that is easily controlled with cautery once muscle reduction is complete. Alternatively, muscle can be excised in this manner directly with a cautery instrument.

In the partial division and excision technique of digastric muscle reduction the excess muscle present is gauged and isolated on a tonsil forceps by pushing the tips of the instrument through the mid-muscle belly at the level of optimal contour and spreading to split the muscle along the length of its fibres. The isolated muscle segment resting on the instrument, consisting of the superficial, protruding portion, is then excised with scissors or cautery by dividing it near the mandible and the hyoid (Figure 71.30). The neck is re-examined and the manoeuvre repeated if necessary until an improved contour is obtained. Usually this entails the excision of the superficial-most half or less of each muscle.

It should be noted that the myectomy, regardless of how it is performed, is a partial and subtotal reduction of the protruding portion of the digastric muscle only, and not an arbitrary excision of the entire muscle belly. In some cases a near total resection will be indicated and can be performed. In addition, partial, superficial digastric myectomy, although an important manoeuvre in the rejuvenation of many necks, will not in and of itself result in attractive neck contour. Other problems must be identified and treated if optimal results are to be obtained. Finally, it should be noted that partial superficial digastric myectomy, although straightforward and conceptually simple, should be regarded as an advanced technique. It should be undertaken by surgeons familiar with cervical anatomy and experienced in more basic manoeuvres used to rejuvenate the neck.

Anterior platysmaplasty

Anterior platysmaplasty (see Figure 71.16 and 71.31) is commonly performed and provides an improved result in most necks. The purpose of platysmaplasty is to consolidate the neck, to reduce irregularities due to horizontal platysmal laxity and to optimize neck appearance when it is flexed and the patient is looking down. Contrary to popular opinion, it cannot create a

sustained improvement in neck contour in and of itself if deep layer problems (subplatysmal fat excess or submandibular gland and digastric muscle hypertrophy) are present, and it is *not* adequate treatment for platysmal hyperfunction and dynamic platysmal bands in most patients.

Typically, platysmaplasty consists of suturing the medial muscle borders of the platysma muscles together from mentum to thyroid cartilage in one or two layers. If redundant muscle is present medially, it is excised and discarded before suturing is performed so that a smooth, edge-to-edge approximation of the medial muscle borders can be made. Experience has shown that this produces a better and more consistent outcome than when excess muscle is invaginated and a multilayer 'plication' or 'corset' is performed, and reduces the likelihood that objectionable midline fullness or bands will result after healing and relaxation of tissues has occurred.

When performing a facelift and neck lift together, platysmaplasty should be performed after cheek SMAS flap dissection and suspension to prevent an accentuation of the effects of ageing and gravity and compromised improvement on the face. Although raising and suspending cheek SMAS flaps first makes platysmaplasty suture placement more difficult, it allows optimal repositioning of the cheek and jaw, and provides for the best overall improvement. If platysmaplasty is performed first, the cheeks and jaw will be pulled inferiorly towards and into the neck, and the effectiveness of the SMAS flap will be significantly diminished.

Platysmaplasty is usually performed using multiple simple interrupted sutures of 3–0 braided polyester (or suture of choice) on a medium to large tapered needle. Long instruments are needed and patience will be required. Optimal improvement generally cannot be obtained if repair is made in one layer or if a running suture is initially used. If the first layer is performed using a running suture some gathering and a 'purse string' effect can occur. This will result in shortening along the line of repair and can cause bowstringing and postoperative midline band formation. If the initial approximation is made using interrupted sutures this problem is averted.

Figure 71.31 Anterior platysmaplasty. repair of platysmal diastasis from mentum to thyroid cartilage (arrows) improves submental support and helps consolidate the neck. It is not adequate or effective treatment of platysmal bands however.

Once initial approximation has been made with interrupted sutures, the line of repair can be oversewn and reinforced with a simple running or running inverting suture without a purse string and shortening effect. The repair need only be snug and should not be tight. If a permanent suture is used, care should be taken to saturate each suture with antibiotic solution prior to placement and to bury all knots.

Platysmaplasty should be performed with the neck in a neutral position. If the closure is made with the neck extended, excessive tightness may result when the patient looks down after surgery. This is particularly the case if platysmaplasty is performed in conjunction with a postauricular transposition flap of cheek SMAS.

If a neck lift is performed in conjunction with a facelift and postauricular transposition flaps are planned, suspension of the flaps to the mastoid should be performed after anterior platysmaplasty has been performed. If the transposition flaps are suspended first, the platysma muscles can be shifted laterally and it may be difficult to join them in the midline. Suspension to the mastoid is performed with interrupted sutures of 4-0 polyglactin (Vicryl) (or other suture of choice). The more proximal portions of the flap are secured with a simple running suture of the same material. This consolidates the deep layer repair in the peribulbar area and prevents the flap from bunching up or rolling up on itself.

Transverse platysma myotomy

Although anterior platysmaplasty will often result in an attractive neck at rest and on the operating table, objectionable appearing dynamic platysma bands and muscle striations will often still be evident in conversation and during animation after surgery if additional steps are not taken. These problems can be minimized by performing *transverse platysma myotomy* (see Figures 71.18, 71.19 and 71.20). The extent of platysma trans-section will depend upon the deformities present and thus will vary from patient to patient.

Platysma myotomy should be performed after anterior platysmaplasty has been completed as the platysma muscle will be uniformly distributed over the anterior neck and under slight tension. Myotomy should be performed low in the neck at the level of the cricoid cartilage. At this level the muscle is thin and will bleed less, and the cut edges are less likely to be visible postoperatively. In addition, a smooth transition across the cervicomenal angle is maintained and lower lip dysfunction is avoided. If trans-section is made higher, these benefits are lost. This is particularly true when myotomy is performed at the level of the hyoid along the cervicomenal angle or when wedges of platysma muscle are removed at that location, as is shown in many plastic surgery textbooks. The platysma muscle is much thicker at that level, the cut edges are more likely to bleed and/or be visible after surgery. In addition, a high trans-section or resection of this sort can result in a severe and unaesthetic transition for the submental region to the neck, and adversely effect platysma action and result in asymmetrical movement of the lower lip during speaking and expression.

Anterior platysma myotomy is best begun through the submental incision just inferior to the inferior-most suture placed when platysmaplasty was performed. The medial platysmal border is identified over the cricothyroid area and grasped and lifted away from the deep cervical fascia with a long DeBakey-type forceps. Myotomy is then made by nibbling through the muscle in small increments with Metzenbaum scissors. As the muscle is divided it usually separates a centimetre or more, exposing the fascia beneath it. Serrated and 'super-sharp' scissors should not be used as they tend to pick up and cut adjacent tissue, and can result in injury to the anterior jugular vein. Unintended injury to the anterior jugular vein will result in annoying bleeding that can be difficult to control. Gentle spreading with scissors tips before each cut is made helps separate the platysma from underlying cervical fascia and facilitates dissection. Myotomy is continued laterally and slightly superiorly according to the preoperative plan. If a 'full-width' division of the platysma is planned, the lateral-most portion of the trans-section is completed through the postauricular incisions by identifying the lateral muscle border, incising it and incrementally extending the incision until it is brought into continuity with the incision made in the muscle anteriorly through the submental incision.

Final contouring of cervicofacial fat

Once correction of deep layer neck problems has been made and platysmaplasty, platysma myotomy and suspension of postauricular transposition flaps have been performed as indicated, final contouring of subcutaneous superficial cervicofacial fat should be performed. This can be done under direct vision using Metzenbaum scissors or a small suction cannula. Final fat sculpting should be continued until all contours are smooth and regular, but it is essential that not all fat is removed if an attractive appearance is to be obtained. In addition, if a 'double chin' or 'witch's chin' is present, an extended dissection of the perimental area and chin pad should be made and fat contributing to these problems excised. Mental and submental fat should then be sculpted and blended to ensure a smooth transition for the chin to the submental area. In full necks, pre-platysmal lipectomy can be performed with a suction cannula using an 'open' liposuction technique by placing the cannula hole down under the skin flap and holding the skin flap down as resection is made. In thin necks, simple excision is made using a scissors technique.

Drain placement

Drains are used routinely and experience has shown that they reduce postoperative ecchymosis and seromas, and allow patients to return to their work and social lives sooner. As a practical matter, drains are generally necessary when aggressive deep neck manoeuvres (subplatysmal fat excision and submandibular gland reduction) are performed, and 'tissue glues' advocated by some surgeons to consolidate the subcutaneous plane cannot be expected to prevent collections in the subplatysmal area. It should be acknowledged that drains will not substitute for poor haemostasis in either plane, however, and will not prevent haematoma formation.

One or two 10 F round 'end-perforated' Jackson-Pratt style closed-circuit suction drains are typically placed subcutaneously in the neck when neck lift is performed. Each drain is placed through a small stab incision on the occipital scalp (in a facelift or extended neck lift) or postauricular sulcus (in a short-scar neck lift) and is anchored at its exit site with a 4–0 nylon suture. Drain placement will be easy in extended neck lifts or when a facelift is concurrently performed as a postauricular incision will be present. In short-scar neck lifts, in which a submental incision only is present, a small liposuction cannula can be used to tunnel from the postauricular stab incision to the neck, and then used to pass the drain back out the incision in a retrograde fashion. The perforated portion of the drain is then positioned beneath the cervical skin across the anterior neck to the opposite side. When extensive modifications have been made to the anterior cervical and submental regions, or when diffuse oozing is encountered, one drain is placed subcutaneously on each side. This provides overlapping drainage of the anterior cervical area. Two drains are generally routinely placed in most male patients as well.

If submandibular gland resection is performed and/or a large amount of subplatysmal fat is removed, an additional drain is placed and its perforated portion is placed in the subplatysmal space after platysmaplasty has been performed. This is most easily accomplished working through the submental incision and by placing a long tonsil or right-angle forceps under the medial edge of the right or left platysma muscle at the inferior-most extent of the platysmaplasty suture line, advancing it laterally and slightly superiorly under the muscle, and pushing the tip of the forceps through the muscle into the subcutaneous space. The tip of the drain is then grasped, pulled retrograde under the muscle and back to the midline, and then cut to length as indicated and tucked underneath the muscle on the opposite side. It is not recommended that a drain be placed in the subplatysmal space before platysmaplasty is performed. When this is done there is a small but significant chance that it could be inadvertently sutured in place and rendered difficult to remove.

Skin closure

If a short-scar neck lift has been performed, a submental incision only will be present and this can be conveniently closed in two layers. Prior to closure it is important to confirm that the wound edge thickness and amount of subcutaneous fat present on each side of the incision are similar. Typically, the wound edge of the cervical side will have a thinner edge and have less subcutaneous fat due to contact with instruments and retractors during preceding steps in the procedure, and the mental, superior side will be thicker and have more fat. If a discrepancy is present, as it often will be, fat is carefully removed from the thicker superior side. The first layer of closure consists of several subcutaneous sutures of 5–0 Monocryl (or other suture of choice) to ensure that fat is present behind the closed wound and so that a depressed scar is avoided. Final approximation is then made with simple interrupted sutures of 6–0 nylon (or other suture of choice).

If an extended neck lift is performed, or a facelift is performed in conjunction with a neck lift procedure, skin will be excised from the postauricular area. The postauricular flap is shifted posteriorly and somewhat superiorly, roughly parallel to transverse neck creases and the mandibular border, in such a manner that skin is suspended under minimal or no tension and that little or no skin need be trimmed from the anterior (postauricular) flap border. Excessive trimming of skin from the anterior border of the postauricular skin flap will require the flap to be shifted along an incorrect superiorly directed vector, and this will produce a compromised result. The first point of suspension is located in the postauricular area at the anterior–superior aspect of the occipito-mastoid incision. The flap is secured at this point with a simple interrupted suture of 4–0 nylon. No incision into the flap is necessary and no deep suture is used.

Once this suspension suture has been placed, the flap overlying the inferior portion of the ear should be carefully divided and the lobule exteriorized. This is a key step in the procedure

that must be performed incrementally and with great care if a visible scar, lobular mal-position, and objectionable 'pixy ear-lobe' is to be avoided. If the incision to exteriorize the lobule is properly made, the apex of the incision should rest snugly against the inferior-most portion of the conchal cartilage. If the incision into the cheek flap is made too far anteriorly or inferiorly, however, artistically appropriate resetting of the lobule will not be possible, and the outcome of the overall procedure significantly compromised.

Postauricular closure along the auriculomastoid sulcus is performed next, and should be completed before trimming and closure of the occipital portion of the incision and resetting of the lobule. It is begun by conservatively trimming the anterior border of the postauricular skin flap into a soft curve to match the curve of the incision made in the auriculomastoid sulcus. The incision is then closed with several interrupted sutures of 4-0 nylon. No deep suture is necessary or used.

Little if any skin should be trimmed from the anterior margin of the postauricular flap along the auriculo-mastoid sulcus. If it appears that a large amount of skin needs to be excised from this area, the postauricular flap has been shifted incorrectly both too far anteriorly and superiorly. In such instances, the previously placed suspension sutures should be removed and the flap re-advanced along a more appropriate, and more posteriorly directed vector.

It is also a significant error and conceptually flawed concept to excise any skin over (superior to) the apex of the occipitomastoid incision and to shorten the postauricular flap along the long axis of the sternocleidomastoid muscle as commonly practised and shown in many plastic surgery textbooks. Despite an apparent redundancy in this area when the patient is supine on the operating table, there is never any true skin excess at this location. This pseudo-excess of skin is present only because of the patient's high shoulder position in the supine position. It will vanish when she or he sits up and the shoulders drop to a normal position. Skin along the axis of the sternocleidomastoid muscle is also needed for side-to-side head tilt. Inappropriate excision of skin over the apex of the occipito-mastoid defect is the ultimate underlying cause of hypertrophic healing in the postauricular region and of a wide postauricular scar.

Trimming and closure of the occipital portion of the incision should be performed after closure of the postauricular area and suspension without trimming along the transmastoid portion of the postauricular incision. A facelift marker should be used to gauge skin flap redundancy along the occipital incision, and all points along the flap should be intentionally trimmed with 2-3 mm of redundancy. It must be remembered that the goal of skin excision is to remove redundancy, and not to tighten the cervical skin flap. If trimming is performed correctly, wound edges should abut one another, and no gaps should be present, *before* sutures are placed. The incision is then closed in one layer with multiple half-buried vertical mattress sutures of 4-0 nylon, with the knots tied on the scalp side and simple interrupted sutures of 6-0 nylon. No deep sutures are required and staples

should not be used. This plan will provide precise wound edge alignment and prevent cross-hatched scars (suture marks). In addition, if the incision is closed under no tension as described an inconspicuous scar will be obtained.

If the postauricular skin flap has been shifted along a proper vector, and tissue distributed appropriately under no tension over the occipital area, a precise fit should be obtained. If neck skin redundancy is large, or if the postauricular flap has been suspended under tension, a 'dog-ear' will often be present at the inferior-most portion of the occipital incision. This should not be chased down the occipital hairline as an obvious scar will result in the fine hair on the nape of the neck. A better result is obtained under these circumstances if the dog-ear is inset posteriorly into the occipital scalp, above the junction of thick and fine hair, and secured with simple interrupted sutures of 4-0 nylon. This requires that a small ellipse of *scalp* be excised from the *scalp side of the incision*, but moves the end of the incision into dense hair where it is well concealed.

Dressings

After all planned procedures have been completed and all incisions have been closed, the patient's hair is washed with shampoo and conditioner and if long it is placed in a soft braid. The hair is then allowed to dry or is blown dry in the recovery room. A final inspection of sutured incisions is made. If poor alignment is found in any area, it is locally re-prepped and sutures are removed and replaced as required.

No dressing is required or applied. Patients are typically discharged with a hat, scarf and sunglasses following the procedure. The traditional facelift and neck lift dressings consisting of tightly applied mineral oil-soaked cotton and rolled gauze are unnecessary if closed suction drains are used, and a strong argument can be made that they are counterproductive and of potential harm to the patient. These dressings place unnecessary and potentially harmful pressure on thin skin flaps in a critical stage of their healing and can compromise already tenuous circulation in them. In addition, they preclude inspection and monitoring of the operative site and can disguise and delay the diagnosis of serious problems such as haematoma, flap ischaemia and pressure necrosis. Finally, patients typically find the traditional face and neck lift dressing cumbersome, confining, unhygienic and claustrophobic, and their family members are often frightened by them.

Postoperative care

Performance of the procedure itself only fulfills part of our obligation to the patient and the care they receive postoperatively is arguably as important as the surgery itself. Diligent postoperative care will also ensure the best result and limit the likelihood that problems and complications will occur.

Patients are discharged with specific written instructions as to how they are to care for themselves, and the surgeon should

always be available to answer questions and see any patient, if needed.

Sleeping and head position

Patients are instructed to sleep flat on their backs without a pillow. A small cylindrical neck roll is permitted if the patient requests or requires it. This posture assures an open cervicomental angle and averts dangerous folding of the neck skin flap and obstruction of regional cervical lymphatics that inevitably occurs if the patient is allowed to 'elevate their head on pillows' as is commonly recommended after head and neck surgery. If patients are allowed to elevate their head on pillows, their neck will inevitably end up flexed and their skin bunched and folded. In addition, a flat-in-bed position encourages swelling to drain posteriorly to the back of the head instead of inferiorly to the anterior neck, where it is not harmful, less noticeable and more rapidly transmitted away from the head and neck area when the patient sits upright. This is particularly helpful if a facelift has been performed as part of the procedure.

Patients are shown an 'elbows on knees' position that ensures an open cervicomental angle while sitting. This posture places the patient's book, magazine, paperwork, notebook computer or meal in a position that allows reading, writing, eating or TV watching to be performed comfortably and safely with their chin up and their neck skin smoothly and uniformly distributed over their neck. If patients are allowed to sit upright during these activities their neck will inevitably end up flexed and their skin bunched and folded.

Cool compresses

Patients are asked to rest quietly and apply cold compresses to their face and eyes for 15–20 min of every hour they are awake for the first 3 days after surgery. For most patients, oedema peaks at about this time. It is not necessary or productive to apply ice compresses continually throughout the day or at night.

Medications

All patients are provided oral (usually non-narcotic) analgesics, sleeping pills, oral dissolving antiemetic tablets, preservative-free ophthalmic ointment and preservative-free 'artificial tears' solution with instructions for their use. Patients are required to use ophthalmic ointment each night for the first three weeks after surgery or until all signs of eye irritation are gone. Artificial tears are used throughout the day on an as-needed basis.

After-surgery diet

Patients are allowed to take their usual diet as tolerated after surgery but are encouraged to avoid sweet, salty, sour, dry and difficult-to-chew foods for several weeks. It is particularly important to avoid these sorts of foods, which stimulate salivation, for 7–10 days if submandibular gland reduction has been performed. Patients are asked to abstain from the intake of alcohol for two weeks after surgery and until they are no longer taking pain killers or sleeping medication.

Wound care

Patients are instructed to begin a daily routine of showering and shampooing no later than 3 days after surgery, even if their drains are still in place. This helps remove crusting about the suture lines, keeps incisions clean and usually improves the patient's general outlook and wellbeing. Patients are also informed that they need not be as thorough as usual when washing their hair and assured that shower water, shampoo and conditioners are not harmful and will not interfere with healing or cause infection.

Hair care

Patients are allowed to use their usual hair-care products but must be warned that their scalp may be partially numb after surgery and that they must be careful to ensure that shower water is not too hot and that hair dryers are not used on high heat settings. Patients are also instructed not to 'perm', tint, dye, highlight, colour or otherwise chemically treat their hair for two weeks after surgery to limit the chance of hair breakage or hair loss. 'Hot curlers' and 'curling irons' must be used with care for several months following forehead lift surgery as patients might unknowingly burn their foreheads and scalps when doing so. Patients are advised to apply hair gel, hair cream, hair spray and similar products sparsely, or preferably not at all, until all sutures have been removed.

Drain removal

At least one drain is usually left in the neck until the first suture removal visit. This is because drain output often quickly falls on the first or second day after surgery during the time the patient is mostly supine and resting, but then typically picks up again when the patient begins to spend more time upright and starts to move his or her head about more. Leaving the neck drain in longer, for 4–5 days, will reduce the likelihood that small collections will form and it will speed the overall resolution of oedema, ecchymosis and induration in the neck area.

Suture removal

When sutures are removed will vary depending on the type of procedure performed. If a short-scar neck lift has been performed, a submental incision only will be present and sutures are removed on the 4th or 5th day. If an extended neck lift or facelift and neck lift have been performed, 6–0 sutures are removed on the 4th or 5th day and half-buried vertical mattress sutures of 4–0 nylon with the knots tied on the scalp side are removed on the 7th to 9th day. If sutures are left in longer, tell tale and objectionable 'suture marks' are likely to occur.

Return to work after surgery

How long it is before patients return to work and their social lives depends upon their tolerance for surgery, their capacity for healing, the type of work they do, the activities they enjoy and how they feel overall about their appearance. Patients are asked to set aside 7–10 days to recover, depending on the extent of their surgery, and additional time off is recommended if a facelift and related procedures are simultaneously

Figure 71.32 Before and after surgery views of a woman aged 65 who has had prior upper and lower eye lifts by an unknown surgeon. *Before:* Note lax skin, obtuse cervicosubmental contour, paucity of subcutaneous neck fat and 'double chin' appearance when the patient looks down. A large submandibular salivary gland is clearly visible in the lateral submental triangle in the lateral view, and the patient appears to have a 'low hyoid'. *After:* The same patient 13 months after facelift, neck lift, forehead lift, upper and lower eyelifts, perioral dermabrasion and fat transfer to cheeks and lips. The neck lift procedure included excision of excess subplatysmal fat, submandibular salivary gland reduction, superficial digastric myectomy, anterior platysmaplasty and full-width platysma myotomy. Note well-defined jaw line and attractive, youthful-appearing neckline, even when the patient looks down. Comprehensive neck surgery has corrected problems that are commonly misinterpreted as a low hyoid position. Surgical procedures performed by Timothy J. Marten, MD, FACS. Figure 71.33 Before and after surgery views of a woman aged 46 who has had no prior surgery. *Before:* Note full neck, obtuse cervicosubmental contour, and 'double chin' appearance when the patient looks down. Palpation of the lateral submental triangle revealed a firm mobile mass consistent with an enlarged submandibular salivary gland. Her preoperative appearance suggest the presence of a 'low hyoid'. *After:* The same patient 11 months after facelift, neck lift, forehead lift, lower eyelifts and facial fat injections. The neck lift procedure included excision of subplatysmal fat, submandibular salivary gland reduction, superficial digastric myectomy, anterior platysmaplasty and full-width platysmal myotomy. Note attractive, youthful-appearing neckline, even when the patient looks down. Comprehensive neck surgery has corrected problems that are commonly misinterpreted as a low hyoid position. The double chin deformity has also been corrected. Surgical procedures performed by Timothy J. Marten, MD, FACS. Source: Photos courtesy of the Marten Clinic of Plastic Surgery.

performed. If the patient is doing well and not experiencing problems, she or he is allowed to return to light office work and casual social activities at that time. It is often wise to begin with a limited workday at first and to adjust schedules thereafter. If a patient's job entails more strenuous activity or physical labour, a longer period of convalescence may be required. Patients are advised not to drive for the first 10 days

after surgery and until they are feeling well, their vision is clear and they are off pain medications.

After surgery activity

Patients are advised to avoid all strenuous activity during the first two weeks after surgery. Two weeks after surgery, patients are allowed to begin light exercise and gradually work up to

Figure 71.34 Before and after surgery views of a woman aged 55 who has had prior eye lifts and a perioral chemical peel performed by an unknown surgeon. *Before*: Note full neck, obtuse cervicosubmental contour and 'double chin' appearance that is exacerbated when the patient looks down. Palpation of the lateral submental triangle revealed a firm mobile mass consistent with an enlarged submandibular salivary gland. Note paucity of subcutaneous neck fat suggesting submental liposuction had been performed at her previous procedure. *After*: Same patient 1 year and 4 months after facelift, neck lift, forehead lift, upper and lower eye lifts, perioral dermabrasion and facial fat injections. The neck lift procedure included excision of a large amount of subplatysmal fat, submandibular salivary gland reduction, superficial digastric myectomy, anterior platysmaplasty and full-width platysma myotomy. Note well-defined jaw line and attractive, youthful appearing neckline even when the patient looks down. The double chin deformity has been corrected by releasing the submental retaining ligaments and blending the fat of the chin and the submental area. Surgical procedures performed by Timothy J. Marten, MD, FACS. Source: Photos courtesy of the Marten Clinic of Plastic Surgery.

Figure 71.35 Before and after surgery views of a woman aged 68 who has had no prior plastic surgery. *Before*: Note poor cervicosubmental contour and 'double chin' appearance when the patient looks down. An enlarged submandibular salivary gland can be seen beneath the skin in the lateral view and confirmed on palpation. Note paucity of subcutaneous neck fat that is typical for patients in older age groups. Platysma bands are visible in the anterior neck. *After*: Same patient 1 year and 9 months after facelift, neck lift, forehead lift, upper and lower eye lifts, partial facial fat transfer and ear lobe reduction. The neck lift procedure included excision of amount of subplatysmal fat, submanbibular salivary gland reduction, superficial digastric myectomy, anterior platysmaplasty and full-width platysma myotomy. Note well-defined jaw line and masculine-appearing neckline even when the patient looks down. Surgical procedures performed by Timothy J. Marten, MD, FACS. their presurgical level of activity. Four to six weeks after surgery, they are allowed to engage in more vigorous activities, including most sports, as tolerated.

Case examples

Figures 71.32, 71.33, 71.34 and 71.35 show patients before and after procedures.

CHAPTER 72

Rhinoplasty

David Stepnick, Catherine Weng and Bahman Guyuron

Department of Plastic Surgery, University Hospitals Case Medical Center, Cleveland, OH, USA

Introduction

The nose is a complex three-dimensional structure with critical structural and functional roles, which, by virtue of its position, serves as the central component of the face. Its relationship to surrounding structures is in part responsible for a harmonious, pleasing visage as a whole. Functionally, the nose provides an airway and acts to warm, filter and humidify air passing through it. Noses that deviate from ideal structural proportions – whether subtle variations of normal or more dramatic posttraumatic or neoplastic deformities – have motivated rhinoplasty surgeons since ancient India 800 B.C.E.

Anatomy

A thorough appreciation and understanding of relevant anatomy is necessary for all surgery. Obviously, recognition of the nuances and subtle variations of nasal anatomy is absolutely vital for execution of a successful rhinoplasty.

Skin

A thorough rhinoplasty evaluation must assess skin type and thickness. The surgeon must anticipate the advantages and limitations afforded by a particular skin type. In general, thin skin is unlikely to camouflage irregularities in the underlying cartilaginous and osseous structures, particularly with grafting. In contrast, thick skin conceals imperfections in the nasal skeleton and may conceal surgical changes performed on underlying cartilage and bone.¹ Sebaceous skin can give the tip a bulbous appearance. Despite individual variability in relative skin thickness, general patterns remain consistent across different skin types and ethnicities. The skin is thickest at the nasion. More caudally, the remaining upper half of the nose tends to have skin that is thinner and more mobile than lower half. In the tip area, there tend to be more sebaceous glands, but in the infratip region, the columella and ala again are usually covered with thinner skin.^{2,3}

Cartilaginous and bony support

An understanding of the bony and cartilaginous structural components of the nose should be complemented by correlation with landmarks of the surface anatomy (Figure 72.1). Caudal to the glabellar protrusion, the highest point of the surface of the nose is referred to as the nasion. The root of the nose, just caudal to the nasofrontal suture line, is referred to as the radix, minor adjustments of which can change the overall character of the nose. The rhinion describes the position along the dorsum where the nasal bones articulate with the upper lateral cartilages and the pronasale refers to the region extending from the supratip break, including the tip and infratip lobule, to the anterior-most aspect of the columella. The tip-defining points are the anterior-most points of the nose corresponding to the intermediate crura of the lower lateral cartilages.

Nasal bones

The bony vault is pyramidal in shape and comprises the paired nasal bones that articulate with the frontal bone superiorly and the ascending maxillary processes laterally. The bony pyramid is narrowest at the level of the intercanthal line and widens inferiorly.² The nasal bones are thickest cephalically and become thinner caudally.^{2,4} The nasal bones are supported superiorly at the nasofrontal suture line, laterally at their articulation with the ascending process of the maxilla, and dorsally at their fusion with the perpendicular plate of the ethmoid. The junction between the upper third and lower two thirds of the nose where the cartilaginous septum meets the nasal bones is referred to as the 'keystone area', as this area is essential for structural support, and stabilizing the nasal dorsum for height and projection.³

Upper lateral cartilages

The upper lateral cartilages articulate with the nasal bones and extend cephalically deep to the nasal bones. Beneath the nasal bones, they are fused as one unit. The upper lateral cartilages are supported primarily by their connection with the nasal bones: they do not rest on or articulate with the pyriform process, but rather gain their support as they cantilever off of their

Figure 72.1 The cartilaginous components of the nose in relation to surface anatomy.

articulation with the nasal bones. On their deep surface they are lined by perichondrium that is continuous with the septal perichondrium.³ Their articulation with the septum forms the internal nasal valve; the angle should be between 9 and 15°.⁵

Lower lateral cartilages

The lower lateral cartilages (LLCs) are paired structures in the caudal third of the nose that can be subdivided into three segments: the lateral, intermediate/middle and medial crura (Figure 72.2a–c). The lateral crus supports the anterior half of the alar rim before turning cephalically. The scroll area is the region where the superior edge of the LLC curls downward as it meets the inferior edge of the upper lateral cartilage. This area provides some support for the internal nasal valve. Superior and lateral to the scroll area, one can find several small sesamoid cartilages connected by fibrous tissue that wraps around the alae laterally.^{2,3} The intermediate crus has the most variability in shape and may be convex, boxy, broad or concave; it forms the tip-defining point. It should be noted that skin over this region is particularly delicate as there is a deficiency of subcutaneous tissue: the skin directly abuts the perichondrium necessitating meticulous dissection.³ The medial crura sit next to each other in the columella. The foot-plate is the area closest to the nasal spine where variable degrees of divergence exist. The columellar segment, the middle portion of the columella, extends towards the intermediate crura where the cartilages may diverge again to reach the tip-defining points.

Several analogies have been proposed to describe the dynamics of tip rhinoplasty, relating the medial and lateral crura of the

LLCs and their attachment to the caudal septum to tip support, projection and rotation. The ‘tripod concept’ of the nasal base is the most popular analogy for understanding the interdependent relationships of the nasal base structures. This theory proposes that the nasal base structurally functions like a tripod with the paired medial crura acting as one leg of the tripod and each of the lateral crura acting as one of the other two tripod legs. Altering the length or strength of the legs will result in changes of the rotation and projection of the tip. Although the tripod theory has ample utility in the understanding and planning of surgery,^{6,7} it has limitations in that it may not be the most accurate predictor of the true forces on the nasal tip. Westreich *et al.* proposed an alternate model, which extrapolates on the tripod concept described as a ‘cantilevered spring tripod’. They measured stiffness and elastic modulus of the different cartilages and found that the septal cartilage had the greatest tensile strength. They also found that the strength and support of the nasal tip depended greatly on the thickness of the cartilage and perichondrial attachments more than the elastic modulus of the particular cartilage. With these findings, they proposed considering the nasal tip as a cantilever from the caudal septum.⁸

Septum

The septum comprises bony and cartilaginous portions. The bony septum is made up of the perpendicular plate of the ethmoid bone superiorly, the vomer inferiorly and posteriorly, and the maxillary crest, which forms the caudal-most projection of the premaxilla, anteriorly and inferiorly. The cartilaginous septum is composed of a single continuous quadrangular cartilage that articulates with the vomer and the perpendicular plate of the ethmoid posteriorly and superiorly and is supported inferiorly by the maxillary crest. The anterior aspect of the quadrangular cartilage supports the nasal dorsum and provides tip projection. The anterior septal angle supports the nasal tip with attachments to the medial crura of the LLCs. The posterior septal angle articulates with the anterior-most portion of the maxillary crest. The amount of cartilage in the quadrangular cartilage varies among patients and is typically less robust in non-white patients.³

Superficial muscular aponeurotic system

In the nose, the superficial muscular aponeurotic system (SMAS) is a continuation of the subcutaneous muscular aponeurotic system, which is contiguous from the galea to platysma. Muscles associated with the nose within the SMAS can be categorized into elevators and depressors of the nasal tip. The elevator muscle group include the procerus, levator labii superioris, alaque nasi and the anomalous nasi. Depressors include the alar and transverse portions of the nasalis, the dilator naris posterior, depressor septi and compressor narium.

Blood supply

Understanding the blood supply of the nose is important in order to avoid ischaemic consequences if this rich blood supply is inadvertently and sufficiently disrupted. The dorsal nasal artery, a

Figure 72.2 (a) Lateral, (b) anterior and (c) inferior views of the lower lateral cartilages.

branch of the ophthalmic artery, penetrates the orbital septum above the medial palpebral ligament and courses along the side of the nose, providing robust blood supply to the dorsal nasal skin. It ultimately anastomoses with the lateral nasal artery, a branch of the angular artery (itself the terminal branch of the facial artery), with numerous branches that enter the subdermal plexus thereby supplying the lateral surface of the caudal nose. The tip of the nose is supplied both by the external nasal branch of the anterior ethmoid artery (a branch of the ophthalmic artery), the columellar artery (a branch of the superior labial artery) and branches of the lateral nasal artery. The external nasal branch of the anterior ethmoid artery passes between the nasal bone and the upper lateral cartilage to supply skin of the nasal tip. Branches of the superior labial artery supply the nostril sill and columellar base (Figure 72.3). Intranasal blood supply is from branches of the anterior and posterior ethmoid arteries, the superior labial and greater palatine arteries, and the maxillary artery.

Venous drainage of the external nose generally consists of veins with names that correspond to the associated arteries, which veins drain through the facial vein, the pterygoid plexus, and ophthalmic veins, the pterygoid plexus and the facial vein. Lymphatic drainage of the nasal tip follows the same path and appears to be limited to the lateral walls, sparing the columella.⁹

Nerve supply

Branches of the second and third divisions of the trigeminal nerves provide sensory innervation of the nose, whereas motor innervation is supplied by the zygomatic branch of the facial nerve. From V_2 , the ophthalmic nerve gives off the supratrochlear and infratrochlear nerves to supply sensation to the rhinion, radix sidewalls. The anterior ethmoid nerve gives off external branches that travel within the SMAS layer to supply sensation to the tip; therefore, careful dissection beneath the SMAS over the tip will preserve tip sensation. From V_3 , the maxillary nerve branches and supplies sensation to the lateral vestibule and columella (Figure 72.4).

Patient assessment

The process of rhinoplasty begins with patient evaluation. Arguably, the foundation of a successful rhinoplasty is established at the initial patient visit, including a thorough, accurate evaluation of the nose; its relation to the rest of the patient's face; identification of appropriate and realistic goals given the patient's anatomy; clear communication; and mutual understanding and agreement of surgical goals between

Figure 72.3 Blood supply of the external nose.

Figure 72.4 Sensory nerve supply of the external nose.

the patient and the surgeon. Meticulous preoperative photo-documentation is compulsory and computer-generated images of potential postoperative goals may be helpful in facilitating patient–surgeon discussion and establishing operative goals.

History

Important components of a complete history include medical, surgical, family and social history as well as thorough review of all prescription and non-prescription medications. Of particular interest is whether there has been any previous nasal trauma or surgery. A history of diabetes, connective tissue disease, anticoagulation or a bleeding or clotting disorder should be noted. Smoking significantly impedes healing and can lead to scarring, skin necrosis and a poor outcome. A psychiatric history may help the surgeon understand a patient's motivation for cosmetic surgery. If a patient's motives are self-driven rather than driven by pressure from peers or a significant other, the patient is more likely to be satisfied with the ultimate surgical outcome. In addition to motivation, it is important to elicit a clear picture of the patient's desires and expectations from rhinoplasty. This should be considered in the surgeon's nasal analysis and proposal of surgical goals and limitations with thorough counselling and establishment of reasonable goals.

Physical examination

Physical exam should include a thorough facial analysis characterizing the nasal structures themselves and their relationship to the face as a whole. A careful intranasal exam should also be performed, including inspection of the septum, turbinates, nasal valves and an assessment of nasal breathing. Finger palpation is an essential component of the exam.

Only in idealized drawings is the face completely symmetric, and strict symmetry of the nose and the face should not be anticipated. The nose should occupy the middle third of the face horizontally and the middle fifth of the face vertically. The nose itself may be divided into thirds vertically. Generally, the upper third comprises the nasal bones, the middle third comprises the upper lateral cartilages and the lower third comprises the tip and the LLCs. Deviations from the ideal should be accurately localized and surgical correction of these variations should address the appropriate structures.

An important feature is the smooth, unbroken and symmetric brow-tip aesthetic line, which is described as a 'gentle sweeping line from the medial brow to the lateral nasal wall to the tip-defining point'; the ideal shape of this aesthetic line in a female nose is that of an hourglass, narrowing in the middle and flaring at the top and bottom.¹

Numerous proportions and relationships have been described to characterize the ideal nose (Table 72.1). In the frontal view, the ideal nasal length is two thirds that of the midface, measured from the glabella to the alar base, and equal to the vertical length of the chin, measured from the stomion to the menton.¹⁰ The width of the alar base should approximate the intercanthal distance and may be up to but not more than 2 mm wider.¹

Table 72.1 Nasal analysis

Frontal view	Brow tip aesthetic line Nasal length = chin vertical = 2/3 midface Alar base width = intercanthal distance + 2 mm Dorsal width = 2/3 alar base width
Profile	Nasofrontal angle 115–130° Nasolabial angle 90° male, 100° female Dorsal straight line until supratip break especially in females Columella and ala should be 1 mm from long axis of nostril
Base view	Equilateral triangle Tear-shaped nostrils Lateral and medial crura should meet at 30°

The radix should be at the level of the supratarsal crease. The width of the bony dorsum should be approximately two thirds of the alar base width.

In the lateral view, the nasofrontal angle should be approximately 115–130°⁴ and the radix should be 4–6 mm deep. In females, the dorsum should extend as a straight line until reaching the supratip break, which aesthetically separates the dorsum from the tip unit. Ideally, the nasolabial angle should be 93–98° for men and 95–100° for women, although this angle varies somewhat based on the height of the patient. In general, shorter individuals may have a more obtuse angle whereas taller individuals may have a more acute angle. In the lateral view, the alar base should be 2 mm above the line between the lower and middle third of the nose.¹¹ The lateral tip projection can be measured from the alar–cheek junction to the tip-defining point.¹⁰

The alar–columellar relationship should be carefully evaluated from the lateral view. When viewed from this aspect, the upper border of the nostril is formed by the alar rim and the lower border is formed by the columellar rim. Gunter described a method of analysing this relationship. A line is drawn which approximates the long axis of the nostril: the ala should be 1–2 mm above this line and the columella 1–2 mm below this line. If the columellar rim is less than 1–2 mm from this line, the columella is considered to be retracted; conversely, if the distance is greater than 1–2 mm, the columella is considered to be ‘hanging’. If the ala is less than 1–2 mm from this axis, it is considered to be a hanging ala; if it is greater than 1–2 mm from this axis it is considered a retracted ala.^{12,13}

The alar–columellar relationship and alar rim deformities should also include analysis from the alar base view. The ideal base view is an equilateral triangle with each ala forming the sides of the triangle and the alar base width forming the remaining side. A concave ala is present when the lateral border of the ala is medial to the line of the equilateral triangle, whereas when it extends lateral to the line of the triangle, it should be considered convex.¹⁴

The ideal nostril is oval shaped, wider than the columella, and should be almost parallel to the vertical axis of the columella in the nose of a white person. The length of the columella should be twice the height of the infratip lobule. The alae should insert

at a soft angle to the cheek with a slight curve medially. Disharmonies of the alar base can be in either the vertical or horizontal plane, and careful analysis is critical, as surgical correction of these deformities differ depending on the nature of the deformity.¹¹

The relationship of the nose to surrounding facial structures affects the perception of nasal features. A sloping forehead may give the illusion of overprojection of the nasal tip whereas a flattened forehead may give the illusion of an underprojected nasal tip. Similarly, an underprojected chin may make the nose appear relatively overprojected and vice versa.

The aesthetics of the nasal tip may be defined by a number of relationships, many of which are quite subtle. The angle at which the lateral and medial crura of the LLCs meet should be about 30° on either side. The ideal nasal tip should be well defined. Subtle variations in anatomy may make it appear boxy or bulbous. Wide lateral crura may blunt dome definition resulting in a boxy tip. A greater than 30° angle between the lateral and medial crura or divergent domes can result in a bulbous appearing tip.¹

Physical examination should include palpation of the bony and cartilaginous components of the nasal dorsum to understand the relationships between them. The tip recoil test is performed by placing gentle pressure on the tip to assess the strength of the LLCs. An intranasal exam should be performed to identify deviations of the nasal septum, turbinate hypertrophy and any internal causes of nasal obstruction. The Cottle or modified Cottle manoeuvre is performed to assess nasal valve collapse.

Although the most thoroughly studied and well-described ideal nasal aesthetics pertain to the nose of patients from the white population, much individual variety exists and these ideals cannot be indiscriminately applied to all noses, particularly in different ethnicities such as the African, Asian, Middle Eastern or Hispanic noses.¹⁵

The African nose has a wide base and low, flattened appearing dorsum. The ascending maxillary process often lacks vertical projection, which contributes to the low dorsum. Increased distance at alar insertion and alar flaring both contribute to the increased interalar distance.¹⁶ There also tends to be increased fibro-fatty tissue and thicker sebaceous skin at the tip, both of which contribute to lack of tip and soft tissue triangle definition.¹⁵

The Asian nose has typical characteristics somewhere in between the white and African nose. There is typically a low dorsum that begins more caudally. Again, the skin at the tip and supratip region is thicker than the white nose but not quite to the extent of the African nose. The alar width is slightly wider than the white nose. Characteristically, in the Asian nose, there is paucity of septal cartilage leading to a less projected tip and occasionally retracted-appearing columella. This should be anticipated in Asian rhinoplasty and consideration of other sources of cartilage grafts should be explored and discussed. There also tends to be weaker LLC.¹⁷

The Middle Eastern and Indian noses share some characteristics with the nose in white populations with similar height of

Figure 72.5 Photographic standardization assists surgical planning and allows accurate pre- and post-op comparison, thereby facilitating the surgeon's self-assessment and critique allowing continual refinement of surgical technique.

the dorsum.¹⁵ However they also frequently have overprojection of the dorsum resulting in a high dorsal hump. There is mild alar flaring and thick skin around the tip region. There is variable skin thickness of tip and alar flaring. Dorsal height also varies between the norms of white and Asian noses.¹⁸

Photography

The standard approach to photography for rhinoplasty is to obtain realistic preoperative photographs using a digital single lens reflex (SLR) camera. Photos should be taken with a standard blue background with appropriate lighting. Many surgeons will have a dedicated space for photography in their office. Standardization of patient positioning, lighting and angles should be maintained. This will facilitate the surgeon's study of the patient's nasal anatomy and facial harmony for surgical planning. Moreover, it permits accurate pre- and postoperative comparison, thereby facilitating the surgeon's self-assessment and critique allowing continual refinement of surgical technique (Figure 72.5).

An important aspect of successful photography is the lighting and positioning for rhinoplasty portraits. The simplest lighting setup is a single mounted flash on top of the

camera itself; however, this can result in harsh and uneven shadows. There are several established, sophisticated lighting arrangements that have been described.¹⁹ The key light system, developed for portrait photography, positions the main light at a 45° angle from the patient, casting a shadow from the nasal tip to the oral commissure. A second fill light is placed at nearly the same angle on the opposite side in a position that it fills the shadow cast from the main light. Then, two backlights are placed behind the patient to separate him/her from the background. The quarter system places two lights equally at 45° angles from the patient.

The traditional six standard photographic views taken for rhinoplasty are the frontal anteroposterior, right and left lateral, right and left oblique and base views.^{20,21} A top view is a useful addition that can be used to better characterize and understand deviations in the crooked nose, especially for patients with dorsal deviation.⁵ Some surgeons routinely obtain a smiling view. Proper positioning in both frontal and lateral views requires alignment along the Frankfort horizontal plane, defined by a line that connects the top of the tragus to the infra-orbital rim; this line should be truly horizontal and parallel to the ground.²⁰

Table 72.2 Rhinoplasty dynamics

Facial dynamic dimension	Procedures that increase	Procedures that decrease
Intercanthal distance	Deepening radix	Osteotomies Augmentation of the radix
Nasal length	Deepening or decreasing height at the radix	Decreasing nasal height at medial canthal level
Width of dorsum	Reduction of dorsum	Osteotomy Augmenting dorsum
Height of dorsum		
Tip projection	Nasal spine graft Maxillary advancement Transdomal suture Columellar strut Anchoring medial crura of LLC to nasal spine Footplate approximation	Dorsum reduction Alar base narrowing Nasal spine reduction
Tip rotation	Cephalic rotation: Reduction of dorsum Reduction of caudal septum Reduction of cephalic margin of LLC Columellar strut placement Footplate approximation Nasal spine augmentation	Caudal rotation
Width of nasal tip	Interdomal or subdomal grafts Onlay graft Subdomal graft	Interdomal stitch Transdomal stitch Lateral crural spanning stitch Tip graft
Width of nasal base		
Upper lip length	Nasal spine augmentation	Nasal spine reduction

Rhinoplasty dynamics

The nose is a three-dimensional centrepiece on the face with critical structural and functional roles. There are many variables and dimensions that can be adjusted to alter the aesthetic appearance, structural components and functional role of the nose. There are many tools and manoeuvres available to the rhinoplasty surgeon to adjust these numerous variables. Although each adjustment may have a primary anticipated effect, such as increasing tip projection or reducing a dorsal hump, it will invariably have consequences, desirable or undesirable, to another variable nasal dimension (Table 72.2).²²

Adjusting the height at the radix or the caudal aspect of the dorsum will have different effects on a number of facial dimensions. Lowering the radix will frequently result in the appearance of increased intercanthal distance and increased nasal length. Augmenting the dorsum at the radix will appear to reduce the intercanthal distance and shorten the nose. In contrast, reducing the height of the dorsum more caudally can have the opposite effect, giving the nose a shorter appearance and the illusion of greater cephalic rotation of the tip. Similarly, reduction of the caudal dorsum will cause the intercanthal distance to appear wider, while augmenting the dorsum will cause the intercanthal distance to appear more narrow. Reducing the caudal dorsum may also reduce the tip projection as the caudal septum has an important role in supporting tip projection. Osteotomies can result in a narrower appearing nose and intercanthal distance.²²

Numerous procedures may be used to adjust tip projection and width; however, not every procedure is appropriate for

every patient. For example, an overprojected tip can be reduced with a cephalic trim of the LLCs only if the cephalic portions of the LLCs are actually the highest projecting part of the caudal tip. If this is not the case, securing the footplate of the medial crura to the caudal septum can decrease or increase tip projection depending on the location on the septum to which they are secured. Reducing tip projection may result in the appearance of a relatively widened alar base and bowed columella. A number of manoeuvres are frequently used to both increase tip projection and increase the angle of cephalic tip rotation. Placement of a columellar strut, anchoring the medial crura to the caudal septum, approximating the medial crura foot plates and advancing the nasal spine can all result in the appearance of increased cephalic rotation and projection. Advancing the nasal spine may also shorten the upper lip. Care must be taken to choose the appropriate procedure for the anatomical constraints presented by each patient.²²

The astute nasal surgeon will be aware of these effects in planning for rhinoplasty to anticipate the most appropriate and effective manoeuvres for a specific patient's anatomy, during surgery make adjustments when needed and postoperatively to assess the results of their adjustments.

Operative approach

For several decades, surgeons have debated the merits of 'open' or the 'external approach' versus endonasal rhinoplasty. In the United States, most rhinoplasty was performed endonasally in

the latter decades of the twentieth century, whereas today, external approach rhinoplasty is the technique of choice for most patients by the majority of rhinoplasty surgeons, including the authors, who reserve the endonasal approach for certain patients needing only minor revisions. One cannot definitively say that one approach is better than the other for all surgeons, as good results can be achieved by some surgeons using one method whereas equally good results can be achieved by others using the other technique. Some criticize external approach rhinoplasty with the assertion that by opening the skin–soft tissue envelope, some of the strength and support of the tip are lost when the soft tissue attachments are separated from the cartilaginous support. Proponents of the external approach feel there is better visualization and understanding of the anatomy, especially for the novice rhinoplasty surgeon and in the teaching setting. Cartilages are observed in their natural anatomic position and can thus be manipulated *'in situ'* as opposed to delivering them to make changes. Endonasal rhinoplasty may be more suitable for noses that may require a limited cephalic trim but otherwise have a well-defined tip and symmetric base requiring minimal, if any, intervention in these areas.²³

Although the primary difference between the two approaches appears to be the mid-columellar incision, which connects the bilateral marginal incisions also used in the endonasal approach, we believe that the more important difference is the ability to directly visualize the underlying structures and their relationships to one another in their resting position. Indeed, most of the trimming, suture and grafting techniques performed are more easily performed with the exposure provided by the external approach.

Endonasal rhinoplasty

A very brief discussion of endonasal rhinoplasty is warranted, although not our preferred approach. Endonasal rhinoplasty is performed using one of several incisions: a marginal incision (at the lower border of the LLC), an intercartilaginous incision (between the upper and LLCs), a transcartilaginous incision, or a rim incision (largely abandoned because of predictable alar notching). To modify the nasal tip with the endonasal technique, the LLCs are typically brought out of the nostrils, or 'delivered'. The bilateral marginal and intercartilaginous incisions allow the development of bipediced chondromucosal flaps consisting of the LLCs and the underlying mucosa. The cartilages are delivered through the nostril from which they came or can be delivered through a single nostril and then modified as required. The main drawback of cartilage delivery with the endonasal approach is that it requires retraction of the LLCs from their normal anatomic position; adjustments are then made with the cartilages out of their normal resting positions.

The plane of dissection is similar to that of the external approach: above the perichondrium and periosteum of the nasal cartilages and bones. Concurrent septoplasty is well described and routinely performed with good outcome, although it is performed through a hemitransfixion incision or a Killian incision

as opposed to from above. Dorsal hump reduction can be achieved using an osteotome or rasps, albeit with less direct visual control to make fine adjustments compared to the external approach.⁷

Many surgeons feel that a primary limitation of the endonasal technique when combined with septoplasty is if there is deviation of the L-strut requiring stabilization with spreader grafts, as this can be difficult to accomplish. Many surgeons also feel that the endonasal technique is more limited in its ability to allow adjustments of the alar rim, base and tip; however, the cartilage delivery technique of endonasal rhinoplasty can provide access to perform cephalic trim of the lower lateral crura as well as a variety of dome sutures.

External approach (open) rhinoplasty

Although every rhinoplasty operation should be individualized to each patient's particular anatomic indications, a systematic order and algorithm may be helpful in operative planning as well as establishing a logical progression of steps and maintaining stability. Local anaesthesia using lidocaine (lignocaine) with adrenaline (epinephrine) should be carefully but judiciously infiltrated into all of the areas of the nose to be dissected, but not adding so much volume that the features and subtle nuances of anatomy are masked.

Numerous variations of the columellar incision exist. The authors use a mid-columellar stair-step incision, whereas many surgeons prefer an inverted V or 5-cornered incision which is connected with bilateral marginal incisions placed at the caudal border of the LLCs. Care is taken not to violate the soft tissue triangles. Dissection of the skin–soft tissue envelope is performed in the subperichondrial avascular plane directly over the cartilage of the LLCs, then the upper lateral cartilages; keeping the dissection in this plane will allow the surgeon to avoid the neurovascular structures near the nasal tip.⁹ The dissection is then continued cephalically to the caudal aspect of the nasal bones, at which point a periosteal elevator is used to elevate the periosteum of the nasal bones in the radix region.

As previously noted, each operation should be individualized to address each patient's anatomy. As required, the radix is addressed first, either by reducing it with a guarded burr if it is overprojected or by placing radix grafts if it is underprojected.

Next, the bony and cartilaginous dorsum is addressed. Preoperative evaluation of the dorsum should have identified whether there is an excess or deficiency of the dorsum. The skin is thinnest at the rhinion or bony–cartilaginous junction and becomes thicker cephalically towards the radix and caudally towards the nasal tip. Therefore, a slight prominence should exist at the upper portion of the upper lateral cartilage in order to compensate for the thinner skin to create a straight profile. Any cartilage or bony hump in excess of this should be removed.³

The upper lateral cartilages are released from the septum, preserving the underlying mucoperichondrium thereby minimizing chances of postoperative internal valve narrowing. Any significant prominence of the cartilaginous and bony dorsum is

addressed together, using sharp dissection and an osteotome or a rasp. For a larger dorsal hump, a Rubin osteotome may be used to reduce the bony hump en bloc.^{23,24} The bony dorsum can be further reduced or smoothed with rasping.²³ Precise cartilage reduction can be achieved by removing consecutive thin slices with a 15 blade until reaching the desired profile. After dorsal hump reduction, the patient may be left with an 'open roof deformity' where the lateral nasal bones and upper lateral cartilages are no longer touching the septum. This deformity is corrected later in the procedure with osteotomies and spreader grafts. When the dorsum is deficient, grafts can be placed to create a pleasing aesthetic.

If there is significant septal deviation, the septum is addressed at this time either from the dorsal approach or intranasally through a hemitransfixion or Killian incision. Also at this time, if cartilage grafting is anticipated, septal cartilage can be harvested. As the old adage wisely professes: 'Where the septum goes so goes the nose'. Several indications exist for septoplasty in septorhinoplasty: obstructed nasal breathing associated with septal deviation, dorsal deviation associated with deviation of the anterior septum and for harvest of graft material for other aspects of the rhinoplasty.

When septoplasty is performed from the dorsal approach, the anterior septal angle is identified: the LLCs are retracted laterally and downward and the septum is identified caudal to its attachment to the upper lateral cartilage. The perichondrial envelope is dissected from the septal cartilage in the subperichondrial plane and, if not already performed or as dissection proceeds, the upper lateral cartilages are released from the septum to provide adequate visualization of the more posterior septum. Preservation of the mucoperichondrium provides support and ultimately reduces internal valve collapse.

Once the septal cartilage and bone is exposed, it is assessed to determine which portion of the septal cartilage must be resected or weakened in order to relieve the deviation. One should also consider how much cartilage grafting material should be harvested. An important principle guiding septoplasty or septorhinoplasty is to maintain the structurally supportive 'L-strut' composed of dorsal and caudal septum. We recommend leaving at least a 1.5 cm, preferably 2–2.5 cm, dorsal strut to maximize the degree of support. If significant deviation exists in the L-strut, this may be corrected and stabilized with unilateral or bilateral spreader grafts.⁵ An effectively placed horizontal mattress suture (e.g. 4-0 PDS®) may correct mild deviations of the L-strut. Gruber *et al.* demonstrated that a 10 mm wide, 0.5 mm thick piece of cartilage with a curvature may be adequately straightened with a horizontal mattress suture placed with an 8 mm longitudinal spacing with the knot on the convex side.²⁵

If there is a spur or deviation involving the bony septum, either superiorly in the perpendicular plate of the ethmoid or posteriorly in the vomer, these may be addressed by resecting the deviated portions. Caution should be exercised during resection of the perpendicular plate; avoiding rocking motions, as CSF leak may occur as a rare complication of septorhinoplasty.

If the inferior edge of the caudal L-strut has been released from the maxillary crest, it can be repositioned in the midline and sutured to the maxillary crest periosteum to secure it. Alternatively a piece of cartilage may be secured with a permanent suture as bridge between the caudal septum and the nasal spine if there is not enough length for adequate projection.⁵

If the septorhinoplasty is being performed to improve nasal airway obstruction, inferior turbinate hypertrophy should be addressed with submucosal resection, inferior turbinate outfracture and/or conservative resection of the hypertrophic portions of the turbinate, being careful not to be overzealous, possibly causing atrophic rhinitis or empty nose syndrome.

Once satisfactory dorsal projection is achieved, osteotomies are planned and executed as necessary. Osteotomies are performed to narrow the bony dorsum, to close an open roof deformity created by dorsal hump reduction or to straighten a crooked bony dorsum. Recalling anatomic considerations, the ideal width of the bony dorsum is about two thirds that of the alar base width. The nasal bones and ascending maxilla tend to be thicker cephalically; therefore, planning osteotomies higher may help to minimize the narrowing effect on the internal nasal valve and nasal breathing. However, if the osteotomy is carried too high or if the medial and lateral osteotomies do not meet, a rocker deformity may result. Another anatomic consideration in osteotomy is the patient age: younger patients tend to have more flexible bone whereas older patients have more brittle and easily fractured bone. Interrupted 'postage stamp style' osteotomies in younger patients may be less effective if they result in greenstick fracture and their nasal bones spring back into place.⁴

It is important to perform effective injection of local anesthetic containing adrenaline prior to the osteotomies in order to minimize bleeding and postoperative swelling. The periosteum of the nasal bones is elevated medially while the lateral periosteum is left attached to bone in order to provide stability to the segment of bone after lateral osteotomy during the healing period. If significant hump reduction has been performed, a formal medial osteotomy may be unnecessary.

In general, medial osteotomies should be performed first, followed by intermediate osteotomies (if indicated), then the lateral osteotomies, in order to maintain stability of the remaining lateral portions of the nasal bones for each succeeding osteotomy. Medial osteotomies are usually performed intranasally by seating the osteotome between the septum and the upper lateral cartilage at the caudal edge of the nasal bone. Since the upper lateral cartilages obtain their structural support from their connection to the underside of the nasal bones, this relationship must not be interrupted.⁴ Medial osteotomies are usually and ideally performed in a laterally fading or oblique direction. If no open roof deformity is present, some surgeons create medial osteotomies that are directed linearly upwards towards the nasal root, but this can result in a rocker deformity. A straight medial osteotomy may be more appropriate in a nose with a deviated

dorsum that may require intermediate osteotomy or if the bony septum needs to be repositioned. If a straight osteotomy is performed, a transverse (anteroposterior) osteotomy may be necessary at the cephalic limit at the level of the medial canthal ligament to connect with the lateral osteotomy and mobilize the bony segment.² Transverse osteotomies should be performed below the level of the canthus to minimize risk of lacrimal system injury, and if performed correctly can provide more precise control of nasal bone positioning.²²

Intermediate osteotomies may be performed for a deviated nasal dorsum. They should be designed for placement at the apex of the deformity, on the side of deviation.

The lateral osteotomy may be performed in a continuous fashion in a caudal to cephalic direction or through percutaneous stab incisions. With either approach, the inferior limit of the lateral osteotomy should be just above the level of the inferior turbinate insertion in the ascending process of the maxilla and care must be taken to preserve the bony triangle at the level of the piriform aperture at the caudal aspect of the maxillary bone. Staying above the inferior turbinate, as in a high-to-low osteotomy, will minimize risk of nasal airway compromise and address a wide bony base at the same time. If only a small open roof deformity exists, low-to-low osteotomy may be used to correct this.²² For correction of the anteriorly wide nose it might be necessary to remove a wedge of bone between the nasal bone and the septum to allow medial repositioning of the lateral nasal bone.

If a continuous osteotomy is performed, a subperosteal tunnel is dissected with a Joseph elevator. A guarded 2–2.5 mm osteotome is used to minimize mucosal tears. The lateral osteotomy connects with the medial osteotomy cephalically. If performing transcutaneous perforating osteotomies, one or two well-placed 2 mm stab incisions through skin are all that is necessary to obtain a series of percutaneously directed ‘postage stamp style’ osteotomies using a 2 mm osteotome. The most inferior punch should be directed slightly higher in order to minimize collapse of piriform aperture. The more superior osteotomies should be placed high in order to maximize narrowing of dorsum and avoid rocker deformity.

Tip and lower lateral cartilages

The ideal nasal tip should be well projected, supported, not over- or under-rotated, and well defined without being bulbous or have skin that is so tightly pulled over the cartilage that the tip appears bifid. Appropriate tip projection may vary in different ethnicities. This should be considered in ethnic rhinoplasty, as overprojection may result in racial incongruity^{15,17} and disharmony with the rest of the patient’s face.

Various cartilaginous trimming, grafting and suture techniques may achieve nasal tip definition and correct mild tip deviations. Conservative trimming of the lateral crus may be performed to even out asymmetries. It is imperative to leave a minimum of 6 mm strip of the lateral crus to preserve enough strength to prevent buckling.²⁵

A lateral crural mattress suture may be used to strengthen the lateral crus or to straighten convexities of the ala, either after over-resection or in the setting of weak cartilage. For the LLC, typically about 6 mm wide and 0.5 mm thick, a mattress suture may be placed with 6 mm spacing between the two loops of the stitch. Multiple stitches may be placed along the length of the LLC for added strength.²⁵ The same concept may be used to provide a subtle increase in strength for the columella. A columellar–septal suture strengthens the columella when only a mild weakness is present that does not require grafting.²⁵

Dome stitches may be used to not only create more definition of the nasal tip but also to correct mild deviations or asymmetries by bringing together divergent intermediate crura.⁵ If there is any chance of knots protruding into the skin, absorbable monofilament PDS® is preferred. If sutures are placed deep in a location with no risk of extrusion or visibility, nylon is also a viable option.²⁵ A hemi-transdomal stitch is placed through the vestibular skin and traverses the most cephalic end of the dome and attempts to evert the lateral crus. A transdomal suture is a horizontal mattress suture that brings together the medial and lateral crura of one of the LLC.²⁶ When placing this stitch, care must be taken to avoid causing the lateral crus to invert as it may result in concavity of the ala. Also, if the lateral bite of the stitch is not placed laterally enough, it may result in counter-rotation and decrease in projection. A transdomal stitch placed appropriately laterally should increase tip rotation, projection and definition.²³ An interdomal stitch approximates the medial crura together and is set back from the tip several millimetres.²⁵

As previously described, in the ideal profile view of the nose, the ala sits 1–2 mm above the long axis of the nostril and the columella 1–2 mm below it. It is vital to identify the correct anatomic problem: when a hanging ala is present, this should be correctly distinguished from retracted columella so that the appropriate problem is addressed.¹³ If a mild alar retraction exists (<2 mm from the long axis of the nostril), an alar rim graft will not only correct this deformity; it will also correct the concavity commonly associated with the retraction. On noses with wide bases and mild alar retraction, a small wedge of alar skin may be resected and the remaining ala repositioned inferiorly. If greater than 2 mm of retraction exists, a V-Y advancement, a composite graft, or an intercartilagenous graft may be required between the upper and lower lateral cartilages on that side.²² These manoeuvres can lower the ala 4–8 mm. A hanging ala may be corrected by excising a small wedge of vestibular skin intranasally or by resecting a strip of cartilage at the caudal edge of the lateral crus of the LLC. A hanging columella can be corrected by resecting a thin strip of the caudal cartilaginous septum or by securing the medial crura to the caudal septum in a tongue-in-groove configuration.²⁷ Columellar retraction can be addressed by columellar strut or extension grafting.¹³

The base view of the nose should approximate an equilateral triangle. If there is convex ala protruding from the triangle, debulking of soft tissue, trimming lateral crura or placing dome spanning sutures may correct this. Concave ala may be corrected

by alar rim or strut grafting with cartilaginous grafts on top of or deep to the lateral crus respectively depending on the severity of the concavity.¹⁴

Grafts

Autologous graft material is preferable to alloplastic implants, as the latter is significantly more prone to infection and extrusion. Common choices of graft material include septal cartilage, conchal cartilage, rib cartilage and temporalis fascia. Cadaveric irradiated cartilage and alloplastic materials such as Medpore®, silicone, and Gortex® are used by some surgeons. For most primary rhinoplasties, septal cartilage is preferred and has several advantages: it is readily accessible and in the same operative field, abundant (in patients who have not undergone septoplasty), and strong, which is ideal for supportive grafts. Auricular conchal cartilage can be harvested without additional prep if its use is anticipated and the ear is prepped into the operative field. Some surgeons prefer a preauricular incision, whereas others prefer a postauricular incision for graft harvest. A significant amount of cartilage may be harvested without compromising the structural or aesthetic appearance of the ear as long as a few millimetres of rim are left in place along the conchal wall. Conchal cartilage is curved and significantly weaker than septal cartilage thus making it less suited for supportive strut grafts and better for alar reconstruction. Potential donor site morbidity includes auricular haematoma or perichondritis, although their risk can be minimized by the use of antibiotics and a bolster dressing.

Rib cartilage may be necessary for significant nasal reconstructive procedures. The rib provides an abundant source of graft material but it carries the minor disadvantage of requiring a second harvest site and potentially causing a pneumothorax. The most common source of costal cartilage for grafting in females is the 6th and 7th rib cartilages, as the incision can be hidden in the inframammary crease. Costal cartilage carries the risk of warping once it is in place. The effect of warping can be minimized by keeping the cartilage in saline for 30–60 min after harvest, determining in which direction twist will occur, and anticipating warp when carving the cartilage. In some cases, securing the rib cartilage in place with a K-wire is a useful manoeuvre to minimize warping. Perichondrium, native fascia or temporal-parietal fascia harvested from the patient can be laid over cartilage grafts to camouflage irregularities. Multiple layers of fascia can be laid on top of each other with each layer of fascia resulting in 0.5 mm of augmentation²⁸ although additional layers of fascia may prolong postoperative swelling. For bulk, any of the above cartilages can be diced and wrapped in fascia. These fascia-wrapped cartilage grafts can add volume in areas such as the dorsum but have little utility as supportive grafts.²⁸ We prefer placement of diced cartilage using a 1 mL insulin syringe in an ideally prepared pocket without fascia. Alloplastic material such as Medpore®, a high-density polyethylene, is theoretically biocompatible and intentionally placed pores allow fibrovascular ingrowth which serves to prevent graft migration. However, the risks of extrusion and infection and the

fact that it is often difficult to remove because of the fibrovascular ingrowth make it less ideal than autologous graft materials.²⁹

Spreader grafts

Spreader grafts may be indicated when there is mid-vault nasal obstruction to widen the internal nasal valve, to augment an overly narrow dorsum, to support a deviated L-strut, to fill a defect from dorsal hump reduction or when there is an inverted-V deformity. We believe that any time a large enough hump is removed to create an open roof, the use of spreader grafts becomes mandatory, otherwise an inverted-V deformity will ensue months or years later. The ideal material for a spreader graft is septal cartilage. Costal cartilage, layered or folded conchal cartilage, or the medial edge of the upper lateral cartilages (autospreaders) may also be used. Typically the cartilage is cut into strips approximately 5 mm high and 30 mm long, spanning the cartilaginous dorsum. If there is a curve in the graft cartilage, it can be scored and oriented so that the two pieces counteract the other's curve. The graft is secured with at least two mattress sutures. The mattress sutures each traverse five layers, securing both pieces to the septum medially and the upper lateral cartilages laterally.⁵

Supportive grafts

The columellar strut graft is the most commonly used graft. The ideal material for a columellar strut is septal cartilage. It can be placed to help support the tip and overcome ptosis and over-rotation of the tip. The medial crura of the LLC can be secured to the graft to prevent hanging columella.¹⁰

For dorsal augmentation and increased tip projection with adequate support, septal extension grafting may be performed. Adequate healthy skin must be present at the tip, as this graft may stretch the skin increasing the risk of skin necrosis. The ideal graft material is either septal cartilage or a straight segment of rib. This graft may be secured to extended spreader grafts that extend beyond the caudal septal angle of the native septal cartilage using sutures.¹⁰

A lateral crural strut graft can be placed to correct a prior concavity of the base view of the ala or to counteract the effect of dome sutures that may lead to concavity. A pocket is dissected on the deep surface of the lateral crus of the LLC beneath the vestibular skin intranasally. The graft cartilage is placed in the pocket and secured to the lateral crura using mattress sutures.

Alar rim or batten grafts, fashioned from septal or conchal cartilage, may be used to support the nasal valve. These grafts can span between upper lateral cartilages and LLCs at various positions. Preoperative assessment should pinpoint the location of nasal valve collapse in order to direct placement of the graft. Cephalic placement on the LLC will stent open the internal nasal valve, whereas caudal placement on the LLC will stent open the external nasal valve.²⁹ Once the appropriate position is decided, the graft is secured with sutures.

The ideal alar rim smoothly transitions from the tip-defining point to the nasofacial insertion, the contour and strength of

which are determined by the lateral crus of the LLC. The LLC is in a position close to the rim more medially but laterally is in a more cephalic position as it moves away from the alar margin: this lack of rigid support can lead to scarring, retraction and/or unpredictable asymmetry. The alar rim graft, placed along the alar margin, is a powerful graft capable of directly altering the contour and strength of the alar margin. Indications include correction of alar flare, cephalic malposition and inadequate alar support, and correction of dynamic margin collapse.³⁰ On patients with cephalically oriented LLCs, the lateral crura are dissected and transposed caudally.

Several types of tip grafts can be used to create a more defined-appearing tip and/or to achieve slight increase in projection of the nasal tip. A shield or onlay graft is cut or prepared using the tip punch device designed by our group and placed as an onlay graft on top of the LLCs or as a shield graft.³¹ A cap graft is created from a horizontal piece of cartilage that crosses both domes with bevelled edges laterally. The cap graft can be used to correct minor tip asymmetries. An infralobular graft can be attached to the septal cartilage in order to increase columellar show in noses with a retracted columella. An umbrella graft can also increase projection and support. After placement of a columellar strut, an onlay to the nasal tip is supported by the columellar strut and overlies both domes. A dome spreader graft can be used to correct a pinched dome appearance. The dome spreader graft is placed after dissecting a deep pocket between the medial crura, placing a small piece of cartilage in the pocket and securing it with monofilament suture.¹⁰ A subdomal graft is used to control the position and the distance between the domes.³²

Alar base adjustments

Alar adjustments should be reserved for the last step after all the tip refinement and supportive grafts have been completed. An overprojected nasal tip or hypoplastic maxilla may give the illusion of narrowed alar width. Similarly an underprojected tip or protruding maxilla may give the illusion of widened alar width. These issues must be ruled out before considering adjusting the alar base positions.¹¹ Alae that are displaced cephalically can be repositioned by resecting an ellipse of skin around the alar base and repositioning the ala medially; this will bring it to a more medial and caudal position. Wedge excisions according to the appropriate abnormality can remove part of nasal sill, ala or both. V-Y advancement and inverted-T excision for wide and thick alae are other manoeuvres that can be useful in certain patients.¹¹

Final steps

Typically, if septoplasty has been performed and there is a mucosal incision, it is closed with interrupted 4-0 chromic sutures and intranasal Silastic® or Doyle® splints are placed. Some surgeons prefer quilting sutures to reapproximate the apposing mucoperichondrial flaps in the absence of the removed septal cartilage. The columellar incision is closed with

interrupted 6-0 fast absorbing catgut sutures. Marginal incisions are closed with interrupted 6-0 fast absorbing catgut sutures.

The dorsum is taped with Steri-strips®. If osteotomies were performed, the dorsum is splinted with a Denver Splint® or a thermoplastic splint. If a rib graft has been used for dorsal grafts, it may have been secured in place with K-wires: these are pulled through the splint and secured in place until they are removed 2-3 weeks postoperatively.

Postoperative care

Postoperative care varies among surgeons. Patients are counselled about the potential for postoperative bleeding, which can be self-limited and treated with oxymetazoline spray. In the immediate postoperative period (24-48 h), patients should keep their head elevated to minimize swelling. Patients should avoid exercise or strenuous activity for 2-4 weeks postoperatively. Postoperative antibiotic prophylaxis may be considered if intranasal splints have been placed or an ear bolster is used after conchal cartilage harvest. Sutures and splints are removed one week postoperatively. Although it is not always necessary or indicated, postoperative steroids have been observed to be effective in decreasing swelling.³³ Perioperative steroids have been shown to decrease periorbital oedema in the immediate postoperative period.³⁴

Complications

After rhinoplasty, the normal postoperative course has some expected inconveniences that the patient should be made aware of preoperatively and should not be considered as complications. Pain, bruising and postoperative swelling are to be expected. If the swelling is excessive or prolonged, postoperative oral steroids may help to speed resolution. Taping the nose may be helpful in decreasing swelling and may be continued by the patient on a nightly basis even weeks after surgery.¹⁵ Gryskiewicz *et al.* feel that after 14 days, Kenalog® injections may be considered every 2-4 weeks for up to six injections.³⁵

Intraoperative complications should be identified and addressed prior to completion of surgery. These include excessive bleeding, iatrogenic injury to the nasal skin or underlying cartilages, lack of dorsal support as a result of fracture of the L-strut, septal fracture; inward displacement or collapse of the nasal bones; 'rocker deformity'; and cribriform plate fracture. The risk of bleeding can be minimized by counselling the patient to avoid not only anticoagulants and non-steroidal anti-inflammatory drugs (NSAIDs), but also supplements that may have anticoagulative effects. Bleeding can also be minimized with control of hypertension, topical intranasal vasoconstrictors, adequate preoperative injection of a local anaesthetic combined with adrenaline, dissection in the proper plane, and careful but judicious use of bipolar cautery. Hypertension is the most common reason for intraoperative bleeding and should be appropriately controlled by the anaesthesiologist. Von Willebrand disease is more common than many realize and patients are treated with desmopressin (DDAVP), also useful in patients who have taken NSAIDs. Obviously, iatrogenic

injury to the nasal cartilages or nasal skin should be avoided, but careful repair should be performed if such an injury occurs. The septum can be fractured in about 1% of septorhinoplasty cases. This is more likely to occur if there has been previous septal cartilage harvest or significant dorsal hump reduction, deficient nasal bones or a severely deviated septum. A fractured L-strut can be addressed with suture fixation to spreader grafts and/or by fixation of the strut to the nasal bones. Intraoperative complications associated with osteotomies can be identified immediately after the osteotomies are completed. A collapsed or unstable displaced nasal bone can be suspended from the septum if still attached to the upper lateral cartilages. Sutures, or infrequently, K-wires can be used to stabilize the bones or, one can place a Merocel® pack intranasally for one week to hold the bone(s) in position. A rocker deformity may occur if the lateral osteotomy is carried too far upward and laterally beyond the radix. With a rocker deformity, inward displacement of the nasal bone will result in outward and lateral displacement of the frontal bone segment. This is corrected by an additional osteotomy in the appropriate position.⁴ If a cerebrospinal fluid (CSF) leak is observed, it should be repaired immediately. Nasal packing and lumbar drainage may be necessary.³⁵

In the immediate postoperative period, complications may include bleeding, erythema related to vascular congestion, infection, skin loss or necrosis, and early patient dissatisfaction. Although mild bleeding may be expected after rhinoplasty, excessive postoperative bleeding is rare 0.9%.³⁵ In cases of troublesome or excessive bleeding, hypertension should be controlled, topical vasoconstrictors should be used, and DDAVP may be infused without the need for additional intervention.³⁶ Packing should be avoided. Early postoperative erythema may be a sign of vascular congestion (more common in revision cases), contact dermatitis or early infection. When erythema appears to be of infectious aetiology, early initiation of aggressive oral antibiotic treatment with is indicated. The skin over the nasal tip is delicate and at risk for necrosis, especially if the patient is a smoker. Its vascular supply can be compromised by excessive soft tissue trimming or cauterization over the ala, which may disrupt the lateral nasal artery, or with grafts that exert too much stretch or tension on the skin.

In the intermediate postoperative period (2 weeks to 2 months), additional complications may be noted such as prolonged oedema, delayed healing, patient concern/dissatisfaction, synechiae, osseous overgrowth, septal perforation, anosmia or 'late' presentation of a CSF leak. As the initial postoperative swelling subsides, subtle defects or irregularities may be noticed; more obvious abnormalities such as graft migration may be recognized and will likely need to be addressed surgically.³⁵ Patients may voice concern about the appearance of the nose because they cannot anticipate its final shape. Osseous overgrowths may occur at the site of bony resections or torn perichondrium and can be addressed with conservative rasping in a revision procedure. Septal perforations may occur, more commonly if bilateral septal tears were created and not repaired. Anosmia that

continues after splints are removed and expected postoperative swelling has diminished may be the result of cribriform plate injury. Clear rhinorrhoea that begins in the later postoperative period can be a late presentation of CSF leakage. CSF leaks are rare after rhinoplasty (1.17%) and usually seal on their own; however, patients with suspected leaks should be counselled to be vigilant in watching for signs of meningitis.

Late complications from rhinoplasty include nasal airway obstruction; various irregularities and deformities; implant exposure, extrusion or migration; scarring, silent sinus syndrome; enophthalmos; and mucocoele formation. Nasal obstruction may result from nasal valve collapse due to over-excision of the lateral crura of the LLCs, mid-vault collapse, aggressive medialization of the bony pyramid, or intranasal scarring in the form of synechiae. Saddle nose deformity may result from over-resection of the septum or bony dorsum. Open roof deformity results from failure to fill the midline defect created from dorsal hump resection with osteotomies and spreader grafts. Unsightly scarring may occur at the columellar incision with notching. Scarring may also occur at the site of percutaneous osteotomies with hyperpigmentation or tethering of the skin. Ethnic incongruity may occur by inappropriate planning in ethnic rhinoplasty. Autologous implants may become infected, migrate, extrude or be associated with skin contracture which must be addressed by removal and replacement with an autologous graft, if appropriate.³⁵

Secondary and tertiary rhinoplasty

It is not uncommon for the rhinoplasty surgeon to be presented with a patient that has had a prior rhinoplasty. It is estimated that between 2 and 30% of rhinoplasties result in secondary rhinoplasty.³⁷ The preoperative assessment described above for primary rhinoplasty, for the most part, applies in revision rhinoplasty. Of particular importance is the patient's previous surgical history, the nature of their concerns or dissatisfaction, the patient's social history and psychiatric history and, of course, a thorough objective evaluation of the patient's anatomy.

Evaluation

Operative history

It is important to attempt to obtain the operative record of any and all previous nasal surgeries as part of the preoperative evaluation of a patient presenting for revision rhinoplasty. The most common reasons for revision rhinoplasty are under-resection or over-resection of the structural cartilages. Consequently, eliciting information from the operative record and comparing it with the patient's physical exam may help the surgeon clarify whether the remaining cartilages need to be trimmed further or reinforced with grafts. Also, the extent of previous septoplasty or septal cartilage removed may help the revision rhinoplasty surgeon anticipate the need for various alternative cartilage grafting sources such as conchal or costal cartilage and whether these sources have previously been used.³⁷

Patient-reported issues

The surgeon needs to have a very clear and specific understanding of the source of the patient's dissatisfaction. Perhaps even more than with primary rhinoplasty, realistic expectations must be established. If the patient's expectations are judged to be unrealistic, it should be made clear and documented whether the surgeon believes that their desired results are attainable.³⁷ A number of patient-reported issues may be unique in the setting of prior surgery. Most of these relate to postoperative complications such as an inappropriately placed graft, graft migration, pain, infection or extrusion of implants, or nasal airflow obstruction secondary to nasal valve collapse from excessive cartilage resection.

Objective issues

A full examination and facial analysis should be performed. The height, width and symmetry of the nose should be assessed. The nasofrontal angle location and angulation should be noted. The dorsum should be visually examined and palpated for irregularity. The bony pyramid should be examined, noting its width, any asymmetries and whether there is an inverted-V deformity. The supratip area should be assessed for pollybeak deformity. Adequacy of tip projection and rotation should be assessed. Assessment of the LLCs should include evaluation for symmetry, bossae, alar rim collapse, the tip-defining points, width, position and columellar angle. Intranasal exam can identify valve narrowing or weakness, synechiae, or septal perforation from prior surgery and give the revision surgeon clues as to how much septal cartilage may be available for grafting.³⁷

Skin

Skin examination in the patient who has had a previous rhinoplasty is important as it can be thinned or scarred from previous surgery, perhaps more often with external approach or with extensive dissection. Also, previously placed alloplastic graft material may have resulted in scarring. The presence of scarring may increase the risk of skin necrosis and poor outcome. When the skin is extremely thin and scarring seems highly likely, it may be prudent to stage the revision procedure by placing a dermal graft and allowing it to heal prior to performing revision rhinoplasty so that a healthy skin flap can be elevated and redraped with a good chance of healing at the time of surgery.²⁸

Structural support

The full nasal exam and analysis as described above will provide insight about the structural support remaining in the previously operated nose. Often due to prior cartilage removal, there may be a lack of support to the tip and alae that may require grafting.

Operative principles and approach

One can argue that for revision rhinoplasty cases, the external approach is particularly advantageous, allowing full examination of the anatomy and assessment of what has been done in

the previous surgery unless the revision surgery is minor, which can be done through a closed technique. In revision cases, it is wise to err on the side of minimal resection, as the structural support has already been compromised by prior dissection and resection. Sources of cartilage for grafting should be considered and planned out prior to surgery. When autologous cartilage is not available, some surgeons use alloplastic grafting material such as solid silicone, Medpore or Gortex. If an alloplast is chosen, the patient should be counselled about the additional risks involved,³⁷ although the authors avoid alloplastic grafts and utilize autogenous materials.

When possible, the nose should be entered through the previous incision unless it has been poorly designed. This can avoid leaving the patient with an additional scar and allow the surgeon to resect and revise an unsightly scar. Dissection on the cartilage should proceed with caution, anticipating scarring from previous dissection. If a dorsal onlay graft is deemed necessary, the recipient surface should be flattened with a rasp to minimize irregularity. If costal cartilage is used, securing it with K-wire can limit warping and migration.³⁷ The septum is addressed as described previously. If the L-strut is significantly weakened, it can be reinforced with spreader grafts.

Tip reconstruction is performed, as described for primary rhinoplasty. If supportive grafts are necessary, one should begin by supporting the columella. Grafts can be secured in various ways including by drilling a K-wire into the maxilla just lateral to the maxillary crest and securing the graft to the wire. Occasionally, when there has been excessive resection of the lateral crura, supportive grafts may not be enough and alar replacement is required. Conchal cartilage has a natural curve that mimics the curve of the LLCs and is a good choice for this indication. The soft tissue is dissected, creating a tissue pocket at the pyriform aperture and the graft is placed in this pocket. An anchor graft may be used in revision cases for alar retraction: conchal cartilage is shaped to look like an upside-down anchor with the sides at each LLC and the middle secured to the septum or a columellar graft. Previous rhinoplasty may create a pinched dome appearance. A dome spreader graft may address this by securing a small piece of cartilage between the medial crura.²⁹

Complications

The spectrum of complications that may occur after revision rhinoplasty is essentially the same as that for primary rhinoplasty, although postoperative oedema may take longer to resolve and there may be a higher risk of skin necrosis in previously dissected tissue.

CHAPTER 73

Genioplasty

Nicholas Lee,¹ Deepak Komath² and Tim Lloyd²

¹Department of Oral and Maxillofacial Surgery, Sheffield Teaching Hospitals, Sheffield, UK

²Department of Oral and Maxillofacial Surgery, University College Hospital, London, UK

Introduction

The chin is one of the most obvious facial structures. Chin size, shape and position play an important role in facial appearance and balance. Therefore surgery to the chin can play an important part in the correction of facial discrepancies. Surgery is either in isolation where the dental occlusion is accepted or as part of an orthognathic treatment plan, including single or bimaxillary jaw surgery and other soft tissue procedures (Figure 73.1).

An important component of nasal aesthetics and facial balance is the position of the chin. An underprojected, or weak, chin can create the appearance of a larger nose than is actually present. This was noted as early as 1928 when Aufricht described augmentation of the chin with osteo-cartilagenous nasal hump. Advancement genioplasties have been used successfully to treat sleep apnoea in retrognathic patients.¹ In 1942 Hofer first described the osseous horizontal sliding osteotomy for the correction of microgenia via an extraoral approach.² In 1957 Trauner and Obwegeser described osseous genioplasty via an intraoral approach.³ This was when Obwegeser was working in Trauner's unit in Graz. They described the bilateral sagittal split osteotomy in the same year.^{4,5}

The chin, like the face, should be considered in four dimensions: vertical, anterior posterior, transverse and in function.

Minor chin deformities can be camouflaged by the injection of fat or fillers. The use of alloplastic implants allows the correction of mainly anterior posterior deformities. Although now a very common procedure, alloplastic materials have been used to augment the chin since the 1940s.⁶ Commonly used materials include porous polyethylene, hydroxyapatite, silicone and PEEK (polyetheretherketone).

Though it is possible to augment the chin with computer-aided design/manufacture (CAD/CAM) bespoke implants, in the long term there are risks of migration of the implant and resorption of the underlying bone. (Figure 73.2). Osseous genioplasty allows stable three-dimensional correction of chin deformities with minimal morbidity.

The aesthetic goal of any surgery on the chin should be to improve or maintain facial balance to the patient's satisfaction. The surgery should be performed transorally with minimal complications.

Surgical anatomy

Osteotomy cuts are carried out below the lower anterior teeth and need to be placed 4 mm below the tooth apices, noting that the maximum average length of lower incisors is 23.5 mm and canines 27 mm.⁷

The mental nerve carries sensory branches to the chin and lower lip. Care must be taken to identify and protect this nerve during surgery. It is important to note that just before it exits the mental foramen, the mental nerve is 5 mm anterior and inferior to the foramen. If an osseous genioplasty is performed, the incisive branches to the lower incisor teeth are sacrificed and the patient should be warned of the resultant altered sensation in the lower incisor teeth and surrounding gum. Interestingly, even though the nerve is usually divided, normal sensation seems to return after about a year.

The mentalis muscles are paired elevators of the central lower lip that originate from the mandible at the level just beneath the attached gingiva of the central and lateral incisors.⁸ Careful surgery to prevent excessive stripping of soft tissues will decrease the risk of lip ptosis. Accurate planning of incision and careful dissection leaving enough superior bulk of mentalis muscle allows repair of the muscle and a two-layer closure.

Any genioplasty has to ensure bone-on-bone contact between segments to allow adequate bony healing.

Aesthetics and functional assessment

Patient assessment

The patient assessment should start with a discussion to allow the surgeon to have a through understanding of the patient's overall expectations. Unrealistic expectations or multiple

Figure 73.1 Bimaxillary osteotomy and genioplasty.

previous cosmetic procedures may be a sign of body dysmorphic disorder. The medical history should be explored and if the patient is a smoker, smoking cessation advice should be considered. At the very least smoking should be stopped in the immediate postoperative period.

The chin cannot be considered in isolation from the face and has to be examined in all three planes of space. The assessment should include the dental occlusion and the relationship of the maxillary and mandibular skeletal bases. The nose should also be examined and its relationship to the face explored, as any facial discrepancies may benefit from orthognathic surgery or a rhinoplasty, either instead of or in combination with a genioplasty.

The chin plays an important role in the overall facial harmony and balance. A small chin can be described as ‘microgenia’,

whereas a large chin is called ‘macrogenia’. Small or large chins can be deficient in any of the three planes of space but should not be confused with a chin that is normal in size but has a posterior chin point due to a retrognathic mandible or one that is normal in size but more prominent due to excess soft tissue.

From the frontal view the face can be examined for transverse discrepancies, facial asymmetries, the degree of lip competence and the form and depth of the labiomental groove. A deep labiomental groove may be a result of overactivity of the mentalis muscles. This can also cause dimpling of the chin button. Injection of botulinum toxin A can help with these issues.

The relationship of the osseous chin to the overlying soft tissues should be examined. Any osseous genioplasty or alloplastic chin augmentation would be expected to produce only 80–85%

Figure 73.2 Bone resorption from implant.

of the total advancement in soft tissue changes. A chin moved posteriorly or vertically would see soft tissue changes of 90%.

The facial midline should be determined and how this midline relates to the nose, philtrum, upper dental centre line, lower dental centre line and chin point. In complex asymmetry cases there is often no true facial midline as a pan-facial asymmetry is often present.

In the lateral view the anterior posterior relationship and chin point can be assessed. The dental occlusion is examined and its relationships to the mandibular and maxillary skeletal bases. Riedel's line (Figure 73.3) allows a quick facial analysis of the chin point. The line connects the most prominent points of the upper lip, lower lip and soft tissue chin point. If the chin is posterior to the line it suggests microgenia in an anterior posterior direction which can be corrected with an advancement osseous genioplasty or implant. If the chin extends anterior to this line then it suggests anterior posterior macrogenia, which may require a reduction or a clockwise rotation of the chin point.

In examining the whole face a 'zero meridian line' described by Gonzalez⁹ (Figure 73.3) can be applied. Here a line perpendicular to the Frankfort horizontal, passing through soft tissue nasion to measure the position of the chin. The chin should be on this line or just posterior of the 'zero meridian line' for good facial balance. Individual preferences should be taken into account; men, for example, often associate masculinity with a strong chin, whereas women have a preference for either a soft or stronger chin, depending perhaps on cultural differences.

Figure 73.3 Dotted line is Riedel's (harmony) line. The distance from the soft tissue chin to a line drawn perpendicular to Frankfort plane should be within the range 0 ± 2 mm.

Figure 73.4 Facial proportions, frontal view.

Facial thirds (Figure 73.4) are used as a guide to the overall facial harmony and any deficiency or excess in lower anterior facial height.

The following medical photographs should be taken as part of the clinical examination:

- Full frontal view at rest
- Full frontal view in smile
- Right lateral view

- Left lateral view
- Right three quarters view
- Left three quarters view
- Worm's eye
- Occlusal views if required.

Radiographs should be obtained either as a two-dimensional set or a cone beam computed tomography (CBCT):

- Lateral cephalogram for 2D cephalometric analysis.
- **CBCT** (Figure 73.5): This allows CT of the bony facial skeleton at a lower radiation dose than a conventional spiral CT scan. The skull can be visualized in three dimensions allowing a true assessment of the facial discrepancy. Three-dimensional cephalometric analysis can be carried out. Once the virtual skull has been segmented then virtual surgery can be carried out. With CAD software, surgical guides, models and custom implants can be fabricated. If needed, 3D models of the skull allow patient-specific implants to be made in the laboratory. Orthognathic planning software as well as allowing the design and planning of the osteotomy also allows the surgeon to visualize the inferior dental nerve and tooth roots. Soft tissue algorithms allow some indication of the soft tissue changes expected.

Operative principles and approach

Osseous genioplasty

The surgery is carried out under general anaesthesia with a nasal endotracheal tube to allow good visualization of the face.

If full-face exposure is needed in complex facial asymmetry cases where the genioplasty is being carried out with other facial procedures then a submental intubation can also be considered.¹⁰

If combined with another orthognathic procedure then the genioplasty should be carried out after any mandibular osteotomies with the patient in intermaxillary fixation while the genioplasty is being carried out.

The oral cavity is rinsed with chlorhexidine digluconate mouthwash. The surgical field is infiltrated with local anaesthesia with a vasoconstrictor (2% lidocaine (lignocaine) with 1:80 000 adrenaline) or approximately 40 mL of tumescent solution. Tumescent solution is mixed in a 250 mL bag of normal saline and contains 1 mL of 1:1000 adrenaline, 1 vial (40 mg) triamcinolone acetate, 20 mL of 5% Marcaine and 1 vial hyaluronidase. It has been shown to improve the surgical field and postoperative swelling in craniofacial surgery and is used routinely in our unit.¹¹ Low-power cutting diathermy or a blade is used to make an incision just through the mucosa at least 5 mm below the attached mucosa from lower canine to lower canine (Figure 73.6a). The submucosal incision is deepened in the midline through periosteum to bone at a 45° angle, making sure that both mentalis muscles are divided, allowing a satisfactory

Figure 73.6 Advancement genioplasty surgical stages.

muscle repair on closure (Figure 73.6b). The superior edge of the flap is elevated to allow an easier mucosal closure.

A subperiosteal dissection is carried out, starting at the midline and working out laterally, identifying the neurovascular bundle exiting the mental foramen. The mental nerve is then identified and protected. The dissection does not need to include the whole chin, just enough to visualize and perform the osteotomy cuts and to give access for the fixation while preserving vascular supply.

Three vertical reference marks are made with a water-cooled fissure bur to allow accurate horizontal repositioning of the chin post osteotomy (Figure 73.6c).

The osteotomy should be performed 5 mm below the apices of the roots of the lower incisors and 5 mm below the mental foramen.

Osteotomy cuts are carried out with a water-cooled reciprocating saw blade (Figure 73.6d) or a piezoelectric saw if available. The angulation is important, as subtle changes will have profound changes in the vertical chin point position and anterior mandibular height. Care must be made to ensure that both the anterior and posterior cortices are osteotomized to avoid an unfavourable split. The final completion of the osteotomy is carried out with an osteotome if necessary and separation by the placement of a Howarth's periosteal elevator in the osteotomy cut and turning 90° (Figure 73.6e).

The mobile chin is then mobilized into the planned position while maintaining its lingual soft tissue and muscle attachments. If an advancement is planned, the surrounding soft tissues including the muscles of genioglossus and geniohyoid are stretched. Fixation is completed with either plates bent at the time of surgery or preformed 'Lindorf'-type plates (Figure 73.6f).

Figure 73.7 Postoperative strapping.

The osteotomy can also be stabilized by bicortical screws through both segments. If screws are used then it is helpful to countersink them into the most anterior plate of bone and for there to be at least two screws to prevent rotation. Any bony steps or spurs are then removed and smoothed.

Closure is carried out in layers with particular attention to the repair of mentalis muscle. At the end of surgery chin strapping is applied to prevent lip ptosis and postoperative swelling (Figure 73.7).

Sliding genioplasty

The sliding genioplasty and variations of the theme is our most commonly performed osseous genioplasty (Figure 73.8a–c).

(b)

(c)

Figure 73.8 (a) Sliding advancement genioplasty. (b) Preoperative. (c) Postoperative.

Anterior posterior advancements or reductions of the chin can be performed. Care has to be made with the angulations of the osteotomy cut relative to the occlusal plane as the chin point will move superiorly, with a reduction of the lower face height with an increasingly more steep osteotomy cut (Figure 73.9). Conversely, with a sliding anteroposterior reduction genioplasty there will be an increase in lower face height. This procedure also results in irregularities in the

lower border of the mandible, notching in advancement and a spur in an anteroposterior reduction. For an increase in the vertical height of the anterior mandible with or without an advancement, the mobile osteotomized segment can be repositioned inferiorly, creating a gap. If large, the gap is grafted with either autologous bone or bone substitutes. To reduce the vertical height of the anterior mandible a double osteotomy cut can be performed and the middle segment removed.

Double osteotomy cuts also allow greater advancement by a creating a double step appearance (Figure 73.10). When performing a double osteotomy it is important to make sure that all cuts are complete and parallel prior to separation and that the most inferior segment is separated first. Failure to do so will result in the surgeon trying to make cuts on a mobile segment.

When the chin is set back, a small ledge on the lingual aspect is created that needs to be reduced to prevent the patient noticing a small palpable step on the border of the mandible (Figure 73.11).

A reduction genioplasty moving the chin posteriorly can produce unfavourable submental and cervical changes. The authors prefer the inferior posterior chin point repositioning osteotomy to prevent these changes.

Figure 73.9 Sliding advancement genioplasty.

Michelet genioplasty

The Michelet genioplasty¹¹ is a useful osteotomy in patients in need of maximum chin point advancement while still maintaining bone-to-bone contact (Figure 73.12a–c). The osteotomy cuts are performed with the aim of keeping a cortical square of anterior labial bone attached to the proximal mandible and a posterior lingual cortical square attached to the mobile osteotomized segment. This is then mobilized and the inferior mobile segment is placed in front but in contact with the superior anterior labial cortical square. The bony cortical squares are now reversed from their normal anatomical position (Figure 73.13). The cortical squares are secured with a titanium bicortical screw, giving maximum chin point advancement with minimal change in the height of the lower facial third. If a reduction of the lower facial third is required, lateral segments can be removed.¹²

Jumping genioplasty

The inferior mobile segment is advanced anteriorly and placed in front of the mandible, moving the chin in an anterior position but decreasing lower facial height (Figure 73.14).

Centralizing genioplasty

In facial asymmetries a centralizing genioplasty can be used to centralize the chin point to the midline in a transverse dimension (Figure 73.15). Wedges can be removed asymmetrically to correct the asymmetry if there is a vertical component.

Box genioplasty

A box genioplasty can be used for simple advancements and to correct a transverse discrepancy (Figure 73.16). For the correction of a transverse discrepancy a box osteotomy is cut with a rectangular wedge removed to allow the mobilized

Figure 73.10 Double sliding advancement genioplasty.

Figure 73.11 Sliding reduction genioplasty.

anterior segment to be centralized, bringing the chin midpoint to the midline. The wedge is then used as a free bone graft to the resulting gap. All is held with titanium plates and screws and any bony spurs reduced. With the box osteotomy it is easier to make your horizontal bone cut parallel to the occlusal plan and you have more control of the vertical position of the chin point. Additionally, your posterior vertical bone cuts are made in a sagittal plane, preserving the continuity of the lower border and avoiding the irregularities that occur with a conventional sliding genioplasty. This is the preferred method of the authors for a simple advancement.

Inferior posterior chin point repositioning osteotomy

This osteotomy allows the chin point to be repositioned posteriorly, giving the illusion that the mobile osteotomized segment has been reduced without any soft tissue changes to the submental and cervical region. A segment of anterior mandible is removed with the posterior base greater than the anterior apex. Increasing the width of the segment removed will also have an effect on lower face height (Figure 73.17).

The T genioplasty

The T genioplasty is useful in dealing with transverse discrepancies, the broad or narrow chin and asymmetries.¹³ The chin is divided in the sagittal plane with either two parasagittal cuts when the chin is to be narrowed or a single midline sagittal cut with an interpositional bone graft to widen the chin point (Figure 73.18). This technique is useful in cases of gender reassignment surgery.

Figure 73.12 Michelet genioplasty.

Figure 73.13 (a) Preoperative Michelet genioplasty. (b) Bicortical screw fixation for Michelet genioplasty. (c) Postoperative Michelet genioplasty. (d) Postoperative lateral cephalogram. Michelet genioplasty.

Extended or wing genioplasty

This is a lower border osteotomy recently described by Triaca.¹⁴ The osteotomy runs the complete length of the lower border of the mandible, with the buccal cut higher than the lingual. This allows an increase in vertical height of the mandible. (Figure 73.19).

The shield genioplasty

Described by Triaca, this procedure is designed to give the lower lip more support by making the buccal bone higher than the

lingual cut.^{15,16} This avoids creating a deep labiomental fold when advancing the chin point.

Combination procedures

In complex chin deformities seen in patients with severe facial asymmetries or craniofacial conditions, a combination of different osseous genioplasty osteotomies may be required to improve the facial profile.

Figure 73.14 Jumping genioplasty.

Alloplastic augmentation

The majority of alloplastic implants are preshaped in a variety of sizes designed to fit over the chin. An alloplastic implant is most suitable for microgenia, where there is an anterior posterior deficiency, but generally less than 5 mm. An implant larger than this is at risk of symphyseal erosions over time.¹⁷

If appropriate, the implant can be custom made. This requires a CT scan – either conventional spiral or CBCT of the jaw. The implant is then either made on an acrylic model produced from the DICOM data (Digital Imaging and Communications in Medicine) or on a virtual 3D model using specialized CAD software.

Silicone is a commonly placed implant, but solid silicone does not allow tissue in-growth so the implant is easily removed.

Porous polyethylene (Medpor) implants are commonly used in craniofacial reconstruction and augmentation. The implants

Figure 73.15 Centralizing genioplasty.

have a pore structure allowing fibrovascular in-growth and integration of the patient's tissue.

PEEK (Polyetheretherketone) is an implant material used in the construction of custom-made patient-specific implants with qualities similar to bone. The alloplastic implant can be placed via either an intraoral or an extraoral approach. The intraoral approach is as the operative technique for the osseous genioplasty with the aim of creating a wide subperiosteal pocket. The soft tissue and musculature needs to be adequately released to allow the alloplastic implant to seat well, especially along the lower border of the mandible. The implant is held with titanium

Figure 73.16 Box genioplasty.

screws. Inadequate fixation may lead to displacement, wound dehiscence and extrusion.

The submental approach is normally performed under general anaesthesia with a nasal endotracheal tube to allow visualization of the face. The incision site is infiltrated with 2% lidocaine with 1:80 000 adrenaline. The incision is made just inferior to a natural submental crease. The dissection is developed superiorly to the inferior surface of the chin. The periosteum is incised and a subperiosteal pocket developed large enough to fit the implant. The mental nerve is identified and avoided. The implant is placed inferior to the mental nerve. Once haemostasis is obtained the sterile implant is placed into the pocket with minimal handling. Titanium screws are used to fix the implant in place and the wound is closed in layers.

Autologous augmentation

An onlay graft of autologous bone or costal cartilage may be required when a conventional osseous genioplasty or alloplastic implant has failed. The stability of onlay bone and cartilage grafts is questionable.

Other procedures that change the chin

Changing the vertical position of the maxilla will result in auto-rotation of the mandible. The chin point will come forward with impaction of the maxilla and go back with inferior repositioning of the maxilla (Figure 73.20).

In a patient with an increased overjet and a chin point in the correct position, a total subapical osteotomy can bring about favourable changes to the appearance of the chin (Figure 73.21).

Complications

Complications following alloplastic augmentation and the osseous genioplasty include:

- the unhappy patient,
- sublingual haematoma resulting in airway embarrassment,
- poor aesthetics,
- paraesthesia of the lower lip and chin,
- lower lip ptosis,

Figure 73.17 Inferior posterior chin point repositioning osteotomy with a rotating reduction genioplasty. (a) Diagrams. (b) Pre-operative lateral cephalogram. (c) Post-operative lateral cephalogram.

- infection,
- bone resorption,
- loss of the osteomized segment, and
- wound dehiscence and extrusion with implants.

Understanding the patient's expectations, the ability to view in three dimensions and a surgical plan will hopefully prevent the unhappy patient. The incidence of neurosensory deficiency in the distribution of the mental nerve following an isolated

genioplasty is in the region of 10–12%, but can be as high as 70% when performed in combination with a bilateral sagittal split osteotomy.^{18,19} Direct transection of the nerve requires a microsurgical repair.

Bone resorption may be seen in large alloplastic implants or if excessive stripping has been carried out of the mobile osteomized chin segment, compromising the soft tissue pedicle.

An infection of the surgical site should be treated aggressively but may result in the removal of the implant, bone or mode of fixation resulting in a later reconstruction.

Wound dehiscence can be secondary to infection but may also occur if the pocket created for the alloplastic implant is too small

and again will result in removal of the implant. Extrusion may follow dehiscence. Excessive stripping of the soft tissues compromising the vascular pedicle may result in avascular necrosis and may require a future alloplastic implant or free bone graft.

Lip ptosis is related to inadequate repositioning and repair of the mentalis muscles prior to soft tissues closure. Correction of the lip ptosis requires soft tissue and mentalis muscle resuspension with bony tunnels or anchors.

The implant or mobilized osteotomized segment can become dislodged due to trauma or inadequate retention. This may

Figure 73.18 T genioplasty.

Figure 73.19 Shield genioplasty.

Figure 73.20 Maxillary Le Fort I inferior repositioning.

Figure 73.21 Total subapical osteotomy.

necessitate the need for a second procedure to realign the implant or mobile segment.

Reduction genioplasties could reduce support for the overlying soft tissues. This results in unfavourable changes to the cervico-mental angle, producing a double chin appearance. Plication of the platysma muscles has been suggested as a method to treat this problem.²⁰ The authors, however, favour submental liposuction or, in the more severe cases, a lower facelift procedure.

Summary

The chin is one of the most obvious facial structures and genioplasty surgery can play an important part in the correction of facial discrepancies. A clear understanding of assessment, planning and surgical technique are imperative to achieve a pleasing result and happy patient.

CHAPTER 74

Blepharoptosis

Alan A. McNab

Orbital Plastic and Lacrimal Clinic, Royal Victorian Eye and Ear Hospital, Melbourne, Australia

Definition

Blepharoptosis is defined as a lower than normal position of the upper eyelid in relation to the globe and pupil. The term is often abbreviated to ptosis.

The upper eyelid normally covers the upper 1–2 mm of the cornea, but this tends to increase slightly in old age. As the cornea has a diameter of 11 mm, the distance from the upper eyelid margin to the inferior corneo-scleral limbus is therefore normally 9–10 mm. This distance can be used as a means of measuring the amount of ptosis, but conventionally, the distance from the upper eyelid margin to a reflection of a point source of light shone directly at the patient is used. This distance is called the margin reflex distance 1 or MRD1. This is normally 3–4 mm. (The MRD2 is the distance from the light reflex to the lower lid margin.) The disadvantage of using the MRD1 over a simple measure from the lid margin to the inferior limbus is that when the upper eyelid margin is lower than the position of the light reflex on the cornea, the lid must be lifted up to then get an indirect measure of how far below the light reflex the lid margin sits. If it is lower than the light reflex it is expressed as a negative value in millimetres.

Anatomy

Knowledge of the anatomy relevant to ptosis is vital in understanding the aetiology and mechanisms of ptosis, and the clinical signs and surgery of ptosis.

The main surface anatomy marking of relevance is the upper eyelid crease or eyelid fold. In white populations this lies about 6–10 mm above the eyelash line. In Asian eyelids, there is much more variability, with the crease being absent or often much lower than in white eyelids, with an associated fullness of the upper eyelid. This is because the orbital septum attaches much lower in most Asian eyelids with the pre-aponeurotic fat pad extending more inferiorly, giving the eyelid a fuller appearance.

The upper eyelid retractor, the levator palpebrae superioris (LPS), is innervated by the superior division of the third cranial nerve (oculomotor nerve). The muscle belly arises from the apex of the orbit on the lesser wing of the sphenoid, just above the optic canal. It travels anteriorly in the orbit below the orbital roof, partly overlapping the superior rectus muscle, which lies immediately below it. As it reaches the anterior orbit, it turns more inferiorly towards the tarsal plate of the eyelid. About 8–10 mm above the superior border of the tarsus, it broadens out into a tendinous aponeurosis. This aponeurosis attaches onto the anterior surface of the tarsal plate, and also sends fibres to attach between bundles of the orbicularis oculi muscle just under the eyelid skin to form the upper eyelid skin crease (Figure 74.1).

The levator aponeurosis expands medially and laterally as its medial and lateral horns. The lateral horn is much stronger and attaches on to Whitnall's tubercle just inside the lateral orbital rim. The lateral horn also partially divides the lacrimal gland into orbital and palpebral lobes, with the two lobes continuous behind the posterior edge of the lateral horn. The medial horn is less well defined and becomes weaker with age. It attaches to the superior border of the medial canthal tendon.¹

There is a smooth muscle component of the levator apparatus, called Müller's muscle, which is innervated by sympathetic nerve fibres. This is a sheet of smooth muscle fibres with a rich blood supply that arises from the undersurface of the levator muscle and extends downwards under the levator aponeurosis to attach to the superior border of the tarsal plate. It is about 10 mm in length.

There is a strong transverse band of connective tissue running from the region of the trochlea to the lacrimal gland, which runs over the superior surface of the levator muscle near the point where it turns more inferiorly towards the tarsal plate. This is called the superior transverse ligament or Whitnall's ligament. There is a less well-defined portion of this structure which passes under the levator muscle, called the transverse superior fascial expansion.²

Figure 74.1 A sagittal section through the eyelids to show the relationship between the levator apparatus, tarsal plate and orbital septum.

The antagonist muscle of the LPS is the orbicularis oculi muscle, innervated by branches of the facial nerve. It runs circumferentially around the eyelids, divided into parts called pre-tarsal, preseptal and orbital. The orbicularis oculi muscle lies immediately below the skin of the upper eyelid, which is extremely thin.

The orbital septum in the upper eyelid extends from the superior orbital rim downwards to attach to the anterior surface of the levator aponeurosis. Behind the orbital septum and lying over the levator aponeurosis and anterior portion of the levator muscle belly is the pre-aponeurotic fat pad, a vital landmark in levator aponeurosis and muscle surgery. Laterally, in the same retroseptal space, the orbital lobe of the lacrimal gland is located. Medially, there is a medial upper fat pad. The tendon of the superior oblique muscle partially separates the central pre-aponeurotic and medial fat pads as it extends down to attach to the globe medial to the medial edge of the levator muscle belly.

The tarsal plate of the upper eyelid is a semilunar-shaped semi-rigid structure made up of meibomian glands set in a fibrous stroma with the conjunctiva firmly adherent to its undersurface. It attaches via the upper limbs of the medial and lateral canthal tendons to Whitnall's tubercle laterally and the frontal process of the maxilla just anterior to the anterior lacrimal crest (anterior limb of the medial canthal tendon) and to the posterior lacrimal crest (posterior limb). The upper tarsal plate is about 9–10 mm in vertical height centrally and about 1 mm thick.

There is a vascular arcade overlying Müller's muscle at its lower edge, and under the levator aponeurosis, just above the superior border of the tarsal plate. A smaller vascular arcade runs just above the lash bulbs near the margin of the eyelid, within fibres of orbicularis oculi.

Aetiologic factors

When considering the causes of blepharoptosis, it is conventional to divide them into congenital and acquired. However, there is some overlap in these two groups.³ The classification shown in Table 74.1 is useful.

Congenital and acquired neurogenic ptosis can be considered together in terms of investigation and management. Third nerve palsies may be partial or complete, and there may be aberrant regeneration complicating the clinical picture. Congenital aponeurotic ptosis is rare, but can also be managed in the same way as acquired aponeurotic ptosis.

Congenital myogenic or dystrophic ptosis may be unilateral or bilateral (symmetric or asymmetric) and is due to a maldevelopment of the levator muscle, which is variably replaced by fatty and fibrous tissue. The muscle contracts and relaxes less than normally. This type of ptosis often occurs with a positive family history and there are a number of genetic defects that continue to be identified. Although it is usually an isolated abnormality, there are well-recognized associations, including poor functioning of

Table 74.1 Classification of blepharoptosis

A. Congenital ptosis	1. Congenital neurogenic ptosis	1a. Congenital 3rd nerve palsy 1b. Congenital Horner's syndrome 2a. Isolated congenital dystrophic ptosis
	2. Congenital myogenic ptosis (sometimes called congenital dystrophic ptosis)	2b. Congenital dystrophic ptosis with associated weak globe elevator(s) 2c. Congenital dystrophic ptosis as part of a syndrome i. Blepharophimosis syndrome ii. Other syndromes (e.g. Noonan's, Saethre Chotzen)
	3. Congenital ptosis with synkinesis (jaw-winking ptosis, others)	
	4. Congenital aponeurotic ptosis (rare)	
B. Acquired ptosis	1. Neurogenic ptosis	1a. 3rd nerve palsy 1b. Horner's syndrome 2a. Myopathic ptosis i. Mitochondrial cytopathies (chronic progressive external ophthalmoplegia or CPEO and its variants) ii. Myotonic dystrophy iii. Oculopharyngeal muscular dystrophy iv. Other myopathies 2b. Myasthenia i. Ocular myasthenia ii. Myasthenia gravis 3a. Involutional aponeurotic ptosis 3b. Involutional myogenic ptosis
	2. Myogenic ptosis	
	3. Involutional ptosis	
	4. Mechanical ptosis (lumps and swellings of the eyelid)	
C. Pseudoptosis	5. Traumatic ptosis (may be multiple factors)	
	1. Globe hypotropia	
	2. Enophthalmos, or a small eye	
	3. Blepharospasm	
	4. Dermatochalasis	

the superior rectus muscle and double elevator palsy. Children with these additional muscle problems will usually have a vertical strabismus with the globe pointing downwards (hypotropia).

Congenital myogenic ptosis may be part of a more extensive syndrome. The best known of these is blepharophimosis or BPES (blepharophimosis, ptosis, epicanthus inversus) syndrome. Numerous other less common syndromes may have ptosis as one manifestation of the condition; Noonan's and Saethre Chotzen syndrome are two examples.

Congenital ptosis with synkinesis is a special subcategory of congenital ptosis. The best-recognized form is Marcus Gunn jaw-winking ptosis. The child will have unilateral ptosis and with contraction of the ipsilateral lateral pterygoid muscle, the levator muscle is stimulated and the lid rises, sometimes higher than the normal position. Synkinesis with other muscles is less common but well described. These include lid elevation with contraction of the medial pterygoid, digastric, the lateral rectus muscle, and with swallowing.

Acquired myogenic ptosis is an important diagnosis to make because of the significant general health aspects of these conditions.

Involutional or age-related ptosis is by far the commonest form of ptosis seen in clinical practice. A mild degree of ptosis is common in the elderly, but more advanced degrees may occur and impact on visual function. Traditionally, the majority of

involutional ptosis has been attributed to dehiscence and/or stretching of the levator aponeurosis, but in a significant proportion of older patients with acquired ptosis, the levator muscle itself appears to be abnormal with infiltration by fatty tissue into the muscle belly.

Some lumps on the upper eyelid may induce ptosis by their weight alone, and this is the classic cause of so-called mechanical ptosis. Other mechanical factors may be at play in some cases of ptosis, including scarring or adhesion between parts of the muscle and other structures such as the orbital roof after fractures, or adhesions between the eyelid and the globe.

Traumatic ptosis is often multifactorial. Traumatic nerve injuries may lead to ptosis, as may injuries to the muscle belly or aponeurosis. Some patients will develop ptosis after episodes of eyelid bruising or swelling and it is thought that such swelling may lead to dehiscence of the levator aponeurosis. Other forms of ocular surgery may sometimes lead to ptosis. The mechanism is not always clear.

Repeated minor trauma may also lead to ptosis. This is thought to be the cause in patients who develop ptosis after many years of wearing hard or rigid gas permeable contact lenses, who often remove the lenses by applying traction at the lateral canthus to remove the lens.

Pseudoptosis has a number of causes. An important one to recognize is hypotropia. With the globe looking down compared

to its fellow eye, the lid will also be lower than normal because the lid follows the eye downwards. If the normal eye is covered and the patient takes up fixation with the hypotropic eye, the lid will usually rise at least partially as well. This uncovers the element of the ptosis which is due to 'pseudoptosis'. Ideally, the hypotropia should be corrected first to eliminate any element of pseudoptosis.

A small or enophthalmic eye will often have a narrower than normal palpebral fissure, due to inadequate posterior support of the eyelid, but this is not due to any abnormality of the levator apparatus or eyelid and is classified as a form of pseudoptosis.

Patients with increased tone in the orbicularis oculi muscle will often have a narrowed palpebral fissure also. This may be due to increased tone with or without an element of aberrant reinnervation after a facial palsy. The lid fissure may narrow further when muscles in the lower face contract. Similarly, patients with hemifacial spasm will display episodic narrowing of the palpebral fissure associated with spasm of other facial muscles on the same side.

Finally, marked dermatochalasis will often look like true ptosis but if the hood of abnormal skin is lifted out of the way, the lid position can then be properly assessed. Many cases of true involutional ptosis will of course also have a degree of dermatochalasis.

Preoperative assessment

As in any medical condition, a proper history and examination is essential. The history will usually easily separate congenital from acquired ptosis. Questions should be asked about time and rapidity of onset and variability of the ptosis, associated diplopia, other neuromuscular problems, any history of trauma, lid swelling or contact lens wear. A family history of ptosis or muscle problems should be sought. Older patients should be asked about a history of dry eye problems as elevating the eyelid in a patient with dry eyes may exacerbate the dry eye problem.

A standard sequence of examination steps will usually give an answer, in addition to the details of the history, as to what has caused the ptosis, and make surgical planning safer. The examination steps may seem arduous, but with experience, a targeted ptosis examination can be performed in a few minutes. The steps should include the following:

- 1 *Measure and record the patient's vision.* This is especially important in children in the amblyogenic age group (less than 10 years of age). There is a strong association between ptosis and amblyopia.
- 2 *Measure the degree of ptosis.* This can be done by measuring the MRD1 (upper lid to corneal light reflex), or the distance from upper lid to lower limbus (normal is 9–10 mm). The degree of ptosis should be measured with the brow held in a neutral position to eliminate any elevation of the lid by the brow.
- 3 *Measure the levator excursion or 'levator function'.* This is the distance the lid moves between extreme up and down gaze. Normal should be about 13–15 mm.

- 4 *Look at the position of the ptotic lid on down gaze.* In congenital myogenic ptosis, because the levator relaxes less well, the lid does not drop as much as normal on down gaze. With involutional aponeurotic ptosis, the lid will drop more than normal on down gaze.
- 5 *Measure the position of the eyelid crease.* This helps in diagnosis and surgical planning. The crease is usually elevated compared to the normal side in aponeurotic ptosis. The crease may be absent in more severe congenital ptosis.
- 6 *Examine the patient's eye movements.* This is a vital part of the examination. Patients with myogenic ptosis will usually have signs of abnormal eye movements, which may be subtle at the first presentation. The range of eye movements, rapidity of eye movements (tested by examining saccadic eye movement), and presence or absence of strabismus in any position of gaze by performing a cover test, should all be performed.
- 7 *Examine the pupils.* The pupil will be enlarged in many third nerve palsies, and in Horner's syndrome the pupil will be smaller on the affected side. This difference is more obvious in dim light where the normal side dilates more.
- 8 *Examine eyelid closure.* Gentle eyelid closure should be tested first, looking for lagophthalmos, indicating orbicularis weakness. Forced closure should be tested also, looking for weakness.
- 9 *Examine for Bell's phenomenon.* This is where the eye rolls upwards on forced lid closure. If absent, the risk of corneal exposure problems is increased with ptosis surgery.
- 10 *Evert the upper eyelid and examine the conjunctival fornices.* The tarsal surface of the lid may be abnormal after previous ptosis surgery, and the conjunctival fornices may be hiding rare disorders such as subconjunctival lymphoma (seen as a salmon patch) or conjunctival amyloidosis.
- 11 *Look for associated clinical signs.* These include brow position (the frontalis muscle on the side of a unilateral ptosis will be usually overacting, elevating the brow), the presence of synkinetic movements (ask the patient to open the mouth and move the jaw side to side), and evidence of other features of myopathies or myasthenia (frontal balding in myotonic dystrophy, muscle weakness elsewhere, fatigability with myasthenia on sustained upgaze, a twitch of the upper eyelid on upward saccades of the eyes, known as Cogan's lid twitch, and occurring with myasthenia).
- 12 *Check that corneal sensation is normal.* This can be done with a strand of cotton teased from the end of a cotton tip. Reduced corneal sensation is rarely seen in ptosis patients, but if present, it markedly increases the risk of corneal complications after ptosis surgery.
- 13 *Examine the ocular surface.* This is best done with a slit lamp after placing a drop of fluorescein in the eye. Alternatively, a direct ophthalmoscope with a cobalt blue filter can be used. The adequacy of the tear film should be assessed as well as the presence of corneal drying. If the tear film is deficient or the cornea stains with fluorescein, there is a significant risk of worsening corneal drying or even ulceration with ptosis surgery.

At the end of the history and examination, a confident diagnosis of the cause of the ptosis can be made in most patients. If there is doubt, or certain diagnoses are suspected, then further investigations or referral to other specialists may be appropriate. The following scenarios deserve further investigation or referral:

- Acquired third nerve palsy. Should be referred for neurological assessment and imaging.
- Acquired Horner's syndrome. Neurological referral.
- Suspected myasthenia. An ice-test is a simple investigation that can help establish a diagnosis of myasthenia. An ice pack is placed over the eye with ptosis for 3–5 min. In myasthenia, the lid should elevate by at least 2 mm, and in patients with diplopia, this may temporarily resolve or reduce. All patients with suspected myasthenia should be referred for neurological assessment and investigation.
- Suspected myopathic ptosis. Neurological referral. Most patients with myasthenia are managed medically. Occasionally, myasthenic ptosis may resist medical therapy and in some cases, surgery can be cautiously offered.
- Reduced vision in a child under 10 should be referred to an ophthalmologist.
- Presence of strabismus. Referral to an ophthalmologist.

There may be other scenarios requiring further investigation or referral and if in doubt about the cause of the ptosis, then assessment by an ocular plastics specialist ophthalmologist or neuro-ophthalmologist is appropriate.

Treatment principles

The principles of surgical and other forms of management of ptosis can be divided into the following groups:

- congenital ptosis
- blepharophimosis syndrome
- jaw-winking ptosis
- myopathic ptosis
- involutional ptosis.

Congenital ptosis

The management of congenital ptosis can be divided into several steps.

- 1 Refer all congenital ptosis for ophthalmological assessment at first diagnosis. Ideally this should be as soon as the diagnosis is made, shortly after birth. The ophthalmologist will assess the infant for refractive error and amblyopia and initiate appropriate treatment. If the ptosis is severe and the vision is not developing normally despite amblyopia therapy (glasses, patching or atropine penalization with drops), then early surgery may be indicated. Otherwise, the surgery can be delayed until accurate measurements of the degree of ptosis and levator function can be made, allowing proper surgical planning.
- 2 If there is a squint present, then the patient should also be referred as early as possible to an ophthalmologist.

The commonest squint present with unilateral congenital ptosis is a hypotropia. If present, the hypotropia should be corrected before any ptosis surgery, because there will often be an element of pseudoptosis present which will be reduced by correcting the hypotropia. Additionally, correcting the hypotropia will reduce the risk of corneal exposure problems by improving globe elevation and the Bell's phenomenon.

- 3 If the vision is developing normally and there is no strabismus, then ptosis surgery can be planned around the age of 3–5 years, when good measurements can be obtained that help in the planning of ptosis surgery.

Surgery for congenital ptosis

If early intervention is required because of the presence of amblyopia, then normally a brow suspension is performed using non-autogenous material such as silicone. This allows for later removal and more definitive ptosis surgery at a later age if required. The technique for brow suspension is discussed later.

If the ptosis surgery is performed electively at or after the age of about 4 years, when good and reproducible measurements of the degree of ptosis and levator function can be obtained, then the choice of procedure will be determined principally by the degree of ptosis and levator function. If the levator function is poor (5–6 mm or less), then performing a levator resection or shortening procedure will lead inevitably to undercorrection. In this setting a brow suspension is preferred.

For congenital ptosis with 7 mm or more of levator function, a levator shortening or resection is preferred. The amount of resection is determined by the degree of ptosis and levator function. Complex tables are published, and the best known of these is that of Beard.⁴ In general, levator function can be divided into poor, moderate and good. 'Good' levator function in congenital ptosis is 8 mm or more. Moderate is 6–8 mm. The range of shortening or resection for congenital ptosis is of the order of 10–25 mm. For genuine congenital ptosis with a myogenic cause, a resection of less than 10 mm is likely to lead to undercorrection. Within the group of patients with moderate levator function, the amount of resection will depend on the degree of ptosis (Table 74.2). An additional useful guide for the amount to resect the levator is Berke's rule of 7's. Under general anaesthesia, if the levator function is 7 mm then the lid should be set to the desired level (usually 2 mm below the superior limbus). If more than 7 mm, it is set lower, and if less than 7 mm, it is set higher.

Additional factors that may influence the amount to resect the levator muscle include:

- The presence of milder ptosis on the other side. Smaller resections may be performed to try and achieve symmetrical bilateral mild ptosis.
- The presence of poor superior rectus function – an additional 4 mm is resected.
- The decision to preserve Müller's muscle or not – an additional 2 mm is resected.

For very mild congenital ptosis (1–2 mm) with near normal levator function (13 mm or more), a posterior approach with

Table 74.2 Amount of levator resection according to degree of ptosis and levator function in congenital ptosis

Amount of ptosis	Levator function	Levator function	Levator resection
2 mm or less	Good	10 mm plus	10–13 mm
3 mm	Good	10 mm plus	14–17 mm
3 mm	Fair	7–10 mm	18–22 mm
4 mm or more	Fair	7–10 mm	23 mm
4 mm or more	Poor	6 mm or less	23 mm or more

Adapted from Callahan & Beard, 1990.⁴

resection of conjunctiva and Müller's muscle, or conjunctiva, Müller's muscle and tarsus (Fasanella–Servat procedure) can be performed (see below).

Techniques

Levator resection

The amount to resect the muscle will have been determined preoperatively. The patient will usually be under general anaesthesia. The following steps will be performed:

- 1 *Mark the upper lid skin crease.* This will be generally marked to match the other (normal) side and should have been measured preoperatively, as it is not always obvious under general anaesthesia.
- 2 *Inject local anaesthetic.* Inject some local anaesthetic with adrenaline into the eyelid; 1–2 mL is injected under the skin in the region of the planned incision. A very small bleb can also be injected subconjunctivally in the superior fornix after everting the upper eyelid.
- 3 *Make an incision.* Make an incision in the marked crease through skin. The wound is then deepened through orbicularis muscle (Figure 74.2a).
- 4 *Expose the tarsal plate.* Dissect downwards onto the anterior surface of the tarsal plate. As the tarsal plate is exposed, the lower end of the levator aponeurosis will be transected, giving it a free lower edge. The tarsus should be exposed for most of its width and over its upper 3–4 mm (Figure 74.2b).
- 5 *Open the orbital septum* (Figure 74.2c). To do this, the upper edge of the wound is grasped and pulled upwards. An assistant grasps the lower edge of the levator aponeurosis. Sharp dissection is performed between the orbicularis muscle and levator aponeurosis, extending under the orbicularis. As the septum is opened, the anterior part of the levator muscle is exposed. A key landmark is the pre-aponeurotic fat pad, a mobile, bright yellow pad of fat that overlies the anterior portion of the levator muscle belly. Once exposed, the fat pad is pulled upwards and the dissection of the muscle belly is extended into the superior orbit. The transverse or Whitnall's ligament will be seen. The dissection can proceed beyond this if a larger resection is required.
- 6 *Separate the levator from the tarsus and conjunctiva* (Figure 74.2d,e). The aim here is to isolate the levator

aponeurosis and muscle on its under surface to allow it to be resected. The initial separation is at the upper border of the tarsal plate. There is a vascular arcade here that bleeds. Müller's muscle lies on the conjunctiva and can be separated by initial sharp dissection, then blunt dissection. As the dissection proceeds, a thicker layer of connective tissue that is white in colour is seen. This is the layer known as the common sheath or suspensory ligament of the fornix, and is the layer of connective tissue that extends forwards between the levator and superior rectus muscles. If damaged, prolapse of the superior conjunctival fornix can occur.

- 7 *Divide the medial and lateral horns* (Figure 74.2f). If the resection is larger (>14–16 mm), then the medial and lateral horns should be divided to allow the muscle belly to advance more easily. The cuts should be made towards the belly of the muscle to avoid injury to the superior oblique tendon medially, and the lacrimal gland laterally. Once these cuts are made, the levator aponeurosis and muscle are able to be shortened or resected the desired amount. In some cases Whitnall's ligament may need to be separated from the LPS to allow it to advance (Figure 74.2g).
- 8 *Place a central suture* (Figure 74.2h). Use a non-absorbable or long-acting absorbable double-armed suture such as 5-0 polyester or vicryl. Pass one needle partial thickness through the tarsus about 2 mm below its superior border at a point just medial to the pupil line, where the peak of the lid contour will be. Pass both needles up under the belly of the muscle to emerge through the muscle 2–3 mm apart at a point determined preoperatively by reference to Table 74.2. Have an assistant hold the muscle on tension and tie a bow in the suture and assess the lid height. Using Berke's rule of 7's, the suture can be adjusted if necessary. Undo the bow once the lid height is satisfactory.
- 9 *Place medial and lateral sutures* (Figure 74.2i). Sutures are then passed in a similar fashion medially and laterally. The central suture can be tied, then the medial and lateral sutures put on a bow to assess the lid contour. Adjustments are made as needed to achieve a satisfactory lid contour, then both are also tied.
- 10 *Trim the muscle.* The levator muscle and aponeurosis and Müller's muscle are then trimmed below the sutures.
- 11 *Reform the lid crease* (Figure 76.2j). This can be done by using an absorbable 6-0 suture from the orbicularis of the lower wound edge to the cut edge of the levator muscle at three or more points. This gives a more natural 'soft' crease. Alternatively, a suture from skin to levator to skin can be used to create a harder crease.
- 12 *Suture the skin.* Absorbable sutures can be used.
- 13 *Apply ointment.* In children, copious ointment is inserted into the eye and over the wound without an eyepad. In older patients, a temporary Frost suture can be used in the first 24 h for corneal protection, with a double eyepad.

Figure 74.2 A levator resection procedure for congenital dystrophic ptosis. Source: Collin, 1989.³ Reproduced with permission of Elsevier.

Figure 74.2 (Continued)

Tarso-conjunctival resection (Fasanella-Servat procedure)⁵

For very mild congenital ptosis with near normal levator function, a tarso-conjunctival resection can be performed. This is an uncommon clinical scenario and the large majority of congenital ptosis will require levator resection or brow suspension surgery.

- 1 **Evert the upper eyelid.** This is most easily done after placing a 4-0 traction suture in the lid margin and using a Desmarres retractor.
- 2 **Inject local anaesthetic.** Anaesthetic with adrenaline is injected subconjunctivally just above the superior border of the tarsus.
- 3 **Mark the area of tarsus and conjunctiva to resect.** This will be 3–4 mm of tarsus centrally (leaving at least 4 mm of tarsus from the margin), tapering medially and laterally. A similar amount of conjunctiva is marked.
- 4 **Resect the tarsus and conjunctiva/Müller's muscle.** Obtain haemostasis.
- 5 **Suture the wound.** This can be done by passing a non-absorbable suture such as 6-0 prolene or nylon from the external surface of the lid to emerge at one end of the wound, then suturing continuously with a small number of bites and emerging externally at the other end of the lid. The suture is pulled tight to minimize the risk of corneal abrasion, and the ends tied together over the skin. It is removed at one week. In very young patients, an absorbable suture can be used with the knots tied on the skin surface.
- 6 **Apply ointment.**

Brow suspension

A brow suspension procedure is indicated when the levator muscle function is poor (5–6 mm or less). If there is bilateral symmetrical ptosis with poor levator function, then the procedure is clearly bilateral. If there is bilateral asymmetric

ptosis and one side has poor levator function, and the other side has moderate function, then again, a bilateral brow suspension is preferred so as to give better symmetry both in primary position and in down gaze.

If the brow suspension is being done in a young infant because of the development or risk of amblyopia, then a non-autogenous material can be used, such as a silicone sling or a strong suture such as 2-0 prolene.

For elective brow suspension beyond the age of about 3 years, then fascia lata is the most widely used material. Alternatively, if present, plantaris tendon can be used.

1 **Harvest the fascia lata.** A small incision is made in the thigh just above the knee on the lateral side overlying the ilio-tibial tract, which runs from the iliac crest to the head of the fibula. There are strong transverse fibres on the fascia lata, which can be stripped off bluntly with toothed forceps to reveal the parallel longitudinal fibres that are to be harvested. For a bilateral procedure, the strip should be about 12–15 mm wide. Less is taken for a unilateral brow suspension. A blunt curved artery forceps can be used to split the fibres and begin the dissection. A length is isolated in the wound and clamped. It is divided at the lower end of the wound and the end then passed into the mouth of the fascial stripper which is then pushed up the thigh, bluntly separating the strip of fascia. Once the stripper is in the upper part of the thigh, the strip is cut and retrieved, and the wound sutured.

2 **Divide the fascia into strips.** The strips should be 3–4 mm wide. Wider strips produce large knots that are harder to bury. The strips can be made by dividing the large strip near one end for a few millimetres, grasping that part and pulling it away from the remainder to make a thin strip. Sharp dissection should not be needed.

3 **Mark the incisions in the lid and brow.** The brow suspension can be performed in a 'closed' or open-sky technique. A closed technique works well for fascia lata. For redo procedures or if silicone or prolene is used, an open-sky method works better. For an open-sky method, the tarsus is exposed as for a levator resection and the material sutured to the tarsal plate before completing the brow suspension (see below under Myopathic Ptosis).

For a closed brow suspension, three small marks are made at a level about 2 mm below the desired level of the skin crease, centrally, medially (just lateral to a point above the punctum), and laterally (2–3 mm medial to the lateral canthus). Two small incisions (about 4–5 mm in length) are marked almost directly above the medial and lateral marks at the upper border of the eyebrow and the third brow incision placed in the forehead to form an equilateral triangle with the two brow incisions.

4 **Make the incisions.** In the eyelid, these are made as small stab incisions with the end of an 11 blade. In the brow and forehead, they are longer to allow the knots in the fascia to be buried, and should be down to pericranium.

- 5 *Insert the fascial strips in the eyelid (Crawford pattern).*⁶ Using a Wright's fascial needle, a pass is made from the medial eyelid wound to the central wound, passing deep to orbicularis and anterior to tarsus, across the lid. Place one strip in the eye of the needle and pull it back through the wound. Place another strip similarly from the central to the lateral lid wound. Then pass the fascial needle from the medial brow wound, at a depth just superficial to pericranium, and beneath the orbicularis in the eyelid, being careful to avoid passing the needle through the lid into the fornix or eye. An eye shield should be used. One end of the medial loop is retrieved, then the other so both ends emerge from the medial brow wound. The same is done from the lateral brow wound with the other loop.
- 6 *Tie the knots in the brow wounds.* The fascial strips are pulled up, leaving one end longer (for later passage to the forehead wound). The lid should rise to the desired level about 2 mm below the upper limbus. If the lid pulls away from the globe before this point is reached, stop at the point just before the lid pulls off the globe. A single throw is made and the square knot completed with a second single throw. The fascial knot should be reinforced with a suture such as 6-0 vicryl passed through the fascial knot.
- 7 *Pass the strips to the forehead wound and tie.* The longer ends of the fascial strips are then passed to the forehead wound. They should be tied with some tension to maintain the desired lid level and reinforced.
- 8 *Suture the brow and forehead wounds.* The eyelid punctures do not need sutures.
- 9 *Apply copious ointment in the eye(s).*

Blepharophimosis syndrome

Children (or adults) with BPES syndrome have poor levator function and will need brow suspension surgery. It is customary to correct the telecanthus and epicanthic folds initially, usually at the age of 3–4 years, and then perform the brow suspension about six months later. Some patients with BPES will benefit from lateral ectropion surgery.

Medial canthoplasty

A variety of techniques have been described for the management of telecanthus and epicanthic folds in BPES. These include Mustarde's technique,⁷ its variation, the five-flap technique of Anderson,⁸ a Y-V plasty, and trans-nasal wire. My personal preference is for the Anderson five-flap technique, which better addresses the epicanthic folds.

The details of these procedures is beyond the scope of this chapter and the reader is directed towards the appropriate sources in the reference list.

Brow suspension

The technique is the same as described for poor levator function congenital ptosis (above).

Jaw-winking ptosis

The surgical management of jaw-winking ptosis is complex and there are a number of options available, depending on the desire to abolish (or ignore) the wink, the desire to achieve symmetry, and any concerns held by the patient or their parents about operating on the contralateral (normal) side.

If the main concern is with the ptosis (always unilateral) only, and the wink is of less concern, then a simple levator resection can be performed. The amount to resect the levator muscle is determined in a similar way to simple dystrophic myogenic congenital ptosis, but a slightly larger resection is often needed to achieve good symmetry in primary position.

If it is desired to abolish the wink, the only reliable way to achieve this is to ablate the levator muscle, creating complete ptosis with no levator function, and then perform a brow suspension procedure. If this is done unilaterally, there will be asymmetry often in primary position, with a degree of under-correction, and more marked asymmetry in down gaze, with hang-up of the upper lid on down gaze on the operated side. This is the reason that some surgeons recommend bilateral surgery in this scenario. The levator can be ablated on the affected side, then a bilateral brow suspension is performed, so that there is better symmetry in down gaze. Further improvement in symmetry can be achieved by ablating the levator muscle on both sides and performing bilateral brow suspension surgery (the Beard procedure). However, many patients and their parents are reluctant to consider surgery on the normal side, which converts a normal eyelid into one with limited excursion and potential complications in later life from incomplete closure and corneal exposure complications.

Levator ablation

If levator ablation is chosen (either unilateral or bilateral), it is most easily achieved via an anterior skin crease approach.

- 1 Make an upper eyelid skin crease incision.
- 2 Open the orbital septum and expose the anterior portion of the belly of the levator muscle.
- 3 Dissect superiorly to expose the belly of the muscle above Whitnall's suspensory ligament. Pass two squint hooks under the belly of the muscle and resect several millimetres of the muscle belly making sure all fibres and the muscle sheath are divided, otherwise the wink will not be abolished.
- 4 Proceed with brow suspension surgery, with the fascial strips sutured directly to the tarsal plate (see above).

Myopathic ptosis

Surgery for myopathic ptosis will depend on several critical factors which include:

- the diagnosis;
- the expected long-term progression of the disease;
- the levator muscle function;
- eye movements; and
- orbicularis oculi muscle strength.

The exact diagnosis of myopathic ptosis should generally be pursued before any surgical correction, because different forms of myopathic ptosis have different natural histories, different relative involvement of extraocular muscles and orbicularis oculi, and some are better treated medically (myasthenia). Additionally there may be genetic counselling issues in many of these patients.

Myotonic dystrophy often carries a worse prognosis than some other forms of myopathic ptosis as orbicularis oculi is more severely affected. Oculopharyngeal muscular dystrophy generally does well with brow suspension surgery, as orbicularis oculi tends to be better preserved, and eye movements are less severely affected, reducing the risk of corneal exposure. Chronic progressive external ophthalmoplegia (CPEO) varies in its severity, depending on the subset. Early-onset CPEO in the form of Kearns–Sayre syndrome is more severe and more rapidly progressive. Systemic problems are also commoner and include cardiac disease, generalized severe myopathy and early-onset diabetes.

If there is any suspicion of a myopathic form of ptosis, appropriate referral should be made to a neurologist with expertise in neuromuscular diseases.

Myasthenia

Surgery is not usually indicated for myasthenic ptosis, which should be treated medically. However, in some longstanding patients, surgery may be indicated for stable ptosis which does not respond to medical therapies. The surgery should be performed cautiously, bearing in mind the increased risk of inducing corneal exposure problems.

Levator muscle surgery in myopathic ptosis

Caution should be exercised in performing levator muscle surgery in myopathic ptosis. It should only ever be used where the levator muscle function is good. Often larger degrees of muscle shortening are required to elevate the lid sufficiently despite the apparently good levator muscle function and this leads to an increased risk in later life of corneal exposure problems. If performing levator muscle surgery (or brow suspension surgery) in these patients, lifelong follow-up is required as these diseases progress and ocular surface complications increase. The surgeon should be prepared to reverse the ptosis surgery if the cornea is at significant risk.

Brow suspension surgery for myopathic ptosis

Often, a more conservative brow suspension procedure is safer in these patients than a levator shortening procedure. The lid can be lifted by the often well-preserved frontalis muscle to a point just above the visual axis, allowing the patient to function reasonably well, and at the same time allowing reasonable eyelid closure and minimizing corneal exposure.

The choice of material used for the brow suspension surgery will depend on personal preference as well as other factors,

such as the ease of reversibility or adjustment later, and the requirement of general anaesthesia if harvesting fascia lata. For oculopharyngeal muscular dystrophy, which carries a relatively good prognosis, fascia lata brow suspension surgery is preferable. Under general anaesthesia, the eyelids should be set open just 2–3 mm, and when awake and the frontalis muscle is activated, the lids will generally rise above the visual axis, and eyelid closure will be reasonably well preserved.

For the more severe forms of myopathic ptosis, many surgeons prefer to use non-autogenous material such as silicone, Goretex® or heavy prolene suture. Local anaesthetic can be used for this procedure also. If using these materials, an open-sky technique is preferred with the sling material sutured directly to the tarsal plate with non-absorbable sutures. The material is inserted in a pentagonal shape (Fox pentagon), with the final knot tied in the forehead. Again the lid should be set just open, about 2 mm.

Involutorial ptosis

The majority of surgical procedures for ptosis will be for involutorial ptosis. The same techniques are used for involutorial ptosis as for aponeurotic ptosis that may occur with long-term hard contact lens wear, after some cases of trauma or lid swelling, or in the blepharochalasis syndrome.

The surgical steps can be broken down into the following:

- 1 *Mark the proposed incision(s) in the upper eyelid.* The placement of the incision will be determined by the desired height of the eyelid crease, which will be made to match the opposite side in unilateral cases. In many cases of involutorial ptosis, excess upper eyelid skin will be excised also, not just for appearance, but to reduce the increased overhang of skin that would otherwise occur if the lid alone is elevated. The amount of skin to be excised should be judged carefully in each patient, and is more easily determined in bilateral cases. Removing too much skin should be clearly avoided, as the risk of corneal exposure is increased when ptosis is corrected at the same time.
- 2 *Inject the local anaesthetic.* This should be kept to a minimum volume, and 1–1.5 mL is usually adequate. An excess volume may cause a mechanical ptosis, and a larger volume is more likely to spread deep to the orbital septum and partially paralyse the levator muscle fibres, making the assessment of the lid height more difficult. Recheck the lid height and levator function before proceeding.
- 3 *Make the skin incisions.* Excess skin is removed at this stage. If the surgery is bilateral, each step can be performed on each side so that the surgery advances in parallel. This makes achieving symmetry easier.
- 4 *Expose the anterior surface of the tarsal plate.* This is achieved by sharp dissection below the orbicularis muscle at the inferior edge of the incision, heading obliquely towards the tarsal plate. As the tarsal plate is exposed, the fibres of the levator aponeurosis that are destined for the tarsal plate, are divided, creating

an inferior edge on the aponeurosis which can be used later for attachment or advancement on the tarsal plate.

- 5 *Open the orbital septum.* Sharp dissection proceeds under the orbicularis muscle superiorly, with an assistant holding the inferior edge of the levator aponeurosis downwards. Dissection proceeds until the pre-aponeurotic fat is exposed, which is then dissected gently off the underlying levator muscle and aponeurosis.
- 6 *Recheck the eyelid levels.* Sometimes the lid may elevate without advancing the aponeurosis, possibly because of adrenaline in the local anaesthetic stimulating the Müller's muscle, or the lid may drop because the aponeurosis has been detached from the tarsus.
- 7 *Pass a double-armed 5-0 or 6-0 non-absorbable suture partial thickness* through the tarsal plate about 2 mm below its superior border, at a point where the peak of the arch of the lid contour should lie. This will usually be just medial to the mid-pupil. Pass each needle superiorly under the levator aponeurosis, between it and the Müller's muscle, to emerge through the aponeurosis. The level at which the sutures pass will be based on several factors, including the appearance of the muscle (is there fatty infiltration and degeneration), and the length and appearance of the aponeurosis. In any event, the level of the initial pass is by trial and error. Once both ends are passed, a bow is tied and the lid height assessed. In most cases, the aim will be to set the lid at or just below the superior limbus (bilateral cases) or 1–2 mm higher than the unoperated side (unilateral cases). Some surgeons assess lid height with the patient lying down, some sitting up. Either is acceptable and each surgeon should be consistent to better achieve more predictable outcomes. If the lid height is not correct, withdraw and reposition the sutures until the desired height is achieved.
- 8 *Insert medial and lateral sutures* once the desired lid height is achieved. The central suture is untied, and similar sutures are passed medially and laterally. The central suture is then tied, and the medial and lateral sutures are secured with a bow. The lid contour is checked and any adjustments made that might be required.
- 9 *Reform the upper eyelid skin crease.* Pass an absorbable suture from the orbicularis muscle adjacent to the inferior skin incision, onto the levator aponeurosis, making sure that the anterior lamella of the eyelid is draped over the tarsus without it being too tight or too loose. Three sutures are sufficient. The skin is then sutured separately.
- 10 *Apply antibiotic ointment.* Dressings can be applied if desired, and ice packs also.

Complications

The potential complications of ptosis surgery are many, but the commonest will be addressed here. These are:

- undercorrection,
- overcorrection,
- poor lid contour, and
- poor eyelid closure with corneal exposure.

Undercorrection

This is common. In many instances, the surgeon may aim for 'undercorrection', particularly in older patients with poor tear film and dry eyes, or in patients with myopathic ptosis where the risk of corneal exposure is much higher.

If undercorrection is present at the first postoperative visit, it is usually better to wait for any swelling or possible underaction of the levator or Müller's muscle due to haematoma to settle before reoperating. This usually means waiting six weeks or more.

Overcorrection

Mild initial overcorrection is common and should be expected in unilateral cases. There is loss of function of the pretarsal orbicularis muscle that will recover over about eight weeks, by which time the lid will drop about 1 mm, occasionally a little more.

More significant overcorrection should be corrected early. The wound can be reopened under local anaesthetic and the sutures released. The levator aponeurosis (in involutional ptosis cases) will recess by a small amount only usually. More formal recessions may be required in more severe cases, with 'hang-back' sutures from the tarsus to the free edge of the aponeurosis.

Poor lid contour

This will not resolve with time and should be corrected. This can be performed early or late. One or more sutures may need to be replaced, higher or lower.

Poor eyelid closure with corneal exposure

This is commoner in the early weeks after ptosis surgery, and can often be managed with increased ocular lubricants including ointment, especially at night when the lid may be open during sleep. Eyelid closure improves in the first eight weeks after surgery, and if after that time the corneal exposure does not settle, then consideration should be given to lowering the lid.

CHAPTER 75

Liposuction and liposculpture

Darryl J. Hodgkinson

The Cosmetic and Restorative Surgery Clinic, Double Bay, NSW, Australia

Introduction

Liposuction is the core procedure for body contour surgeons. It has evolved progressively and at times dramatically over the past three decades. Techniques have been honed and instrumentation expanded to meet the demands of the patient and surgeon for more precise fat sculpting, more refined results, less morbidity, downtime and fewer complications. Non-invasive fat sculpting tools have also been developed to reduce even further the morbidity of more invasive, traditional techniques or even avert the need for surgery or touch-up surgical procedures.

No matter which instruments or techniques are used, a thorough knowledge of the aesthetic and morbid anatomy of the area to be reshaped, is essential for a safe, reliable and attractive result. The aesthetics of each particular area need to be understood prior to and during the design and marking for the procedure.

The indications for and limitations of the results need to be appreciated. Patients' expectations need to be assessed prior to embarking on liposculpture because the results are not always predictable and may not comply with the patients' needs. Complications in the intraoperative and immediate postoperative period can be reduced by astute patient selection and following aspiration guidelines and avoiding prolonged operative time. The patient needs to be informed of these possible complications and management strategies should be in place in case problems arise.

Historical perspective

When the first presentations of liposuction reached the American Plastic Surgeons at the Hawaii meeting of the American Society of Plastic Surgeons in 1982, this heralded a transformation in body contour surgery which soon resulted in the technique of blunt liposuction espoused by its champion, Yves-Gérard Illouz, being enthusiastically endorsed internationally.¹ Courses soon sprung up, conducted in conjunction with members of the American Society of Plastic Surgeons and those who had a

particular interest in body contour surgery, including Frederick Grazer² from Newport Beach, California.

Over the last 30 years, there have been multiple contributors to the science, technology and performance of liposuction. The groundbreaking contributions of Illouz,¹ Bahman Teimourian,³ Gerald Pitman,⁴ Luis S. Toledo⁵ and others contributed greatly to the armamentarium for body contour surgery and the development of the field that has occurred due to increased bariatric surgery as a consequence of the obesity epidemic. The magnitude of the contributions made in the 1980s and 1990s has led to the performance of safer and more reliable liposuction.⁶

Indications and contraindications – patient selectivity

The optimal patient is one who has successfully completed a diet and exercise regime, but still has areas of fatty accumulation. In men these are usually in the abdomen, 'man-boobs' and 'love handles' areas, whereas in women they are usually the outer thighs, inner thighs and hips. Obese patients should only occasionally be judiciously accepted for liposuction, perhaps in isolated areas and with the understanding that there are limitations based on their health and expected overall improvement. It is generally accepted that large-volume liposuction is anything over 5000 mL of fat removal and that greater volumes of aspiration are associated with increasing complication rates.

A history of deep venous thrombosis, especially during pregnancy, long airline flights or a history of blood dysplasias, should be sought. As in any medical history, the patient's prescription medications, including antithrombotic medications, allergies, tobacco use, recreational drugs and herbal medication intake should be obtained. If patients are taking anti-anxiety medications or psychotropic medications, whether to carry on taking these medications or to desist from them needs to be discussed with the anaesthetist if the patient is to proceed with the surgery.

Physical examination

I examine the patient in front of a three-way mirror, in their underwear, to examine the whole figure and discuss the potential improvement that can be achieved with liposuction alone. The examination of each aesthetic area includes the evaluation of how fat is contributing to the distortion of the shape. Patients who have a history of exercise or sports and good muscularity as well as good skeletal axial proportions are generally better candidates for the procedure than those with poor skeletal proportions and flaccid muscularity.

Areas of fat should be observed, palpated and pointed out to the patient in the examination, and skin elasticity assessed visually and by pinch. Patients with excessively aged skin secondary to sun exposure or with stretch marks either from weight gain, weight loss or pregnancy should be told about the limitations in expectations of result based on the quality of their skin. Patients who have had multiple pregnancies with loose, lax abdominal skin and diastasis recti are generally not good candidates for liposuction; an abdominoplasty or resective body contour procedure is more likely to be suggested in this type of patient.

In examining the back, any asymmetries can be pointed out; a mild scoliosis is quite common for example. In examining, the abdomen, the plastic surgeon needs to assess whether there are associated abdominal hernias or peri-umbilical hernias which need to be dealt with as a separate issue. In patients with prior abdominal incisional scars, an abdominal ultrasound or CT scan might be necessary to clarify whether hernias are present if clinical examination is indeterminate.

Aesthetic units and design of liposuction

It is helpful to think of the body as a composite of aesthetic units which combine to form a corporal matrix of the body: the more curvaceous figure in the female and the more angular masculine shape in the male. If these composites are shaped and sculpted in an appropriate manner with liposuction, then the overall figure or shape of the patient will be improved.

Although I use computer imaging for facial surgery, I do not use it for body contour surgery, as I think it is quite possible that this could lead to patients having unrealistic expectations.

The surgeon should not be deterred by comments made by patients in an attempt to limit their results, such as 'my diet will take care of this or that area' or 'I am not worried about that, just do this and do that'. The aim of the liposuction surgery is to create an overall improvement in the shape of the torso and if areas with residual deformity are left untouched the overall shape will not be harmonious.

Before surgery the patient should have been counselled on the risks and complications of the procedure, as discussed in a later part of this chapter. No matter what machine is used, the key to the procedure will be the design, the performance of the procedure, the quality of the patient's tissues and the realistic expectations of the patient.

Preoperative marking (design)

The expected contours are drawn in on the body and a squeeze contour map of the height of the bulges of fat made using semi-permanent, different colour markers (Figure 75.1).

Figure 75.1 Sequence of design of figurative liposuction in a 45-year-old female prior to surgery, anticipating a 3 h procedure under general anaesthesia as an outpatient. Bones are represented in black, muscles in blue, fat is red and green is depressions.

Any divots, as well as cellulite and zones of adherence, should be marked with a different coloured pen during the marking process⁷ prior to the surgery. Patients may inquire about where the incisions are and how many incisions there will be; these are pointed out to the patient and those that cannot be placed in a crease are put, where possible, in the line of underwear or swimwear. Patients are often surprised to see in the three-way mirror and after the drawings that asymmetries exist; they should be reminded that any asymmetries due to skeleton or muscular asymmetries will not be improved by the liposuction procedure.

Liposuction machines

The original liposuction machines were modified aspirators used for uterine suction curettage, and the initial cannulas used by Teimourian³ were also curettage cannulas. The first commercial machines, such as the popular Grams machine, generated about 30 mmHg negative pressure. I have two of these machines still functioning; they require a minimum of maintenance on an annual basis and have been used for most of my 30 years performing liposuction.

Ultrasonic machines became popular in the 1990s⁸ and are still retained with variable amounts of enthusiasm by plastic surgeons. The newer, more contemporary, Vaser[®] machine is a more sophisticated ultrasonic machine with aspiration. It is espoused by those surgeons who claim it as valuable for body etching. Ultrasonic-assisted liposuction machines had solid probes and were of two types: one in which the emulsified fat was aspirated subsequently and the other which had associated suction attached within the probe.

Power-assisted liposuction (PAL) machines, initially air-driven⁹ but now with electrically activated motors have become quite popular. They reduce surgeons' fatigue and give more control than traditional, mechanical lipo-aspiration. Further developments include laser liposuction,¹⁰ ultrasonic¹¹ and hydro liposuction. External devices which offer modest non-invasive results over traditional techniques have also been developed utilizing ultrasound (Liposonix[®])¹² and cryolipolysis, which freezes fat externally, resulting in resorption.¹³

As with any technique, overzealous removal of fat can result in contour deformity. Newer machines that have been developed in the last 30 years introduce risks for the novice surgeon when adapting to the technique. The traditional technique stressed deep to superficial, sub-superficial aspiration with blunt cannulas. Any technique that violates the superficial plane, above the superficial fascia, risks damaging the subdermal structures with resulting irregularity to the skin, corrugations, pits and a 'moth-eaten' appearance which is difficult to treat.¹⁴

Liposuction cannulas

Traditional manual liposuction required a variety of cannulas of varying diameters and configurations to aspirate fat from a progressively deep to a superficial layer, avoiding damage to the

dermis and subdermal plexuses. A large variety of tip designs continue to be advocated and manufactured to surgeons' designs and particular affinities.

Pneumatic PAL, initially gas-powered, now electrical, facilitates back and forwards motion of a cannula, and reduces the effort required of the surgeon in passing the cannula through the fatty deposits. The cannula tips are similar to those used in suction-assisted lipectomy (SAL) cannulas. The handpiece incorporates special design tubing and the intensity of the back and forward vibration of the cannula tip can be adjusted. Near maximum speed is used in most cases. Syringe aspiration with a Tulip[®] system is also available, obviating the need for an aspiration machine. I use it for small areas or for fat harvest and fat injection techniques. Others have used it almost exclusively.⁵

Cannula choice is very individual from surgeon to surgeon, but the trend has been to use more narrow-bore cannulas.

Anaesthesia considerations

Local anaesthesia aided by sedation may be used for moderate amounts of liposuction, usually for less than 1000 mL reduction in selective areas, such as the abdomen, hips or outer thighs. The tumescent technique involves infusion of dilute lidocaine and adrenaline solution into the tissues until they are turgid, producing analgesia and vasoconstriction, allowing the removal of moderate amounts of fat without the patient undergoing general anaesthesia. For larger amounts of fat, up to 5000 mL, it is much easier on the patient and the surgeon to use general anaesthesia.^{15,16}

When contouring buttocks, posterior, inner thighs and with the patient in the prone position, general anaesthesia expedites more precise liposculpting. In the prone position, a special 'prone pillow' is used by anaesthesiologists to stabilize the endotracheal tube.

Positioning on the operating table is important. A common position is the lateral decubitus position, which was first espoused by Gasparotti¹⁴ in the early 1990s because it gives a much more precise contouring to the junctional areas between the buttock, thigh and hip, called the 'G spot' by Gasparotti¹⁴ or the 'sensual triangle' by Schlesinger.¹⁷ Although some anaesthetists are comfortable with the use of a laryngeal mask in the prone position, a well-secured endotracheal tube offers more equanimity to the whole process of liposuctioning in the prone position. Pillows positioned under the hips and chest prevent pressure in the prone position and the time spent in this position can be limited hopefully to no more than half an hour. In the lateral decubitus position, a bean bag can be used to facilitate stabilization. Care should be taken when changing the patient from the supine, to the prone and from one lateral decubitus position to the other.

Anaesthetists must be confident with the technique of the infusion of large volumes of saline, lidocaine and adrenaline into the tissues and should not overinfuse them with additional intravenous fluids, adjusting the intravenous fluids to the

amount of fluid that has been infused into the subcutaneous tissues.¹⁸

When liposuction is combined with other procedures such as abdominoplasty, thighplasty or other body contour surgeries, an indwelling catheter to monitor urinary output is advisable.¹⁹

Tissue infusion

Wetting solutions have been used for liposuction after the 'dry technique' was abandoned due to excessive blood loss and the need for autogenous blood transfusions. The solutions are generally infused with a high-pressure infuser. The solutions are warmed and infused using Klein needles until the tissues become firm, but not as turgid as in the tumescent technique.²⁰ The tissues blanch with the infusion containing adrenaline and lidocaine. Whether the wetting solution actually causes cell hydrolysis is still a matter of conjecture. It is important to warm the solutions to 37°C to prevent hypothermia. The usual infiltration is a 1:1 or 1:1.5 of the total aspirate volume anticipated. The solution is 1 mL of 1:1000 adrenaline, 20 mL of 2% lidocaine and 1000 mL of Hartmann's (Ringer's lactate) solution.

Incision placement

For the arms, a small incision in the posterior elbow and then one in the axilla is needed. For the buttocks, small incisions, generally 2–3 mm long, can be placed in creases and for the chin, a small incision underneath the mentum and one behind the ear facilitate a criss-crossing pattern of the cannula insertion. In the abdomen, incisions in the umbilicus and in the suprapubic region facilitate the same criss-cross patterning and liposhaping. Incisions for traditional liposuction, being only 2–3 mm long, are sometimes left open by some surgeons or closed with one suture to allow for drainage of the excessive fluid which remains within the tissues at the end of the procedure.

Progress of the procedure – technique

After induction of anaesthesia and positioning on the operating table, the area to be liposuctioned is prepared with diluted betadine spray until the whole area is a light brown with the markings and designs are still visible. Sterile drapes are placed around the area to be aspirated and the procedure, no matter what technique is used, progresses, utilizing visual and tactile senses to shape the particular area. By carefully observing the aspirate from the areas, excessive bleeding is prevented. When the 1 L jars are filled, they are changed and left to settle to observe the true total aspirate of fat versus infusion fluid, which is usually a light pink colour due to a small amount of blood also being aspirated.

When each position is completed, the patient is turned and supported on a bean bag, which is suctioned until it is firm so that the patient can be stabilized in both lateral decubitus positions. This position was suggested by Gasparotti¹⁴ because it accurately sculpts the buttock, thigh and hip areas.

The anaesthetist should maintain the blood pressure at about 10–20 mmHg below the patient's normal blood pressure. Urinary output monitoring is advisable for larger volumes, for longer time procedures or combined procedures.

Calf compressors are used both throughout the procedure and also in the recovery room.

Ambient room temperature should be maintained at 26°C and a heating blanket should be available during and after the procedure to maintain the body core temperature as close as possible to normal, as hypothermia is an ever present danger in large liposuctions or liposuctions lasting for an extended period of time with extensive exposure of the trunk. Antibiotics are administered intravenously (1 g cephalothin or cephalazolin).

Dressings, compression and postoperative management

After closure of all the access ports with an absorbable suture, a gauze dressing and Tegaderm are applied. There will be some fluid leakage from the incisions overnight. A compressive garment is applied by the nursing staff on the operating table and the patient is transferred to the recovery room. Analgesia will be needed after the lidocaine within the wetting solution has dissipated and then the patient is instructed to take oral medications which are individualized to the patient's needs.

All patients are outpatients and accompanied postoperatively by an adult carer to a facility close to the clinic. Contact with nursing staff and the surgeon is maintained by telephone and is available overnight. The patient is reviewed in the clinic in the morning and the dressings are changed. The patients remove their garment to shower and reapply the dressings on a daily basis, after which the garment is put on again.

Garments can be a special order but those commercially available, such as SPANX, are suitable for the majority of patients. Most patients tolerate the garments well but are pleased to be relieved of them by six weeks. They usually wear them continuously for two weeks and taper off their wearing of them over the next few weeks.

Adjunctive measures postoperatively

Early ambulation and return to normal activities are encouraged. Although bruising will resolve usually within 2–3 weeks, swelling may persist in the hips, thighs and abdomen, and lymph drainage, massage and ultrasonic treatments by a qualified physiotherapist are recommended for persistent swelling and tissues that are 'woody', indurated or bruised.

Serum needle aspiration is also indicated for collections or suspected collections of serum in the sacrum, back or hip areas. Encouraging return to regular exercise helps to facilitate swelling resolution as well as mental wellbeing.

Complications

Immediate

Haematoma and infection are generally rare, but tragic cases of necrotizing fasciitis have been reported.²¹ Venous thrombosis and pulmonary embolism are an ever present danger which should be anticipated in thrombosis-prone patients.²² Screening by history, examination and laboratory testing should identify patients who are particularly at risk and consideration should be given not only to calf compression, calf stockings and early ambulation but also low-dose heparin subcutaneously in the postoperative period for those patients deemed high risk. An episode of tachycardia or difficulty breathing are other classical signs of pulmonary embolus,²³ and a subtle elevation of temperature, malaise or failure to progress all might suggest a pulmonary embolus. Radiological evaluation, V/Q scanning or CT angiography to rule out pulmonary embolism may be necessary.

Shortness of breath in the immediate postoperative period might also alert the physician to fluid overload or an iatrogenic pneumothorax, in which case the patient should be investigated appropriately with the help of the anaesthetist. If the patient is deteriorating, transfer to a major hospital with emergency room and intensive care facilities must be considered and expedited with alacrity.

Other iatrogenic injuries include rare but documented viscous perforation, if the surgeon unwittingly enters the peritoneal cavity. The risk may be minimized by fastidious preoperative evaluation of the abdomen, including an ultrasound, especially if a previous surgical incision and possible incisional hernia is suspected. A wide diastasis of the rectus muscles after pregnancy could also be a prelude to inadvertent entry into the abdominal cavity. A patient presenting with an acutely painful abdomen after abdominal liposuction could herald this disastrous complication, needing emergency laparotomy and bowel repair.

These cases may be followed by significant infection of the abdominal wall, resulting in necrosis and requiring extensive debridement and reconstruction. A fatal outcome could be the result of such a horrific complication. High index of suspicion and expedited general surgical intervention is vital.

Hypotension in the postoperative period could be due to excessive blood loss. Knowing the preoperative haemoglobin and carefully assessing blood loss in the aspirate should indicate where a blood transfusion might be needed. Postoperative blood work should be ascertained to assess whether the haemocrit has fallen and the patient may require blood transfusion.

Plasma expanders as a volume substitute may be sufficient in a hypotensive patient or be expedient prior to transfusion, although such a sequel is very rare.

Beyond week 1

Seroma formation in areas of firmness and deep tissue induration or infections, can occur and this necessitates the careful monitoring of patients in the immediate postoperative period. Aspiration of seroma and antibiotic coverage for collections if present, are indicated.

Necrotizing fasciitis/toxic shock syndrome

These conditions are fortunately rare, but an awareness of them and a rapid response, referral to an emergency department, in particular to an infectious disease consultant and debridement are the likely sequelae to prevent progression and a possible fatal complication.^{21,24}

Other early complications

The most common problem in the first few weeks postoperatively is swelling and bruising and small seroma collections, which might require needle aspiration.²⁵ Referral to a physiotherapist for lymph drainage and/or ultrasound and massage is often very helpful physically and psychologically.

Late complications

Contour irregularities are less common with more experienced surgeons but if certain areas do not resolve, where the skin is quite adherent in the lateral thigh, posterior thigh or in the medial thigh, secondary liposuction and/or lipofilling may be needed to correct the irregularities.⁷ Usually surgeons rely on time, massage and exercise to smooth them out. Lack of skin contraction and loose redundant skin may require secondary skin resection and lifting procedures, but usually not until 9–12 months after the liposuction, to facilitate maximum skin retraction and tissue resolution.

Overzealous or novice surgeons must avoid removing too much fat, which can cause buttock ptosis or leave linear or circular defects and depressions, requiring secondary remedial surgery, such as liposuction, lipofilling or resective surgery.

Numbness and paraesthesia can occur in any area; however, the hips and arms are quite prone to this annoying sequela. The numbness and paraesthesiae are usually self-limiting within 2–3 months.

Results

Postoperative results are usually photographed six months after the procedure when the patient has resumed all their normal activities. Good results in a male patient's abdomen and a female in the typical areas, namely the hips, thighs and buttocks, are shown in Figures 75.2 and 75.3.

Figure 75.2 Abdominal liposuction in male. (a, b, c) Before; (d, e, f) after.

Secondary procedures

Touch-up procedures should be delayed for six months or more after the initial procedure.

Weight gain should be checked in the postoperative period to ascertain whether fat is residual or newly acquired. Irregularities may require lipofilling, which is available as the best remedial option if a patient's results can be realistically improved.

Certain areas, especially the buttocks, can sag after liposuction and the 'banana roll' is prone to being overresected. A 'hanging' buttock is 'ageing' and might require skin excision, although the scar after excision is undesirable for most patients. Surgical wedge excision is the only acceptable alternative for improvement in some of these patients, however, and the scarring and down side of this surgery may well convince a patient to be satisfied with the improvement in their shape and to be able to accept some degree of looseness of their skin.

Figure 75.3 Liposuction in female – abdomen, hips and thighs. (a, b) Before and (c, d) after.

Summary

In a woman, the creation of smooth and well-defined curves will always improve their figure. As surgeons, we aim to improve the shape of our patients, but the results of our efforts are closely linked to the expectations of each patient being realistic rather than unrealizable. In a male, a more angular and muscular shape is sought, paying attention to the definition of abdominal and chest wall muscularity.

Improvements in shape and figure generally make patients feel more comfortable about themselves, enabling more versatility wearing different clothes, sporting fashions and/or swimwear. Liposuction has established itself as the most valuable

body-contouring plastic surgical procedure available and the demand for it is not abating. Improved equipment and anaesthetic techniques have facilitated better and upgraded results since the introduction of this technique 30 years ago.

CHAPTER 76

Abdominoplasty and body contouring

Alexander Stoff¹ and Dirk F. Richter²

¹Practice for Plastic and Reconstructive Surgery, PAN Clinic, Cologne, Germany

²Department of Plastic and Reconstructive Surgery, Dreifaltigkeits-Hospital, Wesseling, Germany

Anatomy

A profound knowledge of the entire anatomy of the lower trunk and extremities is essential for aesthetic and reconstructive skin-tightening procedures. In addition to knowledge of the main perforating vessels, the course of any important nerve is mandatory to avoid postoperative complications. Furthermore, the knowledge of Borgess lines (relaxed skin tension lines) is crucial for the best possible scar development.¹

Skin

Abdominal skin and fat tend to become distributed in the lower abdomen with ageing and pregnancy. Striae also become common, especially as a result of multiple pregnancies, resulting in a rupture and separation of dermal collagen with consequent skin thinning. Following post-bariatric weight loss, patients have been shown to have pre-damaged skin in recent studies evaluating the content and structure of collagen and elastin compared to patients without bariatric procedures.

The skin of the abdomen has areas of increased adherence to the underlying fascia ('zones of adherence') in the vertical midline area, and occasionally in a horizontal direction just superior to the umbilicus (supra-umbilical skin fold), as well as in a horizontal direction above the anterior superior iliac crest.

Fascia

The abdominal subcutaneous tissue is divided by two layers of fascia: the superficial Camper's fascia and the deep Scarpa's fascia, a strong fibrous layer of connective tissue which is continuous with the fascia lata of the thigh.

Fat

The superficial fat layer has a more compact character with smaller lobules and a rich vascularization, while the deeper fat layer contains larger lobules with a more scattered pattern.²

The umbilicus

In most patients, the umbilicus is probably the most important landmark on the abdominal wall. It is normally situated in the midline, approximately 9–12 cm above the upper border of the mons pubis region. A round or ellipsoid shape may characterize it, in general with a depression of 4–6 cm in diameter. The abdominal fascia in this region can present as weak with an increased incidence for hernias. The blood supply derives from branches of the subdermal plexus, from both deep inferior epigastric arteries as well as a blood supply from the median umbilical ligament. In general, the umbilical stalk is blunted and dissociable from the surrounding fat tissue.

Musculoponeurotic system

The abdominal musculature includes four paired muscles: the *rectus abdominis*, connected in the median linea alba, the *external oblique* and *internal oblique* and the *transversus abdominis* muscle, which incorporate into the anterior and posterior rectus sheath at the linea semilunaris. The rectus abdominis muscles are enclosed by an anterior and posterior sheath, originating at the infracostal margin and attaching at the symphysis pubis. Above the arcuate line (situated approximately midway between umbilicus and pubic symphysis), the anterior rectus sheath is formed by the external oblique and internal oblique aponeurosis, whereas the posterior rectus sheath is formed by the internal oblique and transversus aponeurosis. Below the arcuate line, the posterior rectus sheath is absent, except for the transversus fascia and the peritoneum. At the inferior aspect of the rectus muscles, the pyramidalis muscles are present in 80–90% of patients (Figure 76.1).

Lymphatic drainage

The abdominal lymphatic system is divided into supra-umbilical drainage to the ipsilateral axillary lymph nodes and an infra-umbilical drainage into the superficial inguinal lymph nodes. The lymph vessels in the infra-umbilical area pass through the subscarpal plane, explaining the importance of Scarpa's fascia preservation in abdominal wall surgery.

Figure 76.1 Anatomy of the abdominal musculature with abdominal blood supply. Source: Plastic Surgery, Volume Two, Third Edition, Peter Neligan (ed.). Reproduced with permission of Elsevier.

Blood supply

The blood supply to the abdominal wall comes from numerous major arteries of the thorax and pelvic region, which communicate through many anastomotic interconnections. Two types of cutaneous blood supply are known: direct vessels that supply the skin directly and indirect vessels that 'emerge from the deep fascia as terminal spent branches of arteries whose main purpose is to supply the muscles and other deep tissues'. Moon and Taylor were able to demonstrate connections between the deep superior and deep inferior epigastric systems and their relationship to the cutaneous circulation.³⁻⁵

A detailed knowledge of the arterial supply of the abdominal wall is crucial to abdominal wall surgery, especially in cases of prior abdominal wall surgeries. Huger described different zones of the abdominal blood supply which should guide the surgeon in planning and performing a safe operation.⁴ Huger defined zone I of the abdominal wall as the area that is fed anteriorly by the vertically oriented deep epigastric arcade. Zone III was defined as the lateral aspect of the abdominal wall (flanks) that are fed by the six lateral intercostal and four lumbar arteries. The lower abdominal circulation is provided by the superficial epigastric, superficial external pudendal, and superficial circumflex iliac systems (zone II). A rich plexus between these systems allows collateral flow (Figures 76.1 and 76.2).

In standard abdominoplasty procedures, the blood supply to zone I and main parts of zone II is disrupted after flap mobilization, resulting in an abdominal flap perfusion mainly supplied by zone III. The lateral perforating branches from the lateral

intercostals and lumbar arteries are essential for the remaining flap perfusion. Therefore it is crucial to study any preoperative existing scar, such as subcostal cholecystectomy incisions (Figure 76.2).

Nerve supply

The sensibility of the abdominal wall derives from the anterior and lateral cutaneous branches of the 8th to 12th intercostal nerves, which reach the skin and fascia by passing between the internal oblique and transversus abdominis muscles and finally through the rectus abdominis muscle. The lateral cutaneous branches penetrate the intercostal muscles in the mid-axillary line, ending in the subcutaneous layer.

The motor branches of the rectus abdominis muscle derive from lateral branches of the intercostal nerves 5–12, which pass behind the rectus muscles and enter the muscles at the junction of the lateral 1/3 and medial 2/3. The oblique and transversus abdominis muscle are innervated by branches from the lower thoracic and lumbar dorsal nerves (Figure 76.3).⁵

Peripheral nerves such as the iliohypogastric and ilioinguinal have to be recognized, since they may be injured in lateral transverse lower abdominal incisions, resulting in consistent loss of sensory in the area of the groin and medioventral thigh.

Anatomical landmarks

Normal abdominal anatomic proportions (Figure 76.4):

- The umbilicus is located in line with the most superior point of the iliac crest in 99% of patients.

Figure 76.2 Huger's zones of superficial abdominal blood supply. Source: Plastic Surgery, Volume Two, Third Edition, Peter Neligan (ed.). Reproduced with permission of Elsevier.

Figure 76.3 Anatomical nerve supply. Source: Plastic Surgery, Volume Two, Third Edition, Peter Neligan (ed.). Reproduced with permission of Elsevier.

Figure 76.4 Anatomical landmarks with normal anatomical proportions.

- Distance between the top of mons and anterior valvar commissure (A): average height is 5–7 cm.
- Distance between umbilicus and top of mons (A + B): average height is 11–13 cm.
- Distance between umbilicus and top of anterior and vulvar commissure (C = D).
- Distance between the costal marginal and the iliac crest (E). The proportion of this distance to the width of the base of the rib cage (R) determines whether the patient is long waisted or short waisted. The normal proportion (E:R) is roughly 1:3 (long-waisted approaches 1:2, short-waisted approaches 1:3).
- The rib cage tapers inferiorly. A narrower lower rib cage relative to the width under the armpits helps to emphasize the waist by creating a subtle V.
- Hip width (H). A wider pelvis than rib cage emphasizes the waist; the waist is more defined when $R < H$.
- Natural waist (W) – the narrowest point of the torso. (Note that the umbilicus usually sits below the natural waist

by about 1–4 cm.) Relative to the hips, this waist-to-hip (W:H) ratio in healthy women is roughly 0.72:1; in healthy men, it is roughly 0.83:1. Note that the natural contour of the healthy abdomen reveals a subtle epigastric sagittal depression transitioning to a mild infra-umbilical convexity. A subtle vertical sulcus at the lateral rectus border, which is more distinct in a muscular person, may also be seen (Figure 76.4).⁶

Aesthetic assessment

Abdominal wall

The aesthetic assessment of the abdominal wall includes:

- regions of local adipose tissue and their thickness in centimetres,
- local adipose tissue in the upper and central abdominal region,
- regions of local skin excess,
- local skin excess in the upper and central abdominal region,
- presence of skin folds and their depths,
- areas of maximal looseness and adherence,
- local adipose tissue in the adjoining regions of the flanks, hips and breasts,
- local adipose tissue in the mons pubis region,
- skin laxity in the mons pubis region,
- any asymmetric aspects,
- any bulginess,
- any pre-existing scars and their quality, and
- presence and degree of striae.

Umbilicus

The aesthetic assessment of the umbilicus includes:

- shape and depth of the umbilical stalk,
- position of the umbilical basis on the abdominal wall (to be demonstrated to the patient),
- height of umbilical descent,
- any existing umbilical herniation or adipose tumour,
- any existing eczema, hyperpigmentation or pre-existing scars, and
- any prior operation in the umbilical region has to be clarified, since impaired perfusion after dissection may occur in these cases.

Back, thighs and buttocks

The aesthetic assessment of the back, thigh and buttocks includes:

- regions of local adipose tissue and their thickness in centimetres in the back,
- mobility of the dorsal skin in the lower back region,
- local skin excess in the back region,
- presence of dorsal skin folds and their depth,
- local adipose tissue in the gluteal region,

- regions of local skin excess, measured by pinching in vertical distance in the gluteal and flank region,
- presence of gluteal skin folds and their depths,
- areas of maximal looseness and adherence,
- local adipose tissue in the anterior, posterior, lateral and inner thigh region,
- skin laxity in all thigh regions,
- presence of skin folds in the thigh region (e.g. inner thigh, distal anterior),
- any asymmetric aspects,
- any bulginess,
- any pre-existing scars and their quality,
- any existing eczema or hyperpigmentations, and
- presence and degree of striae.

Patient assessment

History

During the patient's first consultation a review of the medical history is mandatory. We recommend a repeat of evaluation prior to surgery, if it is performed with a delay since the first consultation. The assessment of medical history includes the current weight, the ABSI (a body shape index) and body mass index (BMI), the weight history with weight fluctuations and constancy periods, the frequency of exercises, former bariatric procedures, nutritional disorders, medication, the number of pregnancies and children, history of caesarean section, abdominal surgeries and abdominal hernias, gastrointestinal, cardiac and pulmonary history, and a smoking history. Patients should be asked specifically about previous liposuction in the abdominal area, since they might conceal this prior treatment.

Physical examination

Physical examination is part of every medical history assessment. It evaluates the entire region the patient is concerned about. An examination of the skin tissue and the different fat layers is performed by pinching and measuring the subcutaneous layer thickness. Skin quality with the presence of striae should be evaluated, clarifying with the patient that supra-umbilical striae will not be resected in abdominoplasty procedures (except for fleur-de-lis procedures). In this context, it is helpful to hand out studies on skin quality in post-bariatric patients that have demonstrated damage to collagen structures.^{7,8}

Next, it is important to assess and measure the lower and upper abdominal pannus, documenting any existing eczema or consequent hyperpigmentation. The entire skin excess in the areas inferior to the lower abdominal fold, in the area of the lateral and upper abdomen, the waist, hips and thighs as well as the lower chest have to be included in the preoperative assessment, during upright standing, supine as well as sitting positions. Any pre-existing scars (subcostal, midline, horizontal) in the abdominal area have to be documented, since they can impair the blood supply. Furthermore, the status of the

abdominal musculature should be assessed and any existing rectus diastasis, incisional, epigastric or umbilical hernia excluded. Supportive CT or MRI scans may be performed.

In this context, it is mandatory to evaluate intra-abdominal pressure to avoid any postoperative pressure increase or abdominal compartment syndrome. In cases of elevated intra-abdominal pressure, in the supine position, the abdominal wall elevates above the costal margin and the level of the iliac crest. Abdominoplasty procedures, especially with fascial reconstruction have to be performed cautiously in such cases.

Documentation

It is mandatory to ensure a complete photographic documentation pre- and postoperatively, consisting of different views (anterior, oblique, side and posterior). Postoperative photo documentation can be made at 3, 9 and 12 months. In individual cases it is recommended to perform additional photo documentation of certain arm and thigh positions, tissue characteristics with relaxed and contracted muscles, the patient in sitting position to demonstrate redundant upper abdominal laxity and tissue excess, additional views with the patient holding up and pinching excess tissue in the specific region.

Informing the patients in detail about the operative procedure, alternative techniques and the general and operation-related risks and benefits is an essential part of preoperative documentation. Besides standard and individualized consent forms, which have to be reviewed and signed by the patient at the earliest opportunity and at the latest 24 h prior to the operation, we recommend an audio-visual demonstration for exact understanding. In general, we recommend informing every patient ruthlessly about any imaginable complication. Moreover, patients have to be informed about their postoperative care, including their expected level of activity, and the limitations of the surgical result in cases of existing variables of bone structure, fat distribution and any existing scars.⁹⁻¹¹

Aesthetics

The preoperative aesthetic status of the body region of concern has to be well documented in written and photographic form after a precise physical examination. For a classification of the different deformities, we found the Pittsburgh Rating Scale to be helpful for patient demonstration and selection of the best operative approach.¹² However, we experienced a wider indication for the combined technique of liposuction and excisional procedures in all body regions.

General

Patients are advised to stabilize their weight for at least 6–12 months preoperatively; any desired weight loss should be completed prior to the surgery. Smokers should stop smoking at least six weeks prior to surgery. Patients should take antiseptic showers in the evening and morning prior to the surgery; the skin folds and the umbilicus should be cleaned thoroughly with antiseptic solutions.

If a postoperative blood transfusion is considered (e.g. body lifts), patients have to be informed preoperatively, as this requires a blood typing and informed consent. Anticoagulant drugs and supplements must be avoided 14 days prior to surgery. In cases of a planned abdominal procedure, we advise patients to perform bowel purgation the night before surgery. In severe cases, patients can be restricted to a fluid diet for 24 h prior to surgery.

Patients have to be informed about the intraoperative procedures, including any change of position with the risks of postoperative complication, antithrombotic arrangements, Foley's catheter, drains and garment placement, as well as patient-controlled analgesia. Moreover, they have to be instructed about the postoperative course, regarding thromboembolism prevention, respiratory exercises, early mobilization, avoidance of high abdominal pressure, the estimated time point for drain and suture removal as well as the minimum time required off work and away from exercise. Also, it has to be noted, if the operation cannot be performed as an outpatient, how long the patient will expect to have to stay in hospital.

Diabetes may be a relative contraindication to this procedure, especially in poorly controlled patients. Furthermore, it is important to exclude any skin irritation or inflammation in the area of the abdominal fold and umbilicus. An inspection of these areas during consultation, as well as immediately prior to the operation is strongly advisable.

Prophylaxis for pulmonary embolism and deep vein thrombosis is an essential consideration, especially in smokers and patients taking birth control medications or hormone replacement therapy.¹³ We initialize heparin therapy in all patients the evening before surgery or at latest 2 h prior to the surgical procedure. We inform patients that this specific risk will be decreased if hormonal therapy is discontinued 3–4 weeks prior to surgery.

In cases of an existing extended diastasis or hernia, the reconstruction of the fascia results in an increased intra-abdominal pressure, which may be a source of respiratory difficulties. Therefore, we advise preoperative breathing exercises (utilizing an incentive spirometer) beginning 1–2 weeks prior to and continuing for 2 weeks after the surgery. A cold, dry cough or any kind of respiratory infections should lead to postponement of surgery, since fits of coughing may provoke a rupture of the fascial sutures with consequent secondary bleeding.^{9,10,14}

Operative principles and approach

Various procedures are available with various indications as listed in Table 76.1.

Liposuction

The indication for sole liposuction of the abdomen is seen very rarely. In patients with an abdominal contour impaired by an irregular and solely thickened abdominal fat layer, liposuction may improve the abdominal shape dramatically. Nevertheless, as soon as a patient highlights his or her frustration due to a laxity of skin, it will not be worthwhile to perform liposuction without simultaneous skin excision. Ideal cases for liposuction are patients with localized adipose tissue in the flank/hip region, the infra- and/or supra-umbilical region. They can be optimally treated by liposuction under local anaesthesia as an outpatient. For achievement of maximum outcomes, it could be reasonable to acquire one of the assisted liposuction techniques nowadays available (e.g. laser-, ultrasonic- or radiofrequency-assisted liposuction), which allow simultaneous skin tightening.

In all cases of liposuction in the abdominal region it is mandatory to exclude any existing rectus diastasis or abdominal hernia. If required, diagnostics should include an ultrasonic scan, CT or MRI (Figure 76.5).

Any adjunctive liposuction of the abdominal wall should be performed prior to the abdominoplasty procedure in order to sufficiently thin out the different layers, including the epifascial and subfascial layer.¹⁵ It is important to assess the relation of excess skin and fatty tissue, since in cases of extensive skin excess in the upper and mid-abdominal region a fleur-de-lis procedure may be indicated. In these cases, there is usually no necessity for liposuction in the abdominal region, since a maximal amount of abdominal tissue is resected.

Adjoining regions (e.g. the flanks and hips) may be treated by liposuction during the abdominoplasty procedure, preferably at the end of the operation. Infiltration of tumescence solution should be performed at the beginning of the procedure and liposuction can then be performed after a sufficient time of exposure during the abdominoplasty procedure.^{6,11}

Table 76.1 Indications for different techniques dependent on redundant adipose tissue⁶

	Mini	Standard	HLT	Fleur-de-lis	Body lift	Reverse
Lower abdomen	+	+++	+++	+++	+++	0
Peri-umbilical	(+)	++	++	+++	++	(+)
Upper abdomen	0	++	++	+++	++	+++
Diastasis/hernia	(+)	++	++	+++	++	(+)
Flanks/hips/thighs	0	(+)	+	++	+++	0

HLT, high lateral tension.

Standard abdominoplasty

The standard abdominoplasty is one of the most common procedures in plastic surgery. It enables the simultaneous treatment of the upper abdomen, peri-umbilical area and lower abdomen with optimally concealable scars.

Former traditional abdominoplasty procedures involved wide mobilization of the abdominal wall up to the costal arch in order to ensure a tension-free wound closure. Multiple studies have since demonstrated that circulatory disturbance of the abdominal skin flap is the result of extensive undermining and destruction of the lateral perforators of Huger's zone II. In modern abdominoplasty undermining cranially to the umbilicus is mainly performed in the midline area anterior to the linea alba and both rectus muscles, including the zones of adhesion described by Lockwood and specified by Aly. The lateral abdominal flap may be securely released by additional liposuction or the Lockwood dissector for discontinuous undermining, preserving the lateral perforators and the lateral attachment to the rectus abdominis muscles.^{16–19}

The standard abdominoplasty is indicated in patients that typically demonstrate a localized and diet-resistant adiposity of the abdominal wall in combination with coexisting slack and atonic skin, such as patients after multiple pregnancies, patients with weakness of the connective tissue or patients after weight loss (Figure 76.6).

Markings

The markings are started in upright position with the midline, the borders of the patient's underwear and the expected and desired scar position. Next, the patient is asked to elevate the redundant abdominal tissue for identification of the abdominal fold. A vertical distance of 6 cm is measured from the upper vulvar commissure to the lower incision, followed by marking of the lower incision line parallel to the abdominal fold. By pinching of the abdominal tissue, the upper incision line is

marked next, which can be checked in supine position. It is advisable to mark parallel lines at various heights to ensure a symmetric resection. The patient should always be informed about the risk of an inverted T-scar in the midline if the resection does not completely include the umbilical incision.

Evaluation of possible pre-existing hernias and diastasis should be performed and marked in the supine position. Furthermore, the length of the scar line may be measured bilaterally starting from the midline to ensure symmetry. In this context the surgeon has to be aware that a longer inferior incision will lead to a gently curved upward course of the scar (Baroudi) and a longer superior incision will cause a straighter or downward course of the scar (Pitanguy).^{20,21}

Technique

The operation is started with a repetitive check and trace of the markings. It has to be ensured that the umbilical stalk is thoroughly cleaned.

Initially, the lower incision line is infiltrated with local anesthetics to reduce postoperative pain and the consecutive risk of blood pressure increase. After incision of the lower incision line, preparation is performed down to Scarpa's fascia after ligation of any superficial epigastric vessels. For adequate preparation of Scarpa's fascia, we recommend use of the Colorado® Microneedle and to ensure a sufficient upward pull of the abdominal flap. By preservation of Scarpa's fascia the subjacent lymphatic vessels are preserved. In general, we find a thin fat layer below Scarpa's fascia. Continuous dissection superficial to Scarpa's fascia is performed cranially up to a level as wide as 3–4 fingers inferior to the umbilicus. At that height, Scarpa's fascia is incised, and dissection continues down the anterior rectus sheath.

At the height of the umbilicus, the abdominal flap is incised in the midline and the umbilical stalk is transected circularly and completely mobilized (skeletonized without any remaining fat tissue) from the abdominal flap. Especially in patients after

Figure 76.6 (a, c) A 42-year-old woman with a significant abdominal pannus after three pregnancies and a fluctuant weight of 40 kg. (b, d) Three months after a standard abdominoplasty with a good contouring of the umbilical region.

massive weight loss, the umbilical stalk has to be shortened and fixated to the anterior rectus fascia at the height of the stalk's base, preferably with absorbable sutures at 3, 6, 9 and 12 o'clock positions. Further dissection continues superior to the anterior rectus fascia up to the xiphoid. The linea alba can easily be identified as it is distinctively connected to Scarpa's fascia. In the area of the costal margin, it is essential to restore the lateral perforators for sufficient flap perfusion. At this time point, after finalization of the abdominal flap mobilization, in cases of concomitant rectus diastasis, the plication of the anterior rectus sheath from the xiphoid to the symphysis is accomplished using non-absorbable or absorbable suture material in any preferred technique. In case of a diastasis at the lower abdomen, Scarpa's fascia and underlying tissue may be bluntly mobilized to allow for further midline fascial plication (Figure 76.7). For cases of asymmetrically located umbilical stalk or for further accentuation of waist tightening, an additional paramedian plication of the anterior rectus sheath may be facilitated. Since lateral dissection is avoided up to the costal arch for preservation of the lateral perforators, a discontinuous separation of lateral adhesions using the Lockwood underminer may enable a further flap mobilization.

During tissue resection, bullet forceps or a Pitanguy tissue demarcator can support the estimation of the upper resection line. Further evaluation of the amount of resection may be facilitated by additional vertical flap incisions and temporary wound closure utilizing bullet forceps. The upper incision line is then marked and the resection is performed oblique to the wound edge in a 45° angle to enable a more precise adaptation of varying thick layers. In selected patients with a pronounced abdominal fat layer the fatty tissue beneath Scarpa's fascia should be resected in the entire mobilized area. This may avoid postoperative complications due to superinfected fat necrosis.

After meticulous coagulation the wound is closed temporarily. The new umbilical position is estimated and marked. Several umbilical incision patterns have been described; we prefer the superior based inverted V or U incision. This umbilical section of the abdominal flap is then circumferentially defatted for a circular umbilical depression. The supra-umbilical midline may also be reduced through midline liposuction or open excision. After repeated meticulous haemostasis, Scarpa's fascia is sutured down to the anterior rectus fascia with absorbable progressive tension sutures (Baroudi stitches), starting

Figure 76.7 (a) A 42-year-old woman after two pregnancies and a subsequent rectus diastasis. (b) Three months postoperatively after fascial tightening and standard abdominoplasty.

superior to the umbilicus. Alternatively, the supra-umbilical subcutaneous tissue may be sutured in the midline to the anterior rectus fascia to accentuate a midline depression for superior aesthetics. After the umbilical stalk is pulled through the new umbilical tunnel, additional progressive tension sutures are placed in the lower flap area.

Finally, the patient is bent into beach-chair position and temporary wound closure is performed with bullet forceps, starting laterally to medial. In order to avoid dog-ears, the longer superior wound edge is shifted slightly medially to adapt to the shorter inferior. After the placement of 2–3 drains the final wound closure is performed for all layers, starting with a reconstruction of the superficial fascial layer with absorbable sutures, followed by a subcutaneous readaption and completed with intradermal running sutures. For time reduction in wound closure the use of absorbable barbed sutures (e.g. Quill®) is routinely advisable, such as PDO 2×0 for fascial and subcutaneous closure and Monoderm 3×0 for intradermal closure. Optionally, skin closure time can be drastically reduced applying the two-component skin closure system PRINEO™.²²

After a final wound antiseptic cleaning, suture strips are affixed transversely to the scar. These supportive dressings should remain for three weeks postoperatively. Finally, a sterile wound dressing and an adjustable compression girdle are applied.

We prefer to perform the standard abdominoplasty procedure on an inpatient basis with a minimum 1–3 nights' hospital stay. A slight postoperative discoloration of the umbilicus is usually not precarious, especially when there was no previous surgery of the umbilicus. A complete necrosis of the umbilical stalk is seen very seldom and may be treated conservatively with satisfying results.

Patient satisfaction after standard abdominoplasty is usually high due to a possible treatment of the entire abdomen.

However, the legacy of a long scar with limited treatment effects to the hips and the back region is an unfortunate aspect of this procedure for a certain patient group. In cases of fascial midline plication a tissue gathering may result in the epigastric region. This tissue excess may be easily and safely reduced by open excision or additional liposuction.^{6,11}

Mini-abdominoplasty

The mini-abdominoplasty differs from a standard abdominoplasty in a shorter resulting scar and restricted skin resection. The results of the short scar technique were limited until adjuvant liposuction and endoscopy-assisted procedures had been added for improved results. In this procedure, the extent of mobilization can be increased and the umbilical stalk may be released pre-fascially for inferior repositioning to the anterior rectus fascia (Figure 76.8).

This procedure is indicated in patients with a mild to moderate skin laxity and tissue excess of the lower infra-umbilical abdomen, together with a sufficient distance between the umbilicus and symphysis, mostly more than 12 cm. Liposuction of the upper abdomen and flanks has a supportive effect by improving the abdominal contour. In cases of coexisting diastasis recti or epigastric herniation they can be treated through an endoscopic approach. With respect to vascular anatomy, the mini-abdominoplasty is a safe procedure since a single Huger's zone (zone II) is compromised. In cases of peri-umbilical skin laxity, an umbilical transection can be performed to allow a more effective tightening and an improved visualization of the diastasis recti (Figure 76.9).

Markings

Markings are performed with the patient in the upright standing position. The distance between the umbilicus and the upper incision line should respect a minimum distance of

Figure 76.8 A 31-year-old patient after two pregnancies with two caesarian sections. Pre- (a, b) and postoperative (c, d) oblique and front views of a short scar (mini) abdominoplasty without umbilical transection. Note the low placement of the previous scar.

9 cm to avoid an unaesthetic appearance. For cases with redundant tissue in the lower abdomen and a relatively high position of the umbilicus (approximately 14–18 cm above the pubic symphysis), the lower incision line is marked 6 cm above the labial commissure and the upper incision line 9 cm below the umbilicus. In cases of a distance less than 9 cm after skin resection, an inverse T-scar with umbilical transposition should be preferred.

Regarding the required scar length, the fat distribution in the region of the iliac crest should be evaluated preoperatively and the patients has to be informed about an optimized cosmetic outcome despite a prolonged final scar length.

Technique

This procedure can be performed under local anaesthesia and adjuvant sedation. If a reconstruction of the anterior rectus sheath is required, we recommend general anaesthesia or spinal anaesthesia.

Any supportive liposuction of the abdominal wall and flanks should be performed prior to the abdominoplasty procedure in order to sufficiently reduce the epi- and subfascial layer. Techniques such as radiofrequency- or ultrasonic-assisted liposuction may generate shrinking of the skin for additional skin-tightening effect. In young patients with an elastic skin tone and a long distance between the umbilicus and symphysis an umbilical transposition may be avoided.

The operative technique is similar to a standard abdominoplasty, although abdominal flap mobilization is performed adjusted to local tissue characteristics. In all cases, tissue dissection is performed above Scarpa's fascia. The abdominal flap is mobilized cranially up to the level of the umbilical stalk. If a supra-umbilical rectus diastasis was diagnosed preoperatively we recommend a transection of the umbilical stalk from the anterior rectus fascia and continuing the dissection to the xiphoid and costal margins. The umbilical base should be marked for its refixation. After plication of the anterior rectus fascia the umbilical stalk is fixated to the abdominal wall. For this manoeuvre non-absorbable or absorbable suture material can be used. The abdominal flap is drawn caudally and the umbilical range of motion can be assessed. Hereby, the umbilicus may shift caudally. Prior to the final determination of the upper incision line the fixation of the umbilicus should be completed. Markings should always be done on stretched skin and adhere to a distance of minimum 9 cm between umbilicus and upper incision line.

In patients without a diastasis recti or epigastric hernia flap mobilization is performed cranially up to the umbilical stalk. The estimation of the amount of tissue resection and wound closure are always performed in the same manner as described above. In cases of fascial reconstruction or hernia repair drains may be inserted, in simple procedures without any adjoining procedure they may be dispensable. Patients with a diastasis recti and consequent potbelly with mild skin excess may be appropriate candidates for this technique with impressive improvements after concurrent plication of the anterior rectus sheath.^{6,11}

High lateral tension (HLT) abdominoplasty

In the 1990s Ted Lockwood presented this modified abdominoplasty procedure, which allows a full treatment of the abdomen and limited treatment of the hips and the lateral thigh in terms of a modified incision pattern.¹⁶ Lockwood enumerated several surgical principles that were in many ways diametrically opposed to the ones of a standard abdominoplasty, namely, an extensive discontinuous undermining and a more conservative resection centrally with wider excision of the lateral skin. This procedure finds its rare indication in patients after moderate to massive weight loss, who refrain from circumferential procedures. Nowadays, since most of these patients are likely treated by a circumferential tissue resection, indication for the HLT abdominoplasty is rarely given.

Female patients usually suffer from an additional skin laxity in the lateral thigh region, whereas male patients complain about the typical fat distribution in terms of 'love handles'.

Figure 76.9 A 44-year-old patient after three pregnancies with two caesarian sections. Pre- (a, b) and postoperative (c, d) oblique and front views of an abdominoplasty with umbilical transection. Note the low placement of the previous scar and the high-riding umbilicus as well as the infra-umbilical diastasis recti.

The experienced surgeon may however be confronted with a HLT abdominoplasty procedure that results with lateral dog-ears, despite the extent of lateral tissue excision and scar elongation. Additional liposuction may be supportive, although often insufficient due to a surplus of lateral skin.

Markings

Preoperative markings are similar to those for standard abdominoplasty markings. The inferior incision line is continued laterally to the anterior axillary line and runs upwards to the mid-axillary line at an angle of 45°. The upper incision line starts at the highest point of the umbilicus, continuing parallel to the lower incision line until the anterior axillary line, then turning downwards at an angle of 45° to meet the lower line in the mid-axillary line to form an angle of 90°.

Technique

For this procedure it is helpful to position the patient on an additional cushion in the gluteal area for elevation of the flanks and lateral thighs and optimal access to these regions. Alternatively,

the patient may be changed into a lateral position. The operative technique is similar to that for standard abdominoplasty, although central abdominal flap mobilization is more limited and as far laterally as necessary for a required rectus plication. Additional flap advancement can be achieved through vertical discontinuous undermining, utilizing the Lockwood dissector. The lateral skin resection pattern with significant lateral resection is performed with a subsequent high-tension wound closure. For the lateral wound edges a reduction of subdermal fat and, if necessary, a lengthening of the incision may be performed in order to avoid dog-ears. A lateral elongation of the scar has to be acceptable for a satisfactory result; this is generally well accepted by the patients. Since the lateral abdominal perforators are preserved, extensive liposuction of the entire abdominal wall may be securely performed.^{6,16}

Fleur-de-lis abdominoplasty

Fleur-de-lis abdominoplasty is the most powerful procedure for maximal tightening of the entire abdomen and reshaping the lower body. It was popularized in 1985, and derives from

techniques previously described by Regnault (classic W technique) or Kelly (1910) and Babcock (1916).^{23–26} The procedure enables the elimination of vertical and horizontal tissue excess on the lower and upper abdomen. Using this approach, a maximum improvement of body shape and reduction of waist circumference is achievable. In cases of large abdominal pannus or patients with existing medical handicap, it can be performed as a two-stage procedure. In general, we advise refraining from lateral undermining for maximal preservation of perforators. Furthermore, we recommend a check of the markings intraoperatively prior to resection to avoid postoperative complications.

The suitable indication for this technique is an adequate, mainly horizontal tissue surplus of the lower and, in particular, the upper abdomen, usually in patients after moderate to massive weight loss. Any patient who presents with a pre-existing midline scar may be considered primarily for this technique. To date, we have not experienced a single patient complaining about the midline scar, although we have observed a more pronounced scar formation in the upper median abdomen. However, in cases where horizontal tissue resection was avoided for less scar formation, we have had patients complaining about postoperative existing tissue surplus in the upper abdomen. In these cases, a secondary horizontal tissue resection may be indicated.

In patients with a vertical tissue surplus in the upper abdomen and a request for a breast procedure requiring a submammary incision, an additional reverse upper abdominoplasty may be considered.

Markings

Preoperative marking should be performed while the patient is standing upright. In supine position the lateral tissue moves backwards and makes an accurate estimation of tissue excess difficult.

After marking the lower horizontal standard abdominoplasty incision line at a height 6 cm above the vulvar commissure, the midline should be marked precisely, with the highest point approximately 2–3 cm below the submammary fold. Next the tissue surplus is estimated through precise pinching of the skin and marked in an elliptical pattern. With the patient in supine position the distance from each line to the midline should be measured and equalized if necessary, since any small mismatch may result in an uneven midline scar. Next, the upper horizontal incision line is marked. This line should generally run 3–5 cm inferior to the umbilicus. Finalized markings usually result in an omega-like figure (Figure 76.10). We recommend limiting the superior extent of the scar line primarily by local superficial liposuction rather than a more superior excision. Finally, all vertical and horizontal markings should be checked and measured in upright and supine positions.

Technique

Single-shot antibiotic prophylaxis should be mandatory in this procedure due to the large wound areas and a prolonged operating time. Abdominal flap mobilization is performed as in

standard abdominoplasty procedures, except that the lateral flap mobilization should strictly be limited to the height of the upper incision line to preserve maximal perfusion of the lower medial apex of the flap. As soon the mobilization of the umbilical stalk has been completed, the entire estimated vertical and transverse resection area is temporarily closed using bullet forceps and the required marking adjustments performed. Next, the incision lines are incised and the redundant tissue excised in a monobloc fashion. After haemostasis the flaps are temporarily adapted and drains inserted.

The umbilicus has to be integrated into the vertical scar, and this should be performed in straight and not bended position. At the appropriate umbilical height a limited transverse incision is made on both abdominal flaps with reserved circular fat excision in the peri-umbilical region. The umbilical stalk is then adapted to the abdominal flaps, allowing skin excisions for optimal incorporation. A secondary aesthetically displeasing trumpet-like widening of the umbilicus may result from extensive peri-umbilical skin removal. Therefore we recommend a step-by-step excision with observation of any transverse tensile forces. In general, we insert three or four drains (including the upper abdomen) during subcuticular and intradermal wound closure.

If flap mobilization in the lateral aspect is limited to the resection line and therefore a maximal preservation of perforators established, flap perfusion and dermal wound healing should be uncomplicated. Despite the long scar formation, the aesthetic improvements to the hip and waist are dramatic and not comparable to any other abdominoplasty technique. Furthermore, the back and flank folds may be improved due to maximal recruitment of lateral skin (Figure 76.10).

Postoperative care

The different operations can be performed as outpatient or inpatient surgery. If the hospital offers an intensive or intermediate care unit, patients may be monitored after circumferential procedures for the initial 24 h postoperatively. For reduction of superficial wound tension, we intraoperatively apply transverse vectored Steri-Strips™ for the first three weeks. During the initial 48 h postoperatively, laboratory checks for electrolytes and haemoglobin are performed several times. After abdominoplasty and circumferential procedures, patients are positioned in beach-chair position, if available on an air mattress, with electronically adjustable positions. Thrombosis prophylaxis is administered using low-molecular-weight heparins and compression stockings. Initial wound care includes an antiseptic fluid-collecting dressing, in abdominoplasty and body lift cases two compression girdles, in breast cases a zip sports bra and in arm and thigh cases a circumferential winding. The immediate postoperative compression therapy reduces shearing forces supporting the adhesion of different tissue layers. In this context, drains may remain for a minimum 4 days postoperatively for a

Figure 76.10 (a, c) A 49-year-old woman with a weight loss of 50 kg after Roux-Y bypass. (b, d) Three months postoperatively after fleur-de-lis abdominoplasty and breast reshaping. (e) Markings. She was recommended for a lower body lift, but denied the circumferential procedure due to her financial situation.

negative intracavitary pressure. They are removed when drainage is less than 30 mL in 24 h. Patients are instructed to move their feet frequently and not to cross their legs.

All patients receive pain treatment within the initial 48 h postoperatively, utilizing an individualized patient-controlled analgesia (PCA) pump. Patients are mobilized on the first postoperative day and instructed to do deep breathing exercises to prevent pneumonia. The urinary catheter, which is indicated in any prolonged procedure such as circumferential or combined procedures, is removed after 2–3 days to help with patient mobilization.

Showering is generally permitted after drain removal. Postoperative clinical examination should investigate the possibility of seromas. In cases of hernia or diastasis rectus repair, patients should be asked about bowel function; abdominal auscultation, percussion and ultrasound might be advisable. Any non-resorbable sutures or wound closure material is removed at the latest three weeks postoperatively. For at least three months postoperatively we recommend our patients to cover the entire scars with silicon-sheets for improved scar formation.

Sporting activities should not be resumed for eight weeks postoperatively. Patients should be advised to avoid saunas and

tanning beds. Before patients are discharged, we individually adapt a compression garment for eight weeks postoperatively.

Complications

General symptoms after skin-tightening procedures include postoperative pain or soreness, numbness of the abdominal flap, bruising, general fatigue and discomfort due to increased skin tension for many weeks.

Local complications in all regions include haematoma, seroma, wound infection, fat necrosis, wound dehiscence, paraesthesiae and persisting numbness. Seromas are a very common problem in the abdominal region and usually handled with serial punctures and drainage. Persistent seromas may require a secondary surgical procedure. In general, seromas should be detected in time and treated by simple aspiration to avoid a superinfection or any consequent wound separation.

Minor wound dehiscences are common and self-limiting. Significant dehiscences may be caused by increased tension or marginal wound necrosis. Appropriate treatment of wound necrosis is initial conservative wound care, until the area of necrosis has been demarcated for surgical revision. Additional flap advancement may allow optimal secondary wound closure. Further local complications include dog-ears, hypertrophic or malpositioned scars, and in the abdominal region cosmetic problems related to the umbilicus. Most of these issues can be avoided with good preoperative planning and attention to surgical detail.

Treatment by liposuction may lead to postoperative contour irregularities and dermal tethering. Further swelling may occur in cases of circular liposuction of the extremities.

Systemic complications include deep vein thrombosis, pulmonary embolism, fat embolism, respiratory compromise due to increased intra-abdominal pressure in abdominal cases with fascial tightening and systemic infections including toxic shock syndrome. All of these complications may be potentially lethal. In general, abdominoplasty procedures have a higher systemic complication rate than any other type of routine cosmetic surgical procedures.^{6,9–11,19}

Body contouring after massive weight loss

Reconstructive procedures after massive weight loss resulting from bariatric surgeries or diet therapy include abdominoplasty, lower body lift, upper body lift, breast lift, upper lateral thoracic lift, bra-lift, thigh lift, lower leg lift, upper arm lift, lower arm lift and facelift/neck lift.

Preoperative management

A patient's first consultation should include a detailed description of all procedures planned for reconstruction. It is essential, that the patient be informed about the number of surgical stages

that will be necessary for the desired changes, including any secondary skin-tightening procedures. We recommend clarification of all important issues using a PowerPoint presentation with all available images, including photo documented complications. The patient should be informed about all possible complications. It is clear that the patient will base their decision to be operated on by the designated surgeon on this first consultation.

Prior to the surgery the patient should consult the surgeon for a second time to discuss all open issues. At this time, the patient has to sign the informed consent. We recommend schematizing all discussed scar courses and important tissue displacements. The patient has to be informed about the optional placement of drains, urinary catheter, and type and placement of suture material. Furthermore, any additional proposed manoeuvres (e.g. fascial reconstruction or Scarpa lift) should be clarified.²⁷

Since patients having bariatric procedures may suffer from nutritional deficiency due to a disturbance of nutrient uptake, we ask all patient to have a current blood test during their first consultation as well as prior to the surgery to avoid any late failures regarding the operative scheduling. Any coagulant dysfunction has to be evaluated and excluded preoperatively, where necessary by way of consultation with a haematologist. In this regard, we advise all patients about the supplement of all necessary nutrients (including zinc, selenium, vitamin C) four weeks prior to and four weeks after the surgery.

The sequence of surgical procedures may be discussed with the patient and optionally adapted between the single steps. We favour starting the reconstructive process with the lower body lift, followed by any further indicated procedures. The time frame between each stage should be at least 2–3 months for sufficient recovery.^{9,10,19}

As an important adjuvant therapy in body contouring we offer every patient with obvious connective tissue weakness (striae distensae) the repeated implementation of a surgical needling therapy, initially during the lower body lift procedure. Surgical needling is performed in all requested regions and should be performed in all existing scar areas, leading to a superior scar and skin quality.

Circumferential lower truncal dermatolipectomy

A lower body lift (circumferential lower truncal dermatolipectomy, CLTD, our modification of a lower body lift) is indicated in almost every patient after weight loss. The patient should be informed about the pro and cons of abdominoplasty versus circular procedures.^{9,10}

Markings

Markings are performed in upright standing position. First, the patient is asked to pull up their entire lower abdominal tissue in a symmetric manner. Meanwhile, after the midline has been drawn, a distance of 6 cm to the upper vulvar commissure is marked. At this height an almost horizontal lower incision line is marked to both flanks, followed by the upper horizontal incision line at the height of the umbilicus. Next, the patient has to

turn and the posterior markings are performed. The upper incision line is marked, starting at the highest point of the gluteal cleft and running upwards in a round curved shape to the lateral end of the anterior upper incision line. Finally, the lower incision line is assessed and marked by pinching and connected to the lower anterior incision line.

Technique

Dorsal preparation

The initial skin incision is made along the superior marking line and is carried out down to the level of the underlying superficial fascia, which is exposed using the Colorado Microdissection needle. This easily separates the superficial lamellar from the subfascial lobular fat. Next, the dissection is continued inferiorly just above the superficial fascia. The preservation of fascia to the deep gluteal fat as the 'gluteal superficial muscular aponeurotic system (SMAS)' is conceptually similar to the 'facial SMAS' used in facelifts. The superficial fascia is dissected at the height of the inferior resection line, before flap mobilization is continued further caudally. Lateral gluteal adhesions are released bluntly down to the height of the gluteal fold, before dissection is continued to the lateral thigh, where preparation level is above the tensor fascia lata muscle. Further distal mobilization of the lateral thigh can be carried out bluntly using the Lockwood underminer. With completion of dissection, the waist and gluteal fatty tissue is widely mobilized and covered with robust superficial fascia. This is particularly suited for autologous gluteal augmentations, since patients after massive weight loss frequently have flattened buttocks. For this purpose, 2–3 1 × 0 threads are sutured from lateral to medial, grasping the stable fascia and consequently displacing the gluteal fatty tissue to the middle of the buttocks. For cranial repositioning 3–4 1 × 0 non-absorbable threads are sutured from caudal to cranial at the medial aspect of the buttocks. Reconstruction and tightening of the gluteal adipose tissues lift the gluteal flaps cranially with a subsequent final skin closure under less tension. Furthermore, this manoeuvre improves the shape of the waist.

Detachment in the zones of adherence combined with extended mobilization allows an enormous tightening of skin. A symmetrical resection is then undertaken. We advise use of bullet forceps for determination of the amount of resection. Next, the flap is incised laterally and adjusted for maximum tension. The redundant gluteal flap arising in this way with its lower incision line is measured precisely in the tensed condition for symmetry before the resection of the flap is performed.

In general, the superficial fascial system (SFS) is extremely stable and allows a sufficient suturing for reconstructive purposes. After reshaping the SFS, wound closure is performed in multiple layers with resorbable suture material (see above). Two suction drains are placed in each gluteal/back and lateral thigh region. Before patients are turned into supine position, we perform a temporary closure of the lateral skin excess using a stapler and an occlusive dressing.

Anterior preparation

The inferior incision is checked and re-marked, adjusting the initial inferior line to the laterally ending gluteal incision line.

With all techniques, the dissection level is performed above Scarpa's fascia (see above), which has a number of key advantages: long-lasting swellings can be prevented because the underlying lymphatic vessels are preserved, and the tightening of the SFS craniomedially provides an additional 'inner traction' on the deep penetrating fascial system of the thigh (Colles' fascia). The SFS may then be fixed with 1-0 non-absorbable sutures to the anterior rectus fascia. Approximately three finger-breadths below the umbilicus, Scarpa's fascia is dissected and further mobilization of the abdominal flap is performed cranially above the rectus fascia. The central supra-umbilical adhesion zone is sharply dissected between both rectus muscles, preserving the laterally incoming perforator vessels.

Further preparation is performed as in the abdominoplasty procedure described above. After meticulous haemostasis, the patient is bent and several progressive tension sutures are placed superior to the umbilicus, the umbilical stalk is pulled through the abdominal flap and further progressive tension sutures are placed for reduction of deadspace and superficial tension. Next, temporary wound closure is performed with bullet forceps. Superficial fascial reconstruction, wound and skin closure may then be performed alternatively with barbed sutures or the two-component skin closure system as described previously (Figures 76.11, 76.12, 76.13 and 76.14).^{9,10}

Therapy of 'love handles' in male patients

Male patients frequently complain of local fat distributions in the hip and dorsal region, commonly known as 'love handles'. In the past, these were treated by liposuction. However, patients often complained about a local recurrence with a minimal weight increase. During circumferential preparation, these isolated fat pads can be easily identified and excised (see Figures 76.12 and 76.13). A meticulous haemostasis is advisable, since strong vessels are generally detectable for their isolated blood supply.

Thigh lift

Thigh lifts are an essential part of body-contouring procedures and may be performed through different approaches. Preferentially, the scar is placed at the inner thigh region in a vertical direction, in a horizontal direction in the groin region or in a combination of the vertical and horizontal scars (T- or J-shaped). In very rare cases additional scar placements are required, such as a horizontal scar just superior to the knee. The staging of the procedure should be discussed with the patient. In general, abdominoplasty or lower circular procedures should be staged prior to a thigh lift, since they enable an improvement in vertical direction to the thigh region.

Prior to thigh lift surgery, all patients should have an examination of the deep vein system and should have had any necessary therapy of varicose veins.

Figure 76.14 (a, c) A 42-year-old woman with a weight loss of 67 kg after gastric bypass. (b, d) Twelve months postoperatively, after circumferential lower truncal dermatolipectomy (CLTD) with anterior fleur-de-lis excision, breast reshaping with autoaugmentation, upper lateral thoracic lift and inner thigh and arm lift.

Preoperative assessment

The preoperative evaluation includes the skin quality (e.g. thickness, laxity, presence of striae) as well as the thickness of the subcutaneous tissue in all thigh regions. The circumference has to be measured at the height of the greater trochanter, the middle of the thigh and just above the knee. The thigh should be photo documented in different views (front, side, back, inner side and in an abducted position). With the patient standing and the thigh in a 90° abducted position the overhanging redundant skin should be measured. All existing eczemas and hyperpigmentation should be assessed and photo documented.

Since the range of varying adipose distributions is wide, every patient has to be evaluated and plans for an individualized therapy regime prepared. Male patients generally present with skin and adipose excess in the upper inner thigh regions without any redundant tissue in the other thigh regions. Moreover, they very seldom complain about a local adipose tissue in either the outer and front thigh. Female patients, on the other hand, are characterized by minimum subcutaneous tissue in most parts of the thigh (except for the inner thigh). Other female patients complain about a massive adipose tissue surplus in the thigh region, which is totally resistant to any weight loss. In some female patients the weight may have settled in an acceptable range with maximal reduced adipose tissue in the entire upper and lower body but not in the entire thigh region, where they present with subcutaneous tissue several centimetres thick (DD: lipedema).

Markings

The marking is performed in upright position first. The desired scar course is marked bilaterally and demonstrated to the patient. The symmetry can be easily checked while the patient is standing upright with legs together. The groin crease should be marked precisely to avoid any dislocation or vertical lengthening of the scar, which can be easily observed in vertical procedures. This groin crease line demonstrates the highest point of incision in either vertical, all horizontal or combined procedures.

Depending on the tissue characteristic and any asymmetries, the resection lines are marked next. This can be initially performed in upright and checked for modifications in supine position. It has proven to be helpful to mark these lines in relation to the proposed scar line.

A helpful tool is the double-ellipse marking technique of Aly, which allows safer and more precise marking.

Technique

Regardless of scar placement, we have standardized our technique of thigh lifts as a combination of liposuction and tissue resection. Depending on the local adipose distributions, the liposuction is generally performed first. If patients present with adipose excess in the anterior, lateral and/or posterior thigh, these regions are thinned out through standard vertical liposuction (4 mm cannula), avoiding any horizontal cannula movements. After completion, the marked area of resection in the inner thigh is extensively treated by liposuction (5 mm cannula), removing any detectable fat tissue. Next, the marked resection area is checked using bullet forceps for a temporary approximation. After confirmation of the resection lines the skin is incised and excised by a scalpel or electrocautery-assisted avulsion from proximal to distal. It has been shown to be important to tear off the skin without any mechanical transection, as this allows the sectioning of all vessels, including lymphatic vessels, at the weakest point, reducing the risk of lymphocele, for example. In addition, this technique avoids the development of heat-induced seromas.

Figure 76.15 A 49-year-old woman after 55 kg of weight loss following diet and sportive action. Preoperative (a, c, e) and 12 months postoperative (b, d, f) anterior, medial and posterior view after a lower body lift, inner thigh lift and additional distal thigh and calf lift. Although 55 kg is a moderate weight loss, the skin and tissue excess was significant in this patient, who desired additional tissue excisions in the lower leg region.

After meticulous haemostasis the wound is temporarily closed with bullet forceps, subsequently replaced by staples. It is important to perform the temporary closure as soon as possible to avoid wound closure problems due to an increasing tissue swelling. At this time point any required changes may be performed regarding surplus skin and fat tissue in the groin region or obvious adipose surplus in adjoining regions, which

may easily be treated through liposuction. No undermining is performed to minimize impairment of the wound edge perfusion.

In cases of a sole or additional horizontal incision placed in the groin crease we recommend fixing the distal skin flap to Colles' fascia of the pubic region to avoid any distal displacement of the final scar.

Figure 76.16 A 41-year-old woman after 60 kg of weight loss following gastric sleeve. Preoperative (a, b), three months (c, d) and eight months (e, f) postoperative front and posterior views after an arm lift with axillary T-scar. Note the scar development within the first eight postoperative months.

A drain may be placed before final wound closure commences. Wound closure is performed in the subcuticular and intracuticular layer, using absorbable sutures in single knot or nowadays barbed sutures in running manner as described above. Final application of Steri-Strips (transversely to the wound) as well as a sterile wound dressing is followed by a circular compression dressing which includes the feet and hips. During the first postoperative days, this compression winding is then changed to a custom-tailored compression garment.

During this period we initialize lymph drainage therapy and request a continuation for 4–6 weeks (Figure 76.15).

Arm lift (brachioplasty)

Arm lifts (brachioplasty) are commonly indicated in patients after weight loss to remove skin and fat excess and achieve pleasing and youthful upper and lower arm contours. Furthermore, the ageing patient may suffer from loose and flabby skin in the inner upper arm region. Plastic surgeons will consult with

patients about undergoing surgery for an arm lift if they wish to tighten this skin to look and feel more youthful. The incision extends from the elbow to the axillary crease, and sometimes extending on to the side of the chest. In some instances, liposuction may be used alone or in conjunction with an arm lift to remove excess fat in the upper arms.

In patients after massive weight loss, the redundant upper arm skin frequently crosses the axillary crease and extends onto the lateral thoracic region. This has to be demonstrated and marked with the patient. In a few individual cases, the skin excess extends to the lower arms. This has to be clarified to the patient, since this redundancy will be more conspicuous after an isolated upper arm lift.

Preoperative assessment

Skin laxity (presence of striae) and skin excess has to be evaluated in the entire upper and lower arm with the adjoining lateral chest region. The circular and vertical skin excess can easily be measured on the extended arm. Furthermore, especially in weight loss patients, local adipose tissue may be assessed in the entire arm.

Markings

The positioning of the incision lines depends on surgeon preference and should be demonstrated to the patient. In general, patients have to be informed preoperatively that in all cases the scar may be visible on the hanging arm from a dorsal view. There are several techniques, from which the ideal one can be chosen for the patient.

We perform markings while the patient is standing and elevating his or her straight arm in a 90° position. First it has to be determined whether there is a difference in surplus tissue between the sides. The first line marked should be the anterior line, just at the top of the medial bicipital groove. From this line the posterior line is evaluated through pinching. Alternatively, the double-ellipse technique described by Aly can be used. This technique may ensure a more accurate marking, especially for the novice surgeon. Finally, while the patient stretches both arms straight in front, a check of symmetry may be performed. In cases of tissue excess in the lower arm the markings should extend over the elbow to the lower arm.

Technique

Our technique of arm lifts is performed similar to the thigh lift procedure, as described previously, as a combination of liposuction and tissue resection. In general, patients present with adipose tissue excess in the inner arm region. The preoperatively marked area of resection at the inner arm is extensively thinned out by liposuction, removing any detectable fat tissue. This can ideally be performed with a 5 mm cannula. After completion, the marked resection area is checked using bullet forceps for a temporary approximation before the confirmed resection lines are incised and excised by a scalpel or electrocautery-assisted avulsion from proximal to distal. Again, it has been

(a)

(b)

Figure 76.17 A 48-year-old woman after 80 kg of weight loss following gastric bypass. Preoperative (a) and 12 months postoperative (b) posterior view after a lower body lift, breast and upper lateral thoracic lift and an arm lift. Note the improvement to the back region without any additional scar and the improvement to the axillary contour.

shown to be important to tear off the skin without any mechanical transection, as this allows the sectioning of all vessels including lymphatic vessels at the weakest point. Once meticulous haemostasis is completed, the wound is closed temporarily in the same manner as thigh procedures. Again, as in thigh procedures, it is important to perform the temporary closure as soon as possible to avoid wound closure problems due to tissue oedema. At this point any required changes may be performed regarding excess skin and fatty tissue in the axillary, elbow region or obvious adipose excess in adjoining regions, which may easily be treated through liposuction.

In cases of a sole or additional horizontal incision placed in the axillary crease we recommend fixation of the crease with fastening sutures.

Drains are uncommon but may be placed before wound closure, which is performed in the same way as described for the thigh lift. Final application of Steri-Strips, a sterile wound dressing and a circular compression dressing including the hands is performed in all cases. A custom-made compression garment may be adjusted prior to surgery and dressed intraoperatively. During the initial 4–6 weeks postoperatively we initialize lymph drainage therapy (Figures 76.16 and 76.17).^{28–33}

CHAPTER 77

Simulation learning in plastic surgery

Ali M. Ghanem and Simon R. Myers

Department of Plastic Surgery, Barts and the London School of Medicine and Dentistry, London, UK

The era of simulation in surgical training

The traditional Halstedian model was the foundation of modern surgical training. A block of years with graded responsibilities culminated in a professional and/or academic assessment to acquire the title of surgeon specialist.^{1–3} Today, in a global healthcare system with economic, efficiency and safety challenges, traditional surgical training is questioned. It is no longer acceptable to expose patients to a trainee's learning curve, operative lists must be efficient, there is increasing litigation and a reduction in trainees' working hours. Attaining competency as soon as possible has become the current focus. Simulation has emerged as a tool to address these needs.^{4,5}

Simulation can be defined as a 'technique to replace or amplify real-patient experiences with guided experiences, artificially contrived, which evokes or replicates substantial aspects of the real world in a fully interactive manner'.⁶ The use of simulation concepts can be traced back to the writings of the twelfth-century physician Ibn Zuhr (also known as Avenzoar, AD 1093–1162). In his book *Simplification Concerning Therapeutics and Diet*, Ibn Zuhr documented performing a tracheotomy on a goat to demonstrate the safety of this operation in humans.^{7,8} During the eighteenth century in Naples, Raimondo di Sangro, Prince of Sansevero, built two anatomical machines that illustrate the cardiovascular system.⁹

Modern surgical simulation has evolved with distinct milestones; from the use of cadavers and animals in the nineteenth century to the development of manikin simulators in the late 1960s and early 1970s and most recently to laparoscopic, endoscopic and virtual reality simulators.^{10,11} The role of simulation in surgical training is now beyond 'proof of concept'. The advantages of simulation in modern healthcare systems have been well described in numerous reports establishing the validity and transferability of skills learned in simulation environments to the clinical setting with demonstrable advantages to the system, learners and patients.^{12,13}

That said, systematic analysis of the evidence base has yet to show conclusively added benefit compared to traditional methods.¹⁴ Simulation training is widely perceived as an adjunctive tool, not as a replacement for patient-based operative training experience.^{6,15}

Simulation methodology enables tailored training interventions in a low-threat environment. Simulation can address limited exposure to patients with low-incidence and high-complexity conditions and provide competency. It can also be used to evaluate the outcome of training in a more objective and structured way. Harden and others used this concept with the development of the objective structured clinical examination (OSCE).¹⁶ A shift towards competency-based surgical training comes with two key concepts: objective assessments and simulation lab training.^{2,3,17}

Assessment of surgical skills in plastic surgery

Assessment has two main functions: educational and evaluative. Assessment may aid learning as a 'formative' assessment. Assessment may also be a tool for evaluation as a 'summative' assessment. Beard classified assessment methods according to the skills they assess, summarized best in Miller's triangle (Figure 77.1).^{18,19}

To demonstrate competency, multiple tools are used. Although surgical direct observation of procedural skills (DOPS) and problem-based assessments (PBAs) can be used to demonstrate trainees' competence of 'know how' and 'show how' in relation to a particular procedure, they cannot demonstrate performance, which could, however, be achieved by video-recording of a trainee performing a procedure and conclusively demonstrating that they 'can do' the procedure.

Surgical skill has been traditionally determined by mentors' subjective reports on trainees' ability. One of the first

structured assessment tools was developed by Kopta in 1971.²⁰ The tool assigned a 3-point Likert scale or 'observation guide' to lists of steps he considered important indicators of skill. This tool helped establish that methods such as the Medical College Admission Test (MCAT) did not correlate with measured surgical skill.²¹ In 1993, Reznick introduced the Structured Technical Skills Assessment Form (STSAF) with a checklist and a 5-point Likert global rating scale (Figure 77.2). Reznick's tool demonstrated construct validity and good interobserver reliability.²² This group optimized this method into the Objective Structured Assessment of Technical Skills tool (OSATS).²²

OSATS are performance-based assessments that evaluate trainees in standardized stations each with a specific task (e.g. performing a small bowel anastomosis). The candidate is then rated using both the station-specific checklist and a global rating score sheet. The validity of this tool was not affected whether the models used were live anaesthetized animals or lower bench fidelity station models.²³ Although OSATS has brought major structure and objectivity to assessment methodology it remains dependent on raters' judgement and cannot be considered wholly objective.

Figure 77.1 Miller's triangle relating clinical skill with assessment method.¹⁹ Source: Adapted from Miller, 1990.¹⁹

Skills assessment tools in plastic surgery training

Plastic surgery combines a variety of skills for reconstructive and aesthetic purposes. The level of skill required is reflected in the complexity of the procedure by 'the reconstructive ladder'. Free tissue transfer occupies the highest rung of the ladder, and largely defines the specialty.^{24–26} A key skill in free tissue transfer is vascular microanastomosis. Microsurgery requires very refined movements originating mostly from the intrinsic muscles of the hands in contrast of the wrist, elbow and shoulder movements that are required in, for example, laparoscopic surgery. It also requires a particular level of eye–hand coordination and dexterity and is associated with a steep learning curve.^{27,28} A competency-based curriculum in microsurgical training requires an objective assessment tool.²⁹ Objective assessment is important for feedback that improves skill, and for career planning. The validity of the tool must extend to incorporate all forms of validity: predictive, content, construct, face, concurrent, equitable and fair.³⁰

Methods of microsurgical skill assessment

Rater assessment tools

The study of technical skill in microsurgeons dates back to 1993 when Starkes *et al.* evaluated the accuracy of suture placement, time to complete a standard task, and vessel patency to evaluate skill acquisition in a training cohort. The time to complete a standardized task was the most sensitive measure of experience and skill.³¹ In 1998, they validated an assessment of repair on a slit in a surgical glove with two microsutures.³² In 2003, Grober *et al.* modified previously validated checklists and global rating scores and adapted them to microsurgery.³³

Several modifications of global rating scales have been introduced: by Kalu *et al.* (Figure 77.2),³⁴ Chan *et al.*,³⁵ and by Temple and Ross.³⁶ Global rating scales are based on OSATS and comprise: Likert scale of the components, and an errors list with or without a summative rating (Figure 77.3).

Global rating scale tools have construct and concurrent validity (Figure 77.4), which have been validated in the clinical

Please circle the number corresponding to the resident's performance in each category

Respect for Tissues	1 Frequently used unnecessary force on tissue or caused damage by inappropriate use of instruments	2	3 Careful handling of tissue but occasionally caused inadvertent damage	4	5 Consistently handled tissues appropriately, with minimal damage
Time and Motion	1 Many unnecessary or repetitive movements	2	3 Efficient time/motion but some unnecessary and repetitive moves	4	5 Clear economy of movement and maximum efficiency
Instrument Handling	1 Repeatedly makes tentative or awkward moves with instruments through inappropriate use	2	3 Competent use of instruments but occasionally appeared stiff or awkward	4	5 Fluid movements with instruments
Suture Handling	1 Frequently damaged, broke or lost sutures	2	3 Occasionally damaged, broke or lost sutures	4	5 Suture were consistently handled delicately under the control of the operator
Flow of Operation	1 Frequently stopped operating and seemed unsure of the next move	2	3 Demonstrated some forward planning with reasonable progression of procedure	4	5 Obviously planned course of operation with effortless flow from one move to the next
Quality of Final Product	1 Very poor	2	3 Competent	4	5 Clearly superior

Figure 77.2 The 5-point Likert scale assessment tool introduced by Reznick's Objective Structured Assessment of Technical Skills tool has been modified by Grober *et al.* and Kalu *et al.* for microsurgery skill evaluation.^{22,33,34} Source: Grober *et al.*, 2003.³³ Reproduced with permission of John Wiley & Sons.

Trainee:

Assessor:

Operation + date:

Anastomosis technique: triangulation / backwall / other:

Please tick level (scale 1-5)		1	2	3	4	5
Dexterity	Steadiness	Frequent exhibition of Tremor		Occasionally signs of Tremor		Fluid movements and obvious control of movements
	Instrument handling	Repeatedly tentative awkward moves through inappropriate use		Competent use, but occasionally stiff/awkward		Fluid movements with no stiffness or awkwardness
	Tissue handling	Frequently unnecessary force on tissue/damage caused		Careful, but occasionally inadvertent damage		Consistently appropriate handling with minimal damage
Visuo-spatial ability	Dissection	Frequently uncontrolled grasping of tissue or readjustment of view required		Correct use of instruments at right angle, but occasional uncontrolled grasping/view disturbance		Efficient use of instruments with vessel ends clearly prepared
	Suture placement	Frequently lost sutures & uneven placement		Occasionally uneven suture placement		Consistent delicately placed sutures with adequate spaces
	Knot technique	Insecure knots/frequent thread in knots		Secure knots, but occasionally awkward movement		Consistent secure knots placed effortlessly
Operative flow	Steps	Frequently stopped and unsure of next move		Reasonable progression of procedure		Obvious logically planned course of operation with effortless flow from one move to next
	Motion	Many unnecessary or repetitive moves		Efficient, but some unnecessary moves		Economy of movement and maximum efficiency
	Speed	Excessive time used for each step due to insufficient dexterity		Efficient time, but some unnecessary repetitive moves		Excellent speed and superior dexterity without awkward moves
Judgement	Irrigation	Poor use of irrigation, frequently desiccated vessels		Fair use of irrigation, but occasionally too wet, interfering with operative flow		Appropriate use of irrigation
	Patency test	Unsure of result of Acland test with possible thrombosed patency		Correct clamp removal, but repeatedly using Acland test		Appropriate sequence and time of patency test with confidence of unimpeded flow
	Bleeding control	No check for uncompleted anastomosis before clamp removal		Anastomosis checked but requires sutures for anastomotic leak		Places extra sutures as appropriate before clamp removed

Errors list: (please tick if observed)

Planning	Inappropriate operative field	
	Inappropriate vessel set up	
	Focus lost	
	Loss of central view	
Dexterity	Vessel damp re-application	
	Broken sutures/needle off suture	
	Wrong grasp/damage tissue	
	Opposite wall caught	
	Vessel tear	
	Thread in knot	
Visuospatial ability	Insufficient vessel preparation	
	Empty grasp	
	Unequal stitch bites	
	Suture pulled through	
	Suture cut through	
	Loose knot	
Operative flow	Re-do suture	
	Inappropriate magnification	
	Inadequate loop length	
Judgement	Vessel dessication	
	'pooling'	
	Anastomotic leak - extra sutures	
	'crushing' patency test	
	Excessive sutures	
	Impeded flow - re-do anastomosis

setting and found to be effective in live surgery.³⁷ However, such rater-dependent tools share several disadvantages. Checklists have lower construct validity than global rating scales.³⁸ This can be caused by novices approaching new tasks in a step-wise fashion whereas more experienced surgeons approach the task as a whole, and thus may be negatively scored as they miss some steps specified on the checklists.

Global rating scales address this issue to some degree by offering more flexibility. Despite the flexibility of a 5-point Likert scale in a global rating scale, the descriptions of the grades on the scale are not always clear or objective. For example, one of the criteria on the scale that refers to 'quality of product' in one of the tools is graded on a range of 'very poor' to 'clearly superior'. Both global rating scales and checklists may suffer from rater bias.^{34–36}

The global rating scale is the simplest, most readily available and validated tool in the literature. Nevertheless, there is no consensus on a standard scale nor confirmation of predictive or content validity. The assessments are time-consuming, and interest has grown in more objective methods.

Objective assessment tools

Objective assessment tools would always be favoured over biased rater-dependent tools. In microsurgery, where assessment models and hand movements are very small, significant advances had to be made in technology and equipment. There are currently two main objective assessment tools. The first is end-product assessment and the second is motion analysis. End-product assessments rely on testing the quality of the anastomosis formed at the end of a microsurgical procedure (the end-product), whereas motion analysis assesses the surgical technique used to form the anastomosis (the procedure).

End-product assessments

End-product assessments in microsurgery evaluate the patency of the microvascular anastomosis performed. When used in clinical or live animal setting, this tool can be considered the gold standard, since a patent anastomosis is the ultimate goal of the procedure. Ilie *et al.*³⁹ conducted a study using live

anaesthetized rats as microvascular models. Patency was assessed at 30 min and two weeks after the anastomosis. Measurement of vessel patency was possible and served as feedback to the trainee on how much further training they may require.

The major disadvantages of end-product assessment tools are ethical and economical. There are ethical issues in the use of live animal models. And this tool presents unacceptably high costs including those of licensing, sourcing live animals and housing them for a period of two weeks to assess long-term patency. Perfusion can be assessed in a non-living model by infusion of a fluid dye,⁴⁰ but leakage from the anastomosis can result from any difference in viscosity between the dye and blood, and the lack of clotting factors, rather than poor skill. Therefore, the limits of end-product assessments in non-living models and their ethical and costs limitation in live animal models reduce their utility.

Hand motion analysis

Hand motion analysis (HMA) uses a tool that tracks hand movements through 3D space, and has been developed and pioneered in laparoscopic surgery.⁴¹ Six published studies report its use in plastic surgery.³⁰ Two technologies have been used to assess hand motion for fine motor skills. The first uses electromagnetic (EM) motion sensors (Figure 77.5), and the second is video-based, with infrared cameras that detect hand motion by measuring the distance to reflectors on the operators' hands (Figure 77.6). Ultra-light EM motion sensors have been produced to trace small movements with little intrusion (Figure 77.7).

Electromagnetic hand motion analysis systems

EM motion tracking has been used in other fields, including virtual reality interfaces and gait analysis. Of the six papers referred to above, five have used an EM hand motion analysis device. They all found that HMA correlated well with global rating scores and skill level, although a global rating scale tool should be used with HMA, which provides quantitative data alone, and cannot reflect the quality of execution or its end-product.^{30,42,43} Dosis *et al.* introduced synchronized HMA with video-recording to provide both qualitative and quantitative assessments.⁴⁴

HMA is confirmed as an objective microsurgery assessment tool both in skills labs and in the clinical setting.⁴⁵ Comparison of HMA output (time to complete procedure, number of hand movements and hand travel distance) with global rating scales and checklists shows correlation with concurrent and construct validity (Figure 77.8). Grober *et al.* suggested that HMA may also have predictive validity and could be used to develop learning curves for skill acquisition and competence testing.

The cost of this technology, however, remains a major limitation to its dissemination. Availability is as much an obstacle as cost, and use is often limited to the research environment. For the quantitative data to be helpful, it needs to be defined in the context of skill acquisition learning curves.³⁰

Video-based hand motion analysis systems

This technology involves several 2D video cameras modified with infrared light-emitting diodes (LEDs). Video-based HMA has been used successfully in the assessment of microsurgical skills by Saleh *et al.*⁴⁶ No comparative studies have been conducted against EM systems. The obvious advantage of EM systems over optical-based ones is the lack of requirement for direct line-of-sight. Modern EM systems also have relatively small sensors (Figure 77.7), which may be discretely placed on the subject with minimal interfere with their movements. EM systems have a limited operating range, however, due to an inverse cubic reduction in magnetic field strength with distance, and can suffer interference from nearby metallic objects.

Figure 77.5 Imperial College Surgical Assessment Device (ICSAD) hand motion analysis. An electromagnetic sensor is placed on the dorsum of the hand.^{33,42,43} Source: Grober *et al.*, 2003.³³ Reproduced with permission of John Wiley & Sons.

Figure 77.6 Infrared light reflectors placed on dorsum of hand and fingers to be tracked with video-based motion tracking system as in Saleh *et al.*⁴⁶

Figure 77.7 New-generation ultra-light electromagnetic tracers are more suitable and less intrusive for fine finger microsurgery movements compared with older generation models.

Figure 77.8 Hand motion analysis outcome measures (e.g. number of hand movements taken to complete an end-to-end arterial anastomosis) can demonstrate construct when used to evaluate microsurgery skills in different cohorts. UG, undergraduate medical students; BST, basic surgical trainees/junior residents; HST, higher surgical trainees/senior residents; Positive Control: expert microsurgeons. Average number of hand movements required to complete this task varied significantly between cohorts from approximately 500 to 1000 movements in expert microsurgeons and inexperienced undergraduate students, respectively.

Virtual reality

Virtual reality simulators possess theoretical advantages as assessment tools. The task can be standardized, repeatable and tailored in difficulty to challenge the trainee. They also have an ethical advantage in avoiding animal models.⁴⁷ Virtual reality simulators have demonstrated construct validity in laparoscopic surgery using outcome measures such as time to complete the task and economy of movement.^{48,49} Virtual reality is in its infancy in microsurgery, and the costs are significant.²⁹ The lack of haptic feedback may be of less relevance here. Studies using this tool suggest that virtual reality simulators should be combined with global rating scales or other objective assessment tools until more research results are available. An excellent review of virtual reality in microsurgery by Erel *et al.*⁵⁰ summarizes the current development of the technology in microsurgery and highlights the lack of evidence for validity of the tool.

Models and technologies for plastic surgery simulation training

Most of the developments in surgical simulation technologies have focused on laparoscopic, endovascular and endoscopic applications. However, plastic surgery has witnessed developments in non-living bench models, live animals models, cadavers, virtual reality and software-based computer simulators.

Bench models

Hands-on training using bench models is a cost-effective method to practise surgical skills. Many private companies specialize in the development of such models and Limbs and Things UK/USA, Pharmabotics Ltd. and SynDaver™ USA are among the leading manufacturers of surgical skills training models. Simple skin pads for suturing and skin excision models are common. A fundamental skill in plastic surgery is

the harvesting of a split skin graft. In one simulation model,⁵¹ a device is constructed from a wooden base with two side arms that secure and stretch a skin substitute over a synthetic limb segment formed from a 500 mL bag of fluid solution. The fluid volume is adjusted to simulate the required turgor and shape. The overlying simulated skin element is Microfoam™, which conforms to the saline bag. Laying chicken skin over a simulated body part has been used to teach three-dimensional suturing techniques and local flap surgery.⁵² Higher fidelity cadaveric animal parts can be used as simulators for whole procedures (e.g. tendon repair in the pig trotter).⁵² Formal validation with evidence of objective skill acquisition is rarely presented, however, and as such the role of these models in a comprehensive training curriculum remains ambiguous.

Ilie *et al.*⁵³ organized microsurgical models into five main groups:

- basic manipulation, movement, and orientation in the operative field;
- knot placement/tying principles – apposition of edges, non-dominant hand usage, deformable volumes;
- three-dimensional models;
- the real tissue experience; and
- virtual reality trainers.

This classification can be extended to many skills beyond an anastomosis. For the first, non-living bench models can safely and effectively be used due to their cost-effectiveness and favourable ethical profile. Many synthetic models have already been introduced, including surgical gauze, latex gloves (Figure 77.9), silicone tubes, beads, needles to name a few.^{54–56} These models can assist in rudimentary skill acquisition such as use of the microscope and instruments handling, but little has been reported of predictive validity beyond these basic skills.

More sophisticated simulators allow the experience of an entire procedure. A simple life-size model of the oral cavity of a patient has been developed to simulate the structure of a cleft palate for simulated palatal repair.⁵⁷

A further step in simulation is the integration of skills into a real-life surgical experience with convincing face validity. Both the anatomical and physiological components of the procedure must be simulated. Non-living animal models examples include the rat aorta or chicken thigh model in microvascular anastomosis (Figure 77.10a,b),^{58,59} and the use of fresh cadaveric sheep cranium to simulate craniostomy surgery.⁶⁰

The use of synthetic models has already contributed to reducing the number of live animal models needed to attain a particular skills threshold during training.⁶¹ The three Rs – refine, reduce and replace – increasingly guide the ethical use of animal models in research and training.⁶² The ‘practice rat’ is an example of a more sophisticated synthetic simulator.⁶³

Live animals

The use of live animal models in plastic surgery originated from experimental microsurgery research in dogs.^{64,65} The most widely used animal model in both research and training applications is the rat (Figure 77.11).^{66–68} This model is very versatile – up to 20 basic and advanced microsurgical procedures have been

described.^{66,69–73} Nevertheless, despite the live rat model’s excellent face validity it is limited by the different blood supply pattern, being a loose skin animal. Therefore, simulation of perforator flaps would not be possible in such models. With human perforator flap concept and composite tissue transfer advances in gonadal, limb and facial transplantation, research groups and simulation training have shifted from the rat to large mammals due to the higher fidelity required to simulate these advanced techniques (Figure 77.12a,b).^{74–77}

A very useful exercise in the rat is anastomosis of the hind limb vessels due to their similarity to the human digital vessels. For advanced microsurgery skills, abdominal epigastric flap, tail and limb replantation and kidney transplantation exercises in rodents provide highly effective and reproducible simulation models.^{66,67,78,79}

Despite their utility and popularity, live animal model use is increasingly regulated due to associated ethical issues and heavy costs. Confirmation of predictive validity is also required, by establishing the transferability of skills from animal models to patients and their outcome.

Human cadaveric models

Human cadavers have been used for plastic surgery training for a long time. In 2013, educators from the Plastic Surgery Department in the University of Southern California reported a significant increase in residents’ confidence by incorporating a fresh tissue dissection (FTD) simulation programme into their curriculum.⁸⁰ Confidence increase positively correlated with training year, and varied according to anatomical region and procedure. Confidence was lowest for the head and neck region, rhinoplasty and facelift, in contrast to radial forearm and latissimus dorsi flap surgery.

The same team reported an enhanced-fidelity perfused cadaveric model.⁸¹ Fresh tissue human cadavers were perfused via cannulation of large vessels and centrifugal circulation. This method allowed simulation of life-like surgery and the development of training models for basic and advanced surgical procedures

including local and distant flap surgery. Enhancement of the fidelity of fresh cadaver simulation models by artificial perfusion represents the highest form of whole procedure simulation.

Virtual reality, robotic and computerized mannequins models

Virtual reality simulation was born in the aviation industry. Rapid advances have been made in robotic surgery and simulation modelling for clinical case planning and outcome prediction with many applications in education and training (Figure 77.13).^{82–87} The technology of simulation models is evolving further towards the creation of an interactive computerized patient mannequins simulator that recreates a complete experience of surgery in a threat-free, patient-safe digital environment with reports confirming significant improvement in surgical knowledge (Figure 77.14).^{83,88}

With technological advances in robotic-assisted surgery, numerous applications have been described in plastic surgery.^{89–91}

In parallel, simulation-based training and assessment interventions have been developed to prepare trainees for this emerging and rapidly advancing field.⁹²

Simulation for non-technical skills

The make-up of a good surgeon is not based on technical skills alone. Surgical skills belong to three broad categories: cognitive/clinical skills, technical skills and social/interactive skills.⁹³ Non-technical skills for surgeons can be classified into four categories: decision-making, situational awareness, communication and teamwork, and leadership.⁹⁴

Both technical and non-technical skills are vital for safe surgical practice since communication failure contributes to almost half of errors in surgery.⁹⁵ Recent evidence suggested that non-technical skills can enhance or undermine technical performance.⁹⁶

Teamwork is based on non-technical skills and thus, evaluating and improving these skills is an important factor in improving teamwork, reducing medical errors and provide a

Figure 77.13 The da Vinci robotic simulator can be used as a virtual reality simulation tool for both robotic and microvascular surgery.

Figure 77.14 computerized mannequin patient simulators are useful to recreate training scenarios such as war surgery in a safe environment.

better quality of healthcare.⁹⁷ The UK Good Medical Practice, the USA Accreditation Council for Graduate Medical Education (ACGME) and the Royal College of Physicians and Surgeons of Canada CANMED frameworks all describe the skills of a good healthcare practitioner necessary to provide high-quality care. Multidisciplinary simulation of the clinical environment can facilitate individual non-technical skills acquisition and prepare clinical teams for infrequently encountered scenarios such as surgical emergencies.^{98,99}

Non-technical simulation skills are increasingly assessed in surgical training. Several methods have been developed to evaluate them, including the NOTSS (NON-Technical Skills for Surgeons), NOTECHS (NON-TECHNical Skills) and OTAS (Observational Teamwork Assessment in Surgery).^{98,100,101} Evidence-based simulation methodologies have been used effectively as training interventions to teach non-technical skills in surgery.^{102,103} This method has been used extensively in training of other high-risk professions such as the armed forces, aviation industry and the fire brigade with valuable lessons that can be learned and applied in surgical training.

Evidence for the benefit of plastic surgery simulation training

High-level evidence of the effectiveness of simulation in generic surgical training has been confirmed by a Cochrane review analysing over 30 randomized controlled trials.¹⁰⁴ A critical analysis of the surgical education research of the last decade investigating evidence for educational and training interventions relevant to plastic surgery can be inferred from this work as well as other reviews. The best evidence for a competency-based simulation training programme for plastic surgery supports a laboratory-based mixed-fidelity model programme – low fidelity (for basic skills) and high fidelity (for advanced skills) – that encourages and facilitates deliberate practice in a distributed fashion.^{105,106}

There is strong evidence that technical skills acquired on low-fidelity models transfer to improved performance on higher fidelity human cadaver models, and that self-directed deliberate practice leads to improved technical performance. Although there is significant paucity in the literature to support current plastic surgery education and training practices, the incorporation of regular simulated training on low-fidelity models in microsurgery

provides an effective intervention that leads to acquisition of transferable skills and improved technical performance. Further research to confirm the transferability of skill to the operation room and benefit of healthcare system and patients alike is still lacking.

Evidence for the role of non-technical skills simulation training in the improvement of healthcare systems has been evaluated by a comprehensive expert consensus. Using the CANMED non-technical competencies of the healthcare worker as an effective communicator, collaborator, scholar, professional, manager and health advocate to evaluate the literature, the review confirmed the benefit of simulation in promoting the competencies of medical expert, communication and collaboration. Further work is required to develop the exact role of simulation as a training strategy for competencies related to scholarly skills, professionalism, management and health advocacy.⁶

Priorities for plastic surgery simulation

Integration into training curricula

Once a competency simulation-based programme or an educational intervention has been designed and validated it is necessary to formally integrate it into a training programme. Several options exist but due to the novelty of simulation concepts coupled with logistical challenges, simulation-training methodologies are yet to be seen as a standard practice in plastic surgery. The most important aspect of integration of simulation training into a formal training programme is 'protection of simulation training time'. Our experience in encouraging attendance as part of optional study leave suggests that this does not work very well. Only 25% of trainees confirming their support of simulation training in microsurgery in London managed to attend self-directed and supervised training in microsurgery simulation facility over a 2 year period. Our experience, coupled with that of other educators, suggests that residents should be formally introduced to the simulation component of their curriculum. Four integration approaches have been described: the block-time approach, rotational-integration approach, skills-rotation approach, and the independent-study approach.¹⁰⁷

In the first approach, protected time blocks are provided weekly or monthly for the trainees throughout their rotations. In contrast, The rotation-integration approach provides simulation-training modules that are synchronized with a specific clinical rotation, for example, a basic bench model microsurgery skill course as part of a clinical rotation of reconstructive microsurgery. It is critical for these two approaches to be effective that time provided for simulation training is truly protected and that the simulation training is synchronized with clinical training provided so that there is a natural progression of skills learned from the lab to the clinical environment.

The third (skills-rotation) approach provides a simulation module within the training programme that all trainees must complete to progress in their training. This option guarantees

protected simulation training time that may be designed to provide all basic competencies required for a particular level of training. The University of Washington in the USA has pioneered such an option by designing a two week Emergency back-up, Vacation, Academic and Technical Skills (EVATS) rotation that has been very successful at ensuring integration of simulation training into the residency programme.¹⁰⁸

The last (independent-study) approach is an option that may be suitable for certain sets of surgical skills. For example, individual deliberate practice to improve microsurgical skills could be facilitated in this method following formal completion of a basic skills course. In this approach it is important to choose modules that do not require close supervision. That said, formal feedback and competency assessment (e.g. by video-recording of completed exercises) should be provided as independent learning here constitutes a formal component of the training curriculum.

Standardization

The need for standardization of training in plastic surgery at a global level is a major challenge. Variation extends from the scope of the specialty in general, to teaching and education of particular techniques. A review of microsurgical training centres worldwide established considerable variation in basic microsurgery courses' characteristics.¹⁰⁹ Given this wide variations, it would be helpful to have a basic standard of course duration, models, exercises, graded complexity and competency achieved, to ensure a universal standard of training and the possibility to compare and contrast the relative benefits of these divergent courses in training outcomes.

Skill maintenance and revalidation

Revalidation aims to assess surgical skill level and any skill loss over time.^{110,111} Assessment of senior clinicians should enable a safe threshold to be established that might be expected of a competent plastic surgeon. Once this threshold is fixed, future assessments can be made against it. Revalidation requires valid assessment tools that adequately evaluate competence. Simulation strategies offer a valid evidence-based foundation. Simulation-based interventions are particularly beneficial when used as part of on-going skills maintenance programme. It has been shown that distributed training leads to higher skill retention.¹¹² Even at more senior levels, simulation offers an effective tool to ensure continued levels of competence as part of the process of revalidation.

Simulation limitations and pitfalls

A nationwide survey by the Association of Surgeons in Training identified disparities in the availability of simulation training facilities by region and specialty in the UK.¹⁵ This variation may impact on the integration of simulation into the plastic surgery curriculum. The lack of validation studies of some simulation-training models and interventions cast a valid doubt as to whether they meet adequate educational standard. The costs of

high-fidelity training models and technologies are another major hurdle. This factor limits many training programmes' ability to acquire and develop advanced simulation models and educative interventions. It is estimated that the current annual cost of training surgical residents in the US is US\$53 million, when prolongation of the operation procedures is taken into consideration.⁶ Investment in simulation training is financially beneficial for healthcare systems. Evidence from neonatal care in the developing world confirms that low-fidelity task trainers and simulation-based educational strategies can be designed to provide cost-effective solutions with measurable advantage for both trainees and patients alike.^{113–115}

When such difficulties are overcome and a simulation facility is established, engagement of trainees and trainers continues to be a limiting factor for expanding simulation training. Engagement of the educative faculty is a further pressure. Some simulation centres have invested heavily in simulation equipment with no subsequent effective training programmes due to the lack of a motivated faculty. On the other hand, trainees may not appreciate the existence of simulation facilities, may not be released, or appropriately supervised in their use leading to poor utilization.

To optimize simulation training, an investment in coordinated multidisciplinary, multispecialty centres that ensure easy access from clinical areas and open access to simulation-training equipment is required to ensure utilization, educational benefit and return on investment.^{116,117}

A major and continuous challenge to expansion of simulation-based training is to establish conclusively its benefit on real clinical outcomes. As a result, inferential and cost-effectiveness studies are continuously required to establish the predictive validity of simulation models and educational interventions before advocating their integration into formal surgical training programmes.

Finally, even with any proven advantage of simulation-based training in shortening early parts of trainees' learning curves, by reducing medical errors and promoting good surgical practice, simulation cannot completely substitute key clinical experiences and learning from actual surgical practice. Plastic surgical expertise can only be achieved through clinical practice, no matter how long and frequent exposure is within simulation facilities. Simulation methodology can facilitate a more complete understanding of expert performance and, therefore, ensure that surgical training programmes of the highest quality are developed with this expert performance as the standard.¹¹⁸

Conclusion

The utility of simulation in surgical training is well established with proven validity and demonstrable transfer of skills to the clinical setting. The use of a step-wise simulation-based methodology to complement clinical training in plastic surgery has positive consequences on trainee confidence, leading to shorter

and flatter learning curves. Simulation training can better prepare trainee plastic surgeons for clinical practice, improve patient safety and service efficiency.

Despite the development of various models and simulation-based learning tools in plastic surgery, the role of simulation in the specialty's training curriculum is less well established. It is necessary for simulation-based training to be fully integrated and funded in formal plastic surgery training programmes. It is also necessary to develop a skilled faculty of educators in well-coordinated simulation facilities.

Further research is needed to expand the role of simulation in plastic surgery within training, performance evaluation, certification and revalidation. Simulation, therefore, has the potential to become an integral part of the development of better and safer plastic surgery services for patients worldwide.

CHAPTER 78

Military plastic surgery

Robert M.T. Staruch and Shehan Hettiaratchy

Academic Department of Military Surgery and Trauma, Royal Centre for Defence Medicine, Birmingham, UK

Introduction

The field of burns, plastic and reconstructive surgery in the military covers a unique spectrum of surgical disease. Surgeons have long been found at the periphery of the battlefield and this tradition has continued into conflicts in Iraq and Afghanistan as surgeons develop new strategies to cope with the increasingly complex wounds produced from modern weapons.¹

This chapter focuses on the injuries to soldiers during conflict and the physical mechanisms that explain the type of tissue disruption seen. An explanation as to the decision-making process and surgical techniques used by military plastic surgeons will be explored.

The principles of war surgery

The practice of war surgery is starkly different from that of normal civilian surgery.^{2–4} The limitations on time, supply, surgical capability, access to evacuation and physical expertise are a few of the factors that influence the decision-making process when practising surgery in conflict conditions.⁵ There are several paradigm shifts in science that have had profound effects on the practice of war surgery.⁶

Paradigm shifts

The advent of triage by Dominique Larrey under Napoleon Bonaparte was a major shift in war surgery and medicine that improved survival.^{7–10} The requirement for prevention of contamination and haemorrhage is where the military plastic surgeon is vital. As high-intensity blasts have become a significant mechanism of injury there has been a large increase in the amount of soft tissue disruption, especially in the limbs.¹¹ Meticulous inspection and debridement of devitalized tissues are essential in conjunction with arrest of haemorrhage from small or large vessels. Some of the terminology used in war surgery is explained in Box 78.1.

Compounding 'X' factors

The factors that substantially impact surgical decision making are the logistical confounders on the ability to operate.¹² The lack of resupply for key equipment or of a secure evacuation chain for patients will influence the care that patients receive. Ultimately, the requirement is to operate for as short a time as possible so as to be ready for any further casualties that may need surgical care. In addition, conserving equipment so that one can do 'the most for the most' means often leaving certain surgeries for a later stage, especially if they are not life threatening. Specialist equipment such as microscopes may be unavailable, limiting microvascular procedures. Conflict is dynamic and chaotic; surgeons often need to be prepared to move quickly, and the prolonged evacuation time can often augment the triad of coagulopathy, hypothermia and acidosis. Fighting this deadly triad as well as meeting the clinical guidelines of the golden hour and platinum minutes is a huge challenge faced by military clinicians. In previous conflicts evacuation timelines have been prolonged (Op Iraqi Freedom USA 4.5 h, 1.5–72 h evacuation); this often necessitates the deployment of surgeons forward to undertake limited damage control surgery.

The concept of war wounds

Research from Afghanistan has highlighted the differences between the severities of civilian and military injuries. The application of wound management principles discussed in the literature can only begin once the complex energy transfer to tissue from projectiles is understood. This allows military surgeons to plan and comprehend the progression of a wound.

The wounds that result from these high-energy blasts are contaminated from a multitude of factors, such as foreign bacteria, soil, human tissue and metallic fragment debris. In addition, the tissue is devitalized from the shock wave of the blast, which causes cellular disruption on both a mechanotransduction and cellular hypoxia level. As cells are removed from

Box 78.1 Terminology

- *The golden hour* – The theory that the chance of survival is greatest if patients receive life-saving intervention within the first hour.
- *The platinum minutes* – Chance of survival in catastrophic injuries is increased with important life-saving interventions, such as tourniquets, within minutes of injury.
- *Damage control resuscitation* – Early permissive hypotension and haemostatic resuscitation.
- *Damage-control surgery* – Rapid, specific surgical intervention with predetermined goals to halt life-threatening haemorrhage and surgical pathology for stabilization of the patient. Time in theatre is limited to a minimum.

their natural extracellular matrix and unable to respond to changes in wound tension, many cells undergo anoikis. A subsequent cellular population undergo necrosis due to the local hypoxia and cellular trauma. Cells are unable to mount an immune response to local contamination or systemic inflammation as the energy disrupts gene transcription.^{6,13} At the local wound level there is a prolonged cellular necrosis, which maintains a destabilized tissue much longer than is traditionally seen in civilian patterns of injury. The cellular dysfunction affects the ability of local blood vessels to withstand the shear stresses from surgical reconstruction, making soft tissue reconstructive options limited.

The energy transfer into the tissues acts as a vector to force the contaminant substances into the tissue planes. This deep widespread contamination facilitates progressive tissue necrosis. It also is difficult to assess the depth of the contamination field on first inspection. Progressive tissue lavage and inspection allows the true contamination field to be assessed and reduced.¹⁴

The principles of war wound management involve prompt debridement of contaminated and obviously devitalized tissues. It is important to conserve tissue for later reconstruction. Anatomical structures must be identified for further reconstruction. Although vascular structures must be maintained or repaired, this should be weighed up against the requirement for swift damage control surgery. Prolonged operating times must be avoided. Limb salvage is crucial, but long operations to maintain marginally viable limbs has to be considered in view of further trauma that may arrive. Internal fixation of bony injuries should be avoided due to the degree of contamination. The use of negative pressure dressings to tamponade the wound is a new concept that appears to be successful. The aim of the immediate surgery should be to preserve tissue with minimal contaminants so that more definitive reconstruction and salvage may take place at specialist centres.¹⁵

Classifying war wounds

The assessment of cavitation size, wound contamination and involvement of neurovascular and bony structures¹⁶ provides plastic surgeons with one way to gauge wound severity. However the large soft tissue deficits seen in recent conflicts in Afghanistan and Iraq has meant surgeons require a new classification to

grade such wounds, which are often over 2 cm and may have a complex morphology. The use of CT to produce a precise impression of the soft and hard tissue injury involvement cannot be underestimated. In particular, this has proved invaluable in planning of subsequent reconstruction and in focusing the initial life-saving surgery.

The mechanisms of injury

Injury protection

The overwhelming mechanisms of injury in modern conflicts are penetrating injury from ballistics such as rifle rounds as well as overwhelming blast injury from powerful explosives.^{17–20} Protection from these mechanisms has evolved into a science of itself, with the aim of producing increasingly light materials that can withstand high-energy contact.^{17,18,21} Such materials must be robust enough to survive the arduous conditions that soldiers operate in and provide some of the expected modern material properties – namely waterproofing, breathability and a reduction in weight. This improvement in protection has shifted injury pattern back into the extremities. Particular breakthroughs have been in neck, ocular and perineal protection.

Blast mechanics

Blast injury is not solely limited to the battlefield and unfortunately is increasingly being seen in civilian settings.²² The terrorist bombings in London in 2005 and Boston in 2013 are examples of explosive devices in a civilian setting that may cause patterns of injury similar to those seen in conflict.²³ Understanding the physics behind these devices and how they disrupt air/fluid or air/tissue interfaces is important for management.

Blast physics

An explosion is a sudden release of energy from a source. The explosion and subsequent energy release perpetuate a wave of energy that travels outwards from the source. The largest explosion ever recorded was in Krakatoa in 1883 where the sudden eruption of molten lava from a volcano into the ocean produced enough energy to evaporate 1 cubic mile of ocean water; this equates to about 5 billion tonnes of TNT. The explosion was felt over 3000 km away.

Explosions release gas as a result of rapid energy release. The expansion and contraction of heated gas and the propagation of this heated gas away from the epicentre gives a diverse set of implications on tissue and structures. The rate of this energy release from a compound is termed the detonation velocity. It is important in subsequently determining the size of the shock wave and strength of the blast. The comparison of the detonation velocity from the epicentre against the speed of sound is termed the Mach number. The shock wave refers to the gas/air interphase that propagates out from the explosive epicentre, travelling faster than the speed of sound. It is this wave of energy that is pathognomonic of blasts. The wave is a high-pressure area that gradually

overtakes lower pressure areas, which in the initial phase, accelerate overall pressure. This is the pressure wave that individuals feel after an explosion. The wave acceleration is dependent on three factors: pressure, temperature and air density.

As the pressure wave is an area of high pressure and density, the subsequent cooling of the gas and negative pressure effect behind the wave creates a wind that follows the shock wave. This blast wave is dragged with the shock wave and pulls with it loose fragments in the vicinity. As the shock wave travels further away from the blast epicentre its velocity decreases and the distance between the shock wave and blast wind increases.

The shock wave itself can reflect off surfaces and therefore once again increase its disruptive power. As the speed of the gas is defined by density of air, a reflection of the shock wave on a surface can cause the shock wave to travel back through itself. The high temperature of the gas causes the shock wave to accelerate, and in some circumstance overtake itself, in the opposite direction, compounding the blast energy felt in between, and resulting in even more damage. This explains why blasts in confined areas result in more severe injuries.

Blast patterns of injury

The interaction between the shock wave, blast wind and the air/tissue interface produces several different patterns of injury.

Primary blast injury

Primary blast injury refers to trauma from the shock wave. The shock wave produces a rapid increase and decrease in air pressure and density. In addition, this rapid acceleration and deceleration causes severe disruption and shear to soft tissues. The air/fluid interfaces are particular vulnerable, as well as points for soft and hard tissue attachment, where shear forces could cause a ripping effect. The tympanic membranes, lung parenchyma and the large and small intestines are particular vulnerable in primary blast injury.

Secondary blast injury

The secondary blast injury refers to the effects caused by the blast wind. The wind not only carries explosive fragments from the device but also picks up surrounding loose material. These fragments provide a penetrating injury to soft and hard tissue. Such effects can be noted by the peppering of skin with small pieces of dirt or stones from the ground.

Tertiary blast injury

The interaction of the shock wave with surrounding structures and buildings can produce structural deformation. The collapse of walls or buildings or vehicle roll can produce crush and blunt trauma to the body. Crush injuries to limbs can produce a substantial myoglobin release and compartment syndrome. This is particularly found in long bone or extremity fractures, injury to the buttocks or abdominal wall. In addition, pelvic fractures may produce an abdominal compartment syndrome that may require decompression through an emergency laparotomy.

Quaternary blast injury

The blast also produces a reaction that combusts chemicals. However incomplete combustion produces thermal burns or airway compromise and/or asphyxiation through carbon monoxide or cyanide inhalation. Radioactive material is another factor that has to be considered in military blast injuries and the resultant medical problem could be a radiation injury. The exposure to a radioactive or chemical agent will require the use of special chemical/biological/radioactive/nuclear (CBRN) protection and patient decontamination prior to treatment.

Finally, the blast injury produces profound cellular dysfunction. Study of neutrophil function of blast patients has shown a significant reduction in functional neutrophils. This immunocompromise can mean that patients mount an overwhelming sepsis to local bacteria that colonize wounds from the blast.

Figures 78.1, 78.2 and 78.3 demonstrate the devastating injuries caused by blast injury through primary to quaternary mechanisms.

Penetrating injury

The study of ballistics refers to projectiles that have been launched or shot.²⁴ Although the tendency is for clinicians to associate this science with bullets, it must be remembered that fragments picked up in a blast wind can display ballistic properties.

Figure 78.1 Improvised explosive device blasts have caused a devastating injury zone to the lower limbs, perineum and the upper limbs, particularly the hands.

First, the physical attributes of the ballistic are important – namely the shape and composition and structure. Some historical compounds used for bullets were rounded and relatively soft. Modern-day bullets are often harder and have a pointed or rounded nozzle shape, which displays different travel characteristics. Second, the characteristics of the flight path for these ballistics, such as the velocity of the bullet, its stability in flight and finally its yaw or tumble, are crucial. The yaw refers to the degree of rotation of the bullet during its flight.

Figure 78.2 The decision for limb salvage is vital for soldiers, but this must be balanced against the available time and likelihood of success.

Historically, scientists and the literature have referred to bullets as high or low velocity. This is a misleading misnomer that refers to speed of flight. The low velocity was considered to be below 600 m/s or 2000 ft/s. Conversely, any bullet over 600 m/s (2000 ft/s) was 'high velocity'. In the study of bullets it is better to consider them as high energy or low energy, as low-velocity bullets can still be high energy, particularly shotgun cartridges. Low-velocity bullets were traditionally shot from handguns, especially in the civilian setting. Military weapons, such as the SA80 rifle used by British forces, fire a high-velocity round.

As energy must be considered to differentiate rounds, the link between kinetic energy, mass and velocity should be established and explained. Kinetic energy is equal to the sum of mass and the square of velocity. Hence although both mass and velocity will produce a proportional rise in kinetic energy, the increase in velocity will substantially increase kinetic energy over mass.

The efficiency of the projectile in its time of flight critically decides its ability to disrupt tissue. The more efficient its time of flight, the less energy it will impart to the atmosphere and therefore lose, hence the more it will deliver to the target. The speed of the projectile as it hits the target and the subsequent density of the target will govern the permanent and temporary cavity. Again, the thickness or depth of the target will also govern the amount of permanent and temporary cavitation.²⁰

Permanent cavitation refers to the disruption caused by the cross-sectional area of the projectile. The faster the projectile travels through the tissue, and the thicker or deeper that tissue is, the more energy that will be transferred as the projectile is allowed to yaw through the tissues, hence deviating from its

(a)

(b)

Figure 78.3 (a) The hand has sustained a particularly distinctive pattern of injury through improvised explosive device blast injuries that has not been documented before from other mechanisms of blast. The decision to salvage or not must be taken in the context of any other function-limiting injuries that have been sustained. (b) The upper limb injury, particularly to the hands, has required complex reconstructive choices with both new and old, often unused, flap choices. The decision was made to salvage this hand which, after delayed reconstruction, was of important functional use.

flight path. This energy transfer will produce a temporary cavity that will disappear as the round leaves the tissue and therefore creates a negative pressure gradient similar to that described in blast. This will pull the temporary cavity together and therefore mask its true size. In relatively thick tissues, such as the abdomen, there is more time for the round to yaw and transfer its energy. This results in more tissue disruption. The degree of disruption is proportional to the depth of tissue penetrated, or length of time the projectile is within the tissue cavity. Hence through and through penetration of extremities, such as the ankle or calf, present relatively little time for energy transfer from the projectile. Furthermore there is minimal time for the projectile to yaw, or rotate during penetration. The elasticity of the tissue is therefore important. Structures such as bone that are tough but relatively brittle will fracture easily and are poor absorbers of energy. Lung parenchyma has low density and is relatively elastic and therefore can undergo some relative deformation prior to breakage and hence is good at energy absorption from the projectile. Structures such as liver or spleen are excellent examples of tissues that have poor elasticity and are easily damaged by poor energy absorption.

Finally, it was originally believed that the speed of the projectile was the determinant in the amount of tissue disruption. Although this does govern the relative amount of kinetic energy in the projectile, it is in fact the density of the tissues that is the key factor in what determines tissue susceptibility to disruption.

Deployed plastic surgery

The war surgery team

Military surgery relies on critical teamwork. Plastic surgery brings a wealth of unique techniques that can help in improving patient outcome. However, in severe trauma patients such skills are futile without the full capabilities of the trauma military surgical team – skills brought from the orthopaedic and general surgical disciplines.

The military plastic surgeon

The role of the deployed plastic surgeon is to contribute to the surgical skill set of the team to ensure that maximum reconstructive potential of each patient is achieved. Initially this involves aiding surgical debridement to preserve as much viable tissue as is possible. The plastic surgeon is often best placed to determine what structures can or cannot be reconstructed to a good functional level long term. The use of early aggressive resuscitation techniques through pre-hospital care has increased the number of survivors with a high surface area of tissue devastation. These conflicts are unique in this sense. A wealth of different procedures have been required to salvage tissue for the reconstructive phase. The construction of an established hospital in the conflict area with a wide variety of expertise has meant that patients can undergo procedures previously thought to be outside the remit of damage control surgery; this allows

more scope for later reconstruction. Although bringing the full civilian trauma team closer to the point of wounding has, without question, improved outcomes, such resources cannot be expected in the future.

Principles of plastic war surgery

First, it is essential that damage control surgery takes place over all other surgery. All patients should be managed with a trauma principles approach. Life and limb must be preserved first through control of haemorrhage and management of life-threatening conditions. Subsequently, meticulous debridement and tissue conservation can take place. If time allows then procedures to preserve borderline tissue or important joints may take place. The phrase 'out of sight out of mind' is the clinical enemy in these patients and can lead to a missed large bleeding wound from a blast. It should be remembered that surgery on major trauma victims is resource intensive. The conflicts in Afghanistan have benefited from a quickly evolving well-established logistical chain that has allowed a gold standard in resource-intensive resuscitation of these patients.^{11,12,25–27} The aim in any complex wound from war is to achieve debridement with maximal tissue preservation, fracture fixation and wound control with dressings.

Wound debridement and management

The aim in the acute phase is to reestablish critical small vessel flow, assess tissue viability and debride dead tissue and preserve what may be recovered through resuscitation. Such patients have just come from the stressed environment of the battlefield. Although every effort has been made to meet the nutritional requirements of soldiering, these patients are often in nutritional deficiency, which concurrent to their already stressed state, affects their ability to mount an immunological response. Although nutritional supplements may be unavailable in the deployed setting, the restoration of adequate oxygenation through resuscitation with whole blood products (1 : 1) can partially bridge this gap and has significant positive outcomes for avoiding the lethal triad. Optimizing such patients prior to theatre is paramount as part of the damage control process. Salvaging these patients if they go into the lethal triad and towards multi-organ failure is difficult and therefore every effort should be made to adequately resuscitate them.^{27–32}

Study of the rate of osteomyelitis within the first 5 h of wounding as well as the rate of bacterial replication have identified that the first 6 h are crucial for primary debridement.³³ Jackson's model of the burn wound also has some translation to the open wound. The central wound area is one of necrosis, which is surrounded by an area of devitalized tissue and subsequently engulfed by normal cells. In many fields of surgery a radical debridement, which removes all necrotic and devitalized tissue, leaving normal tissue only, is appropriate. In military trauma where healthy tissue is at a premium, one has to adopt a more sparing approach. Meticulous assessment of tissue viability along with small marginal debridements of necrotic tissue

is essential. Devitalized tissue must be continually reassessed with the hope that it may be salvaged through aggressive resuscitation. This approach leads to multiple wound assessments and changes of dressings in theatre, yet it conserves vital tissue. It is also at the mercy of the progressing tissue necrosis, which can present gradually days after the injury.

The importance of microbiology in guiding tissue management cannot be overstated. Tailoring antimicrobial therapy is a feature of the definitive surgery phase, however early antibiotic therapy is vital and at the earliest possible occasion swabs of all wounds should be taken. Clinical Guidelines for Operations, the UK military's evidence-based guidelines for all clinical work on operations, has appropriate first-line antimicrobial advice for patients with severe trauma. Early antimicrobial therapy helps in arresting the substantial cellular, immune and inflammatory response to the injury.

Vascular control

In the severe trauma patient with an extremity amputation, proximal control is crucial.³⁴ In such patients aortic cross clamp through an emergency laparotomy may be necessary. Rapid assessment of a limb's future viability or the necessity to undertake a surgical rescue is a difficult decision for the deployed plastic surgeon. Experience alone has led to a small set of key questions to be asked when considering such a move. The decision to undertake such a procedure should be weighed up against the risk to the patient, the gains from salvaging tissue and the limb (taking into account any loss of function) and the

overall burden of trauma for the operating table. A vascular repair in a borderline mangled upper limb may salvage a much-needed hand. The limb salvage algorithm shown in Figure 78.4 highlights the decision-making process.

Nerve repair

In the acute stage nerve repair is not indicated and identification of the proximal and distal ends should warrant labelling and burying under viable muscle to provide nutrients and prevent early degeneration. Prevention of severe nerve retraction within the compartment is important and should be undertaken. However, such patients will undergo a migratory necrosis and this may affect nerve tissue viability and this is why primary repair is contraindicated. Although nerve repair is important in the subacute phase in the correct facility where time, patient and logistical constraints are not limiting factors, it should not impede prompt damage control surgery and evacuation.

Tendons and muscles

Tendon and muscle debridement, identification and apposition are important. However, in the acute period identification of the profoundly dead tissue should be the priority. Identification by muscle stimulation by finger stimulation, tone and colour are important in deciding viability. In the sedated patient anaesthetic agent will have an effect on the ability of muscles to contract and this should be kept in mind when finger stimulating potentially non-viable muscle. Once again a marginal approach to debridement should be employed. Furthermore, muscle compartments

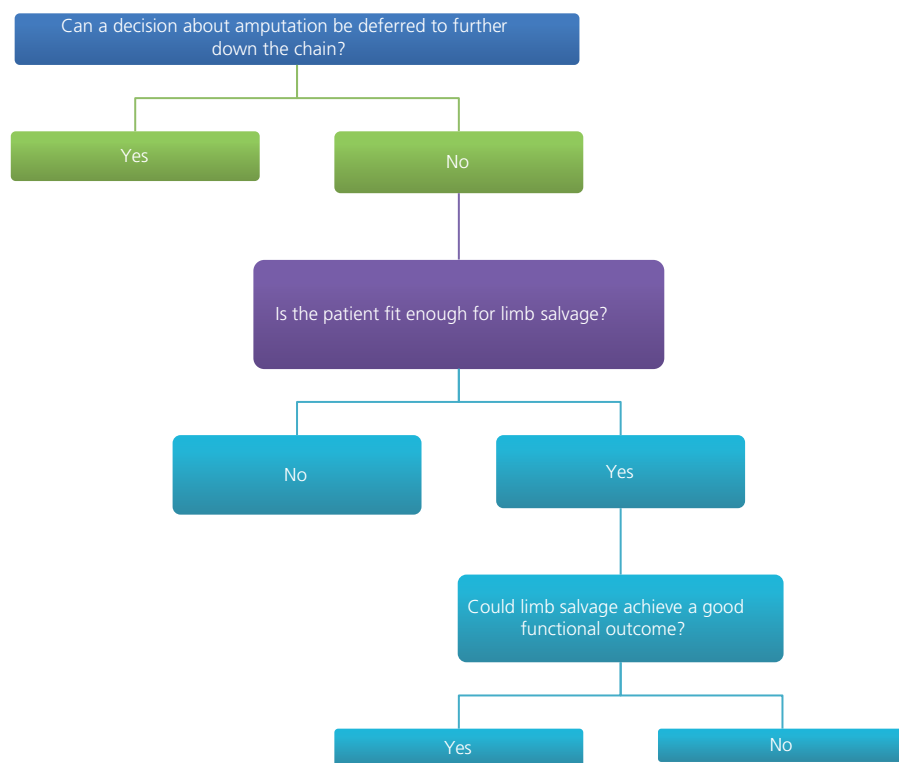

Figure 78.4 Limb salvage algorithm.

within the acute zone of injury may need to be incised and released to pre-empt compartment pressure increase. Prompt lavage of the muscle, its residual sheath and compartment to rid the area of contamination will enable closure with negative pressure therapy to temporize the wound. Furthermore, assessment of limbs to rule out the requirement for fasciotomy is necessary.

Fractures

Early fixation of fractures is paramount in balance with the patient's physiological state and the overall time constraints in theatre. Fixation of long bone fractures to prevent continuing blood loss is important. However, the use of internal fixation is contraindicated due to the susceptibility for infection and osteomyelitis. There have been numerous reports of the use of external fixating devices in the acute setting for salvage of fragmented joints with mixed success. The use of such devices should be following the lead of the orthopaedic teams for optimal success. Any signs or symptoms of contamination of the fixating rods should lead to removal and replacement. The combination of external fixation and topical negative pressure therapy to simultaneously splint the wound and fracture has been utilized with some success.

Dressings

In the acute setting the use of topical negative pressure therapy for its ability to provide a sealed contaminant-free wound has proven to be useful in these patients. The eventual replacement of silver and gauze-based dressings in theatre by topical negative pressure therapy has improved wound care. However, once again such a device cannot be expected in future deployments, therefore the surgeon needs to have a grasp both of the dressings offered in their theatre and the most appropriate dressing for the wound. The use of crepe bandage, gauze and silver dressings was the accepted norm in the early stages of recent conflicts. The use of the marginal necrosis has led to a dressing change and wound inspection at the 24–48 h mark and again this needs to be considered, especially in a prolonged evacuation chain.

Delayed reconstruction

Such severely injured patients enter a prolonged period of catabolism. This can last for up to a year and, combined with a highly sensitive immune system (especially in those after a massive transfusion), the need for surgery should be balanced between 'What *needs* to be done' and 'What *should* be done'.¹

The initial aims for these patients are wound closure, which facilitates the transition from a chaotic systemic inflammatory response syndrome (SIRS) response to one of relatively ordered healing. The goals of preliminary reconstruction in the subacute setting are defined as appropriate coverage of amputation stumps, nerves, tendons and muscle units in a clean wound. Particular attention should focus on fracture fixation as well as covering nerve grafts and musculotendinous units. The priority of reconstruction should be functionally based. This must be

undertaken in a multidisciplinary team approach so as to ascertain the patient's expectations in the context of their injury. As the patient transitions to the rehabilitation phase, the wear and tear of physiotherapy and readjustment to relative self-sufficiency guides the subsequent reconstruction.

Particular reconstructive techniques in the acute setting have proven marginally unsuccessful. Microvascular free tissue transfer has a 15% unpublished failure rate. This again is probably because of the overwhelming SIRS response. The friability and lack of vessels to connect free flaps to is also a major issue. The choice of muscle and flap is important. The use of the latissimus dorsi as a workhorse flap is contraindicated in the bilateral lower limb amputee, who will need this for upper limb function. The gracilis, if not obliterated in the initial injury, has proven an excellent workhorse with minimal donor site morbidity.

In relation to lower limb amputee reconstruction it has been found that the 2-year point is the optimal time for definitive surgery. At this time a staged stump revision that utilizes a rotational flap, excision of any heterotopic ossification and appropriate burying of nerves has good outcomes for prosthesis. In addition, the use of Botox is excellent to arrest sweating into a prosthesis.

Ultimately, the reconstruction of these soldiers needs well-defined aims that consider the patient's understanding of their best effort functional outcome in a multidisciplinary team approach.³⁵ These patients present a reconstructive challenge, but not one that is outside the scope of the basic principles of the reconstructive ladder.

Conclusions

Military plastic surgery requires a breadth of skills from the surgeon to overcome a vast array of unforeseen clinical and environmental challenges. Success in this field is not just about applying high-quality surgical techniques, it requires the ability to make sound judgements on the most appropriate short- and long-term surgery that is best for the patient.

Recent conflicts have given war surgeons a relatively fast evacuation time from point of wounds to specialist centre. This has allowed surgeons to use reconstructive techniques early to achieve some of the best outcomes ever seen from such injuries. However, future conflicts may be conducted under very different circumstances. Military plastic surgeons need to have the surgical skills to deal with a wide range of injuries and to be flexible enough to cope with unpredictable circumstances that war brings.

FRCS(Plast) examination

FRCS(Plast) is the Intercollegiate Exit Examination in Plastic Surgery run jointly by the four Royal Colleges of Surgeons in the United Kingdom. Passing this exam, along with satisfactorily completing 6 years of higher surgical training in plastic surgery, leads to award of a Certificate of Completion of Training (CCT), which allows entry onto the Specialist Register. This enables a surgeon in the UK to work as a consultant in their speciality within the National Health Service or in private practice.

The format and regulations relating to the FRCS(Plast) examination are revised from time to time and for up to date information the website of the Intercollegiate Speciality Boards (ISB) and Joint Committee of Intercollegiate Examinations (JCIE) is best consulted (<http://www.intercollegiate.org.uk>).

In brief, there are two sections to the exam, which cover the whole of the plastic surgery syllabus, including basic sciences, medical ethics and statistics. Section 1 consists of two written papers: multiple choice questions (2 h) and extended matching item questions (2.5 h). The papers are not negatively marked, though the pass mark varies each sitting as it is set for that particular paper by a separate panel of examiners. In the past it has been in the region of 60–70%. Of note, some questions are subsequently withdrawn if they are deemed by the panel to be ambiguous or not of the appropriate standard.

Candidates successfully completing Section 1 can then progress to Section 2, which is usually held a few months later. Both sections have sittings twice a year.

Section 2 is the clinical part of the FRCS(Plast) and is held over two days: one day clinical cases, the other oral exams. The clinical cases are made up of two medium/long cases lasting 15 min each and two rounds of short cases, each round consisting of five short cases and lasting 30 min. Candidates may be asked to interpret X-rays, CT scans and other pieces of diagnostic imaging related to the case in question.

The oral exam is made up of three separate 30 min vivas, each with a different pair of examiners. The broad subject areas for each viva are:

- 1 Trauma (hand/maxillofacial/lower limb) and burns
- 2 Acute head and neck tumours, cleft management and genitourinary reconstruction
- 3 Basic sciences and generic plastic surgery, aesthetics, ethics, medicolegal and consent issues.

Each viva has three distinct parts on different topics. One examiner will ask the questions while the other marks, alternating roles for each topic. Although there are separate topic areas, questions can be on any part of the plastic surgery syllabus and candidates may be shown clinical photographs or asked to draw certain schematic diagrams, such as the cross-sectional anatomy of the lower leg, geometry of local flaps, different cleft lip repairs, etc.

Marking

Each constituent part of Section 2, the short cases, the long cases and the oral exam, contains a certain number of marking events which are each given a score between 4 and 8 (6 is a pass). A breakdown of the weighting of scores for the different parts is given in Table 79.1. Thus a single short case or individual viva topic equates to one marking event, each long case contains three marking events. The scores for each part is doubled (individual pass marks given) and added together to give an overall score. The overall pass mark is 300.

When attributing a score, the examiners take the following areas of a candidate's performance into consideration: overall professional capability, knowledge and judgement, quality of response and 'bedside manner'. A copy of the marking descriptors that will be used by the examiners is sent to candidates in advance with their examination pack and there is also an up to date copy on the JCIE website (<http://www.intercollegiate.org.uk>). It is advisable for candidates to check this for any changes to the marking scheme that may subsequently occur.

Personal experience – learning resources

Preparation is very much an individual thing, as are textbooks, but one extremely useful resource to be recommended is the *frcpsplast.com* website, which contains a panoply of revision notes, landmark papers and tips from previous candidates. Registration is via

Table 79.1 Breakdown of the weighting of scores

	Number of events	Pass mark
Long cases	6	72
Short cases A	5	60
Short cases B	5	60
Viva 1	3	36
Viva 2	3	36
Viva 3	3	36
Total overall		300

email and access free. The Intercollegiate website has a few sample MCQs and EMQs, although these are quite limited in number.

A point for overseas candidates is that management practices do vary slightly from country to country and it is important to be familiar with certain UK guidelines, such as those for skin cancer (produced jointly by the British Association of Dermatologists and the British Association of Plastic Reconstructive and Aesthetic Surgeons (BAPRAS)) and lower limb trauma (produced jointly by the BAPRAS and the British Orthopaedic Association). The latter can be downloaded from the BAPRAS website. The National Institute for Health and Care Excellence (NICE; www.nice.org.uk) also produces a range of clinical guidelines (in addition to evaluating new interventions or technologies and cost/benefit analysis), some of which are particularly relevant to plastic surgery (e.g. pressure sore management, fat grafting, venous thromboembolism prophylaxis), and candidates should be familiar with these.

Good (if a little long) summaries of guidance on consent and ethics can be found on the General Medical Council website (www.gmc-uk.org) under the section entitled Good Medical Practice.

Personal experience – the exam

Taking the FRCS(Plast) examination is a little like taking your driving test. The key to passing the test is not about being a great driver; it is about demonstrating you are a competent driver, safe to be released in your car unsupervised onto the unsuspecting public. Likewise, success in the FRCS(Plast) is not about trying to show the examiners that you are a brilliant surgeon, what is paramount is that you are a safe surgeon, who, when released unsupervised as a new consultant, will come up with sensible management plans to the clinical problems you encounter.

So, just as the learner driver does not try to impress his or her examiner with wheel spins and handbrake turns out of the test centre, so the plastics trainee should be wary of allowing complicated flaps or the latest niche aesthetic techniques to be the first things to come out of his or her mouth when asked how they would tackle common clinical scenarios. The examiners are not thinking ‘how clever is this candidate?’, they are thinking ‘If this candidate was appointed as my consultant colleague next week, is he or she going to get into trouble which I would then have to sort out?’

A bit like driving, everyone’s an expert and sometimes the volume of advice candidates are given can be overwhelming, but below are a few tips I found useful.

Five tips

1. Each long case is worth a whole viva

One of the editors of this book gave me some very sage advice while I was studying for my FRCS(Plast) exam: ‘Everyone obsesses about the viva, but if you look at the people who fail it’s invariably a long case that has sunk them.’

There is a natural tendency, given the broad range of the syllabus, to obsess about the viva. It is worth remembering, however, that although a bad viva topic or short case can be compensated for by a strong performance elsewhere, if a long case goes badly it is much more difficult to recover from. It all starts with the history, and although it is easy to think that taking a history is something you have done countless times and do not need to practice, in the exam situation it is easy to forget things if you do not have a well-drilled routine. Long cases that go awry invariably stem from an inadequate history and examination, and the examiners’ ‘difficult questions’ are simply a consequence of this.

2. Be nice

It may appear to stretch credibility to say that, after 6 years of medical school and countless years of surgical training, your success will be influenced by mere pleasantries. But it is, and may well be the last thing on your mind while trying to retain a myriad of plastic surgery information in your head.

First, you are marked, both directly (and subconsciously), by the examiners on your manner with the patient. Second, the patients can be themselves a little nervous (especially some of the elderly ones) and will provide a far more coherent history if they are made to feel at ease. Third, and perhaps most importantly, in the clinical exam impression is everything. ‘Niceness’ comes across as calmness, and calmness conveys competence. And it is competence that the examiners are looking for.

3. ‘I don’t know’

There is nothing wrong with saying this – within reason (clearly if you say this when asked to draw a Z-plasty the exam is not going to end well). Obviously in an ideal world you would know everything, but in the real world there is a limit to everyone’s knowledge and the examiners know this.

In response to correct answers, the examiners will ask more searching questions in an effort to allow you to score more marks for that section. If you are asked an extremely difficult question then the chances are you are doing extremely well, so if you don’t know, it is reasonable to say so or make it clear you are making an educated guess and give your reasoning. Do not undo previous good work by making up something ludicrous or waffling for ages using up time when you could be scoring marks on something else.

4. If you do know the answer – be succinct

There was a perceived (and dubious) wisdom when I was at medical school regarding vivas. The theory went that if you were asked a question on a subject that you knew something about, you should try to spin the answer out for as long as possible. Because the longer you did, the less time would be left for the examiners to ask you questions on subjects about which you knew nothing. Here, the exact opposite is true. If you know the answer, give it fully but succinctly and move on to the next question – this is the only way to accrue more marks. Likewise, in the clinical cases, the time goes very quickly and a candidate who starts promulgating at length in response to a straightforward question may find the bell ringing before they can be asked anything else (thus limiting the marks they can score).

5. Be yourself

By this stage in their careers most candidates will have successfully completed many exams and this one is no different. For the clinical cases, imagine you are in the outpatient clinic and run through your history and examination routines. If you have always examined a hand in a particular sequence then stick to it, do not change two weeks before the exam because someone says you should do it differently.

One minor difference in exam technique from previous trainee exams is that answers that might have begun with 'You could ...' must now become 'I would ...'. You are answering from the point of view of a first day consultant.

Perhaps the best bit of exam advice ever was given to me by a non-medic. Years ago I was taking my MRCS (a junior surgical exam) viva at the Royal College of Surgeons in Edinburgh. We candidates were standing lined up in the corridor, knees knocking in our rented suits, as we waited to enter the examination hall. As we filed in to confront our examiners, an elderly porter, who was tending to one of the display cabinets near the entrance, growled at us in a thick Glaswegian brogue, 'Look 'em in the f***ing eye boys'.

FRACS(Plast)/EBOPRAS examinations

The fellowship or boards of plastic surgery equivalent exams are the final trial of ordeal for most trainees, who have done exams over a large portion of their adult lives. Their respective examining boards put the general structure of all four exams together, with the aim of presenting a safe surgeon who has adequately covered the entire plastic surgery curriculum. This is perhaps the most stressful academic period in a prospective surgeon's training career. All exams have their own unique quirks of exam technique and examiners habits or favourite topics. In recent years the various boards have attempted to provide a more standardized format to ensure reproducibility and fairness. As they begin to prepare for the final exam, each candidate finds their favoured study modality. Group study with a long-term timetable and regular tutorials from recently passed surgeons

and more experienced senior surgeons form the basis of most trainees' approach to the exams. The structure of the FRACS(Plast), FRCS(Plast), FRCSC and European Board of Plastic Reconstructive and Aesthetic Surgery (EBOPRAS) exams is described below with reflections on personal experience.

The Australasian College of Surgeons invites final year trainees from a 5 year specialist training programme conducted by the Royal Australasian College of Surgeons to sit the fellowship exams. All candidates must have passed a PRSSPE (PRS Science and Principle Examination) multiple choice exam usually as a SET 2 (second year of training) candidate. The final fellowship has the following components:

- I Two written papers, each of 2 h duration, two questions in each paper and multiple parts in each questions
- II Clinical – long cases: two cases/patients, each of 30 min duration
- III Clinical – short cases: six cases, each for 5 min
- IV Surgical Pathology & Operative Surgery (SPOS) 1 viva: two scenarios, each of 12.5 min
- V SPOS 2 viva: six slides, each of 5 min
- VI Anatomy viva: 25 min.

The scoring is a closed marking system – 8, 8.5, 9, 9.5. Support can be given in each of the marks; 9 is a clear pass, 8.5 is borderline fail, 8 is a clear fail. Any candidate can be failed on one critical error irrespective of the marks. Critical errors are considered those decisions that may be life- or limb-threatening. Although all seven segments are considered equal in value, during court of examiner discussions more emphasis is placed on clinical components in particular long cases. These exams are held twice a year.

The EBOPRAS exam is divided into written and viva components. The written exam is a multiple choice exam covering clinical as well as basic sciences. The viva component is divided into two 25 min sections. Clinical scenarios covering congenital, trauma, tumour management, aesthetic and general reconstruction are conducted by two examiners.

As a candidate I had the dubious pleasure of sitting three of the four exams discussed here (FRACS(Plast), FRCS(Plast), EBOPRAS). Each had their own strengths and weaknesses, however the common theme is that the examiners were not intent on failing the candidates, but to discover what their knowledge limits were and, more critically, where their clinical limits laid. The FRACS is the most rigorous of these exams in terms of expected depth of knowledge, but it is not necessarily the broadest exam. The written form is significantly more detailed and in my opinion more in line with the expectations of the specialist surgeon. The FRCS exam is the broadest exam; each candidate is assured that a series of congenital, trauma, aesthetic and general reconstructive viva questions will be asked. The arrays of short cases were undoubtedly the best outpatient's clinic any candidate is ever likely to attend. The EBOPRAS exams similarly seek to cover the same broad base. The candidates are often qualified surgeons and, as such, the exam format may seem more like a semi-formal discussion

among colleagues than the tutor to pupil format of the FRACS and FRCS exams.

The most pertinent advice for a prospective candidate is a broad formal clinical experience. This experience is best gathered in the trenches of interminable dressings and initial consultation clinics. Formal long case, short case practice and presentation is essential not only to success but also to crisp and succinct decision-making process. This will become less formal but nevertheless form the crux of your clinical practice for years to come. The examiners are destined to have more clinical experience than the candidates and this is where the candidate can compensate by depth and breadth of knowledge. The more a candidate reads and knows around a topic the more confident and systematic they will become in replying to questions and putting clinical scenarios into a correct perspective. Review CME articles from *Plastic Reconstructive Surgery Journal*, *Clinics in Plastic Surgery* and *Hand Clinics* formed the basis of my own reading in addition to the standard single-volume texts (the latter I often found inadequate). Revision and complete command of surgical anatomy is mandatory in clinical practice of plastic surgery. Unfortunately, neither the FRCS nor the EBOPRAS exam stress this component. This results in what is a palpable deficit in many of the British and European candidates' knowledge base.

FRCS exams

At the end of plastic surgery training in Canada, candidates are invited to sit the Canadian Plastic Surgery Royal College examination. The title Fellow of the Royal College of Surgeons of Canada (FRCS) – Plastic and Reconstructive Surgery is awarded following successful completion of this examination. The FRCS is a renowned designation recognized worldwide and is usually a requirement for specialty licensure in Canadian jurisdictions. This final certification exam consists of two components: a written section and an oral examination approximately two weeks later. Candidates are required to pass both the written and the oral components in order to successfully complete the exam. The examination addresses all facets of plastic and reconstructive surgery, including basic science, basic principles and techniques, paediatric plastic surgery, craniofacial surgery, burns and wound care, head and neck reconstruction, aesthetic surgery, trunk and lower extremity reconstruction, breast and hand surgery. A more detailed description of the plastic surgery curriculum can be found at www.royalcollege.ca.

Personal experience

Although this examination is stressful and comes at the end of a long and arduous residency training, it is considered to be a fair exam. There is an enormous quantity of information to master (as evidenced by the content of this book), but in the end, review and critical appraisal of the material while preparing for the exam will make any potential candidate a better plastic surgeon.

Failure is usually a function of two primary deficiencies: lack of knowledge and lack of examination-taking skills. The former shortcoming, a lack of knowledge, occurs simply because candidates did not read enough. Some may be more proficient at memorizing the material, but ultimately, with weeks, months and years of commitment everyone should be able to learn the required knowledge. There are no excuses. Preparation for the Plastic Surgery Royal College exam does not begin a few weeks or months before the exam, it starts at the beginning of the candidate's residency. The latter point cannot be emphasized enough. It is of the utmost importance that early on residents read around their cases and on the topics relevant to their current rotation. Consistent and continued acquisition of information throughout residency is key. A strong knowledge base is a function of discipline and dedication to acquisition of the material. It is simple: if one does not have sufficient knowledge, one will not pass this exam. So, the secret to success? Read, read and re-read.

It remains an unfortunate truth that even when armed with the knowledge required to pass the exam, failure may ensue due to a lack of examination-taking skills. However, as the word skill implies, this can be gained through experience and training. With regard to the oral examination, very often anxiety can overshadow one's ability to relay information in a proficient and succinct fashion. In like manner, for the written component, failure to pace oneself can often result in one falling short of completing the entire series of questions. The latter limitations can be improved with continued practice. Indeed, preparation for the exam can be likened to training for a marathon, and as any seasoned runner can attest, in order to achieve the objective of a long run, one must first devise a practice plan of shorter runs. Likewise, at the outset of one's final year of residency, formulation of a good reading and oral exam practice plan is essential. Training is always easier in a group, and organizing a study group of 3–4 residents with whom one can review the material, questions, cases and articles is recommended. Each member is likely to have a particular strength, which would assist the other residents in the group in gaining a better understanding on that topic.

Remember, the objective of the exam is not to impress the examiners nor is it a platform to exhibit innovative solutions to common clinical problems. Rather, it is to demonstrate that once in practice, without the direct guidance and supervision of senior colleagues, one has the necessary competence and will exercise the safety requisite to independent practice.

Written examination

The written examination, which can be taken in French or English, consists of two 3-h sessions of short answer questions (approximately 45 questions per session). The questions cover the entire breadth of plastic and reconstructive surgery, including basic science, embryology, anatomy, classifications, etc. The questions are prepared by plastic surgeons across Canada and submitted to the Examination Board of Plastic

Surgery. Following a rigorous review process, a final set of questions is selected to appropriately assess candidates' competence. These questions vary in complexity, from listing a series of answers to completing a number of questions relating to a specific clinical scenario or particular pathology.

Tips and pearls for the written examination

- 1 Do not be late.
- 2 Pay attention to the instructions provided by the invigilators and outlined in the booklet.
- 3 In order to answer all the questions, manage the allotted time thoughtfully. For instance, if there are 45 questions worth one mark each to be completed in 3 h, approximately 4 min should be allocated to each question.
- 4 Answer the question in a clear and concise manner. If, for example, the question is to 'list three risk factors,' then provide three, not four or five. Extra credit is not given for any additional answers provided.
- 5 Make an effort to write legibly. If the examiner cannot read the answer, then credit will not be granted.
- 6 Answer all the questions to accumulate the maximum number of points.

As an adjunct to point 6, it is highly recommended to not linger on those questions where the answers are not straightforward. Rather, mark these more difficult questions with 'post-it' stickers, so that they can easily be identified and answered once the rest of the exam is completed.

Oral examination

The oral examination can also be taken in French or English. It consists of two 1-h sessions, each session consisting of eight clinical scenarios with associated questions (six of 8 min duration and two of 4 min). The objective of the oral component of the exam is to assess the candidate's application of theoretical knowledge and clinical judgement. More importantly, the examiner seeks to ascertain that the candidate is safe with regard to clinical decision making.

The examinee is permitted 15 min prior to the start of the examination to review the series of clinical scenarios. Typically, two examiners will independently evaluate each candidate. Upon entering the room, the examiners will introduce themselves and give the candidate a short explanation about the oral exam. The clinical vignettes, illustrated with photographs, radiological imaging, etc., cover all areas of plastic and reconstructive surgery and with questions related to each. The aim of a scenario may be to evaluate a clinical problem, design a treatment plan, manage a complication, etc. Ultimately, it is important to understand that the examiners want candidates to pass the exam, and as such, they will guide you through the scenarios when necessary in an effort to elicit all information critical to passing the question. Examiners are instructed to not lead the candidate, so one should not expect any positive or negative reinforcement for responses given. Examiners may, however, redirect the candidate if responses are completely erroneous. At

the end of each session, the candidate is allotted 4 min for so-called sober second thoughts, where modifications or clarifications of any answers can be made.

Tips and pearls for the oral examination

- 1 Practice, practice and practice oral examinations. Whereas the written component of the exam is a reflection of knowledge acquired, the oral exam is, in principle, a skill that requires much practice to master. The latter also pertains to drawings and/or markings.
- 2 Answers are an indication of the candidate's thought process, and so structured and succinct answers demonstrate that the candidate's approach to a clinical problem is organized. It exhibits experience and preparedness for clinical practice.
- 3 As a corollary to point 2, it is important to listen carefully to the question and answer the question specifically. For instance, if asked for a specific investigation, do not elaborate on history and physical exam. Likewise, if asked about 'your preferred flap option for the given defect,' do not list a number of potential reconstructive options. Instead, state your surgical plan.
- 4 Show confidence, but avoid arrogance.
- 5 In the event you do not know the answer, it is acceptable to state it, rather than present a guess. In like manner, pausing (briefly) to reflect and properly formulate a response is appropriate.
- 6 Pertinent and selective consultation of other subspecialties is advisable. However, referral of every problem and/or every patient is inappropriate and demonstrates a lack of knowledge, judgement and/or confidence.
- 7 The Royal College exam is not the time to conceive of a new treatment option or suggest an innovative operation. Be safe and provide a well-established solution for the clinical problem at hand, and preferably, one seen or done during your training. If presented with a controversial topic, begin by explaining that this is an area of controversy and exercise caution when stating your response. Remember, ultimately, the examiners want to ensure you are a safe surgeon.
- 8 Stay positive and focused. If one question/scenario did not go well, do not dwell on it and instead concentrate on the next question. Do not let one question disturb your focus or confidence for the following questions. Keep in mind that at the end of the session, there will be time for any sober second thoughts.
- 9 Remember, the examiners ask the questions, not the examinee. By asking for more than the occasional clarification, the candidate may give the examiner the impression that they lack knowledge or confidence. Moreover, this is a waste of time, time which should be maximized to answer the question.
- 10 Formulating a standard template for each potential topic is useful as the type of cases tend to be repeated.
- 11 Finally, approach each case as though confronted with the clinical scenario in actual practice.

Conclusion

To conclude, it is indeed a difficult process, but with the right approach and adequate preparation, a passing result is an achievable task. Ultimately, review and critical appraisal of the material while preparing for the exam will make any potential candidate a better plastic surgeon. These are all fair exams, and

most graduating residents are well prepared to pass. Candidates would do well to remember that the objective is not to impress the examiners, but to demonstrate that once in practice, without the direct guidance and supervision of senior colleagues, one has the necessary competence and will exercise the safety requisite to independent practice.
